INTRODUCTION

Plasma waves are fundamental to the very definition of a plasma, since a plasma is first a collection of charged particles that is essentially neutral, but it must also be a minimum size. For any finite temperature, there is a characteristic thermal speed $v_{th} \equiv (2\kappa T/m)^{1/2}$; and plasmas are characterized by the plasma frequency, $\omega_p = (ne^2/m_e\epsilon_0)^{1/2}$, which is the frequency of oscillation when the plasma density is locally disturbed from equilibrium, creating a local charge imbalance, and the

Debye length, $\lambda_D = (\epsilon_0 \kappa T/ne^2)^{1/2}$, is roughly the distance a thermal particle travels in a plasma period. This is a fundamental length in a plasma since it represents an effective distance beyond which fields from individual particles are essentially shielded. A plasma must generally have many particles in a Debye sphere to prevent binary collisions from being dominant, and must be many Debye lengths across for it to be dominated by the long-range electrostatic forces between particles rather than external fields. Near the edges of plasmas, this latter condition invariably fails, so that when static external electric fields are applied to a plasma, the fields inside are typically small compared with those near the edge. It is possible to generate large oscillating fields inside, however, if one couples to one of the characteristic plasma waves.

Plasmas support a rich variety of waves and are subject to a wide range of instabilities. Even in a cold plasma, there are generally two types of waves at every frequency, but the variation in angle between the wave vector and the magnetic field in a magnetized plasma adds significant complications, and there are cutoffs and resonances at virtually all angles of propagation. When thermal effects are added, many new but very important phenomena are added, including collisionless damping and numerous waves that have no cold-plasma counterpart. The addition of plasma gradients and nonlinearities adds instabilities and other new phenomena, leading to a bewildering array of effects to be considered. While some of these waves can be examined with a minimal number of effects, some require a significant level of sophistication to explore. In this article, a description of the broad variety of effects is first given for an unmagnetized plasma with few details. For the more general case with a magnetic field, cold-plasma theory is then presented as a foundation. Warm-plasma effects are then treated through both fluid models with finite plasma pressure and kinetic models. The examples are chosen to be illustrative rather than exhaustive. Some effects of boundaries are included, as well as some effects of inhomogeneity, especially in terms of instabilities and in terms of absorption and emission. Finally, there is some discussion of weak plasma turbulence but little of strong plasma turbulence. Several fundamentally nonlinear plasma phenomena are described, but the full range of nonlinear waves of practical interest is beyond the scope of this article.

For every topic covered, the literature is too vast to give all of the appropriate references. In the books listed under Further Reading, two are textbooks on plasma waves and give additional details and references on virtually every topic covered here.

1. UNMAGNETIZED PLASMAS—AN OVERVIEW

In the absence of a magnetic field and with no thermal motions of the particles, the motion of particles in response to an oscillating wave field is relatively trivial. From the equation of motion, assuming plane-wave dependence $[v_j, E \sim \exp(i\mathbf{k}\cdot\mathbf{r} - i\omega t)]$, one finds $v_j = iq_jE/\omega m_j$ for species j and the current by $J = \Sigma_j q_j n_j v_j$, where the sum is typically over $j = i, e$ for the ions and electrons, although multiple ion species are possible. The vector wave equation then becomes

$$\mathbf{k}(\mathbf{k}\cdot\mathbf{E}) - k^2\mathbf{E} + (\omega^2/c^2)K\mathbf{E} = 0, \tag{1}$$

where $K = 1 - (\omega_{pe}^2 + \omega_{pi}^2)/\omega^2$ with $\omega_{pj}^2 = n_j q_j^2/m_j\epsilon_0$. The two independent solutions are $K = 0$ when $\mathbf{k} \parallel \mathbf{E}$, $n^2 = K$ when $\mathbf{k}\cdot\mathbf{E} = 0$, where $n = kc/\omega$ is the index of refraction.

1.1 Plasma Oscillations

In the first case, with $K = 0$, there is no wave since k (or n) is undefined, and the plasma simply oscillates undamped at the *plasma frequency*, ω_p ($\simeq \omega_{pe}$ since $m_e \ll m_i$), and these are called *plasma oscillations*. This is unrealistic, however, since with any finite temperature, this result is modified.

The first generalization is to describe the plasma by a Boltzmann equation for each species that describes the evolution of the distribution function. By taking moments of the Boltzmann equation and truncating with a simple pressure term, the frequency is found to be

$$\omega^2 = \omega_{pe}^2(1 + 3v_e^2/2v_p^2), \tag{2}$$

where $v_e^2 = 2\kappa T_e/m_e$ (κ is Boltzmann's constant) and v_e is called the *thermal speed*, and

$v_p = \omega/k$ is called the *phase velocity*. Since there is now a relation between ω and k, this describes a propagating wave. If higher moments of the Boltzmann equation are taken, the relation becomes more complicated,

$$\omega^2 = \omega_{pe}^2\left(1 + \frac{3v_e^2}{2v_p^2} + \frac{15v_e^4}{4v_p^4} + \cdots\right), \qquad (3)$$

and so it is apparent that the series expression is useful for $v_e \ll v_p$. When this is not satisfied, we need yet another method of analysis.

Instead of taking moments of the Boltzmann equation, we may solve it directly along with the Maxwell equations assuming an initial-value problem in time with wavelike periodicity in space. This *kinetic theory* analysis leads to a dispersion relation [a *dispersion relation* is an equation relating ω to k, whose general form is $D(\omega,k) = 0$] of the form

$$1 = \sum_j \frac{\omega_{pj}^2}{k^2v_j^2} Z'\left(\frac{\omega}{kv_j}\right), \qquad (4)$$

where $Z(\zeta)$ is the *plasma dispersion function* (Fried and Conte, 1961) defined by

$$Z(\zeta) \equiv \frac{1}{\sqrt{\pi}}\int_{-\infty}^{\infty} \frac{e^{-z^2}}{z - \zeta}\,dz, \quad \mathrm{Im}(\zeta) > 0, \qquad (5)$$

and $Z'(\zeta)$ is the derivative of $Z(\zeta)$ with respect to its argument. This function is complex for real argument, and when $\zeta \gg 1$, the dispersion relation reduces to Eq. (3) plus an exponentially small imaginary term [$\sim \exp(-\zeta^2)$], which leads to damping. The damping becomes strong when the phase velocity is near the thermal speed.

The kinetic-theory solution is much more accurate than either the cold-plasma or moment-expansion models, but it is possible to analyze the damping as being due to those particles in the distribution that travel at very nearly the same speed as the phase velocity, in which case they see a virtually stationary electrostatic potential well. As they oscillate in this potential well, they exchange energy with the wave and wave damping results. For any oscillation, of course, there must be a *finite* well depth, which implies that the damping is fundamentally *nonlinear* in character, whereas the kinetic-theory analysis is linear and assumes an infinitesimal amplitude. For truly large amplitudes, nonlinear effects become strong, leading to several different kinds of behavior. First, one finds that the number of particles trapped in the potential well increases with amplitude, and while the damping following an initial disturbance begins at the linear rate, as the particles begin to bounce and complete a full cycle, they bounce on both sides of the well and begin to give energy back to the wave and the wave amplitude may cease falling and begin to rise again. The wave amplitude may oscillate for a number of cycles, eventually settling down to a steady state where there is a group of trapped particles traveling with the wave, which maintains a steady amplitude. Below a certain threshold, there is no finite-amplitude steady-state solution, but the decay may be slower than indicated by the linear theory.

This same type of analysis indicates that if there were an unusual case where there were more trapped particles going slightly faster than the phase velocity than were going slower, whereas the usual case would have more traveling slower (the distribution function is normally a monotonically decreasing function of velocity), the wave amplitude would grow. This is characteristic of a *plasma instability* and occurs whenever the distribution is not a monotonically decreasing function of velocity, and the growth occurs over a range of phase velocities where $df/dv > 0$. As the amplitude grows, particle trapping becomes stronger and eventually saturates the amplitude, and velocity-space diffusion eventually modifies the zero-order distribution function until it is monotonic.

Whenever the amplitude is large enough to lead to a saturated amplitude, another kind of plasma instability arises, since a group of trapped particles may have a bounce frequency ω_b that is an integral submultiple of the wave frequency, so that $\omega = n\omega_b$. This leads to parametric instabilities at frequencies $\omega \pm \omega_b$, and the growth of these unstable waves eventually destroys the saturated wave until everything decays away. When there is a variety of unstable waves, the situation is described as *weak turbulence*.

Finally, for large enough amplitudes, slight variations of amplitude in space (due either to focusing or to random fluctuations) lead to ponderomotive forces that tend to expel plasma from the regions of highest wave amplitude. The creation of a region of lower density (sometimes called a *caviton*) is unstable and leads to collapse of the localized wave structure. This is a strongly nonlinear process, and the collapse of many such cavitons may lead to *strong turbulence*.

Ignoring boundaries and effects of plasma inhomogeneity, we already see the enormous range of processes that occur in plasmas, from linear to strongly nonlinear, and all of these scenarios are known in experiments. The purpose of this section is to illustrate the rich variety of effects that occur and to indicate the possible difficulty in describing accurately all of the phenomena, since many may overlap and occur simultaneously.

1.2 Electromagnetic Waves

Some, but not all, of the effects described above apply also to the transverse-wave solution where $n^2 = K$, which describes an electromagnetic wave traversing a medium with an effective dielectric constant. In this context, electromagnetic waves are those whose wave fields are primarily transverse to the direction of propagation, while the wave electric field for an electrostatic wave is essentially parallel to the propagation direction, as was the case for the plasma wave above. The transverse wave with $n^2 = K$ is called the *ordinary wave* (O wave) and also occurs in a magnetized plasma if the electric-field vector is parallel to the magnetic field. For this case, it is possible that $K < 0$, which occurs whenever $\omega < \omega_p$, and the electromagnetic wave cannot propagate. The cold-plasma model is frequently adequate for this case, whereas it is rarely adequate for the electrostatic case above since thermal effects usually dominate (with no thermal effects, there is no wave). An example of this occurs for radio waves, which propagate in free space, but upon encountering the ionosphere, they *reflect* at low frequencies and transmit at high frequencies, accounting for some of the differences between AM ($\omega < \omega_p$) and FM ($\omega > \omega_p$) propagation. This also accounts for the communications blackout during shuttle reentry and for the transparency of many insulators (low density of electrons implies low ω_p) and the shiny appearance of metals (with high electron densities).

The fluid equations are of little benefit for these waves unless collisions dominate the damping, and the kinetic-theory analysis leads to a dispersion relation of the form

$$n^2 = 1 + \sum_j \frac{\omega_{pj}^2}{\omega k v_j} Z\left(\frac{\omega}{k v_j}\right). \tag{6}$$

This appears to imply that there is damping of this wave also, since the plasma dispersion function is always complex for real argument, but this is not as obvious as before since here $v_p > c$ so that there are *no trapped particles* since no particles see a stationary potential. In fact, to treat this case properly, one must use a *relativistic* analysis so that while the momentum may vary over an infinite range in the relativistic distribution function, the velocity never exceeds the velocity of light.

An interesting example of nonlinear effects on the O wave is in the case of intense laser irradiation of a solid. After the plasma is formed, the incident wave is effectively shielded from the material as the plasma frequency rises to exceed the wave frequency. In extreme cases, the wave amplitude may be so strong that an electron is accelerated to relativistic energy in a single quarter cycle. With the increased effective mass, the effective plasma frequency is lowered, allowing the wave to penetrate slightly deeper into the plasma.

2. COLD-PLASMA WAVES

While waves in a cold plasma are the simplest to treat, the inclusion of a uniform magnetic field already makes this topic one of considerable complexity. Historically (Gillmor, 1982), the analysis is due to Wilhelm Altar and E. V. Appleton, who together found the dispersion relation for electrons only (assuming infinitely massive ions), including collisions (Appleton, 1932). The principal assumptions of cold-plasma theory are that the plasma is uniform and charge neutral and that every particle of the same species moves only in response to the wave electric field and the static magnetic field (taken to be in the z direction).

The calculation begins with the equations of motion for a single charged particle of species j in an electromagnetic field,

$$m_j \frac{d}{dt}\mathbf{v}_j = q_j(\mathbf{E} + \mathbf{v}_j \times \mathbf{B}); \tag{7}$$

the expression for the total current,

$$\mathbf{J} = \sum_j n_j q_j \mathbf{v}_j, \tag{8}$$

where the sum is over the species; and the Maxwell equations. With the wave fields and the velocity varying as $\exp(i\mathbf{k}\cdot\mathbf{r} - i\omega t)$, the wave equation may be written

$$\mathbf{k} \times (\mathbf{k} \times \mathbf{E}) + (\omega^2/c^2)\,\mathbf{K}\cdot\mathbf{E} = 0, \tag{9}$$

where the equivalent dielectric tensor $\mathbf{K}$ is

$$\mathbf{K} = \begin{pmatrix} K_1 & K_2 & 0 \\ -K_2 & K_1 & 0 \\ 0 & 0 & K_3 \end{pmatrix}, \tag{10}$$

with dielectric tensor elements given by

$$\begin{aligned} K_1 &\equiv S = 1 - \sum_j \frac{\omega_{pj}^2}{\omega^2 - \omega_{cj}^2}, \\ iK_2 &\equiv D = \sum_j \frac{\epsilon_j \omega_{cj}\omega_{pj}^2}{\omega(\omega^2 - \omega_{cj}^2)}, \\ K_3 &\equiv P = 1 - \sum_j \frac{\omega_{pj}^2}{\omega^2}, \end{aligned} \tag{11}$$

where $K_1 + iK_2 \equiv R = S + D$ and $K_1 - iK_2 \equiv L = S - D$ along with the definitions of ω_{pj}, the plasma frequency for species j given by $\omega_{pj}^2 = n_j q_j^2/m_j\epsilon_0$ where n_j is the density of species j and q_j the corresponding charge; of ω_{cj}, the cyclotron frequency for species j given by $\omega_{cj} = |q_j|B_0/m_j$; and of $\varepsilon_j \equiv q_j/|q_j| = \pm 1$. The two equivalent sets of tensor elements in Eq. (10) are the common S, D, R, L, and P notation of Stix (1962) and the cold-plasma limit of the more general dielectric tensor elements to be described later. The Stix labels are mnemonics for the Sum $[S = \frac{1}{2}(R + L)]$, Difference $[D = \frac{1}{2}(R - L)]$, Right or Left ($n^2 = R$ or L for a right- or left-handed circularly polarized wave), and Plasma terms, respectively.

2.1 Cold-Plasma Dispersion Relation

We define the vector index of refraction $\mathbf{n} = \mathbf{k}c/\omega$, whose direction corresponds to the direction of the phase velocity, and choose $\mathbf{n}$ to lie in the x-z plane so that $n_x = n_\perp = n \sin\theta$, $n_y = 0$, $n_z = n_\parallel = n\cos\theta$, where $\perp$ and $\parallel$ are with respect to the static magnetic field. A nontrivial solution of Eq. (9) requires that the determinant of coefficients vanish, which leads to

$$An^4 - Bn^2 + C = 0, \tag{12}$$

where

$$\begin{aligned} A &= S\sin^2\theta + P\cos^2\theta, \\ B &= RL\sin^2\theta + PS(1 + \cos^2\theta), \\ C &= PRL. \end{aligned} \tag{13}$$

The solutions of Eq. (12) may be written in either of two forms: as a quadratic in n^2,

$$n^2 = \frac{B \pm F}{2A}, \quad F^2 = B^2 - 4AC \geq 0, \tag{14}$$

or in terms of the angle between the phase velocity and the magnetic field,

$$\tan^2\theta = -\frac{P(n^2 - R)(n^2 - L)}{(Sn^2 - RL)(n^2 - P)}. \tag{15}$$

The general condition for a resonance, where $n^2 \to \infty$, or where $A \to 0$, is given by Eq. (13) or Eq. (15) as

$$\tan^2\theta = -P/S, \quad \text{Resonance}; \tag{16}$$

and the general cutoff condition, where $n = 0$, or $A \to \infty$, is given by Eq. (12) as

$$C = PRL = 0, \quad \text{Cutoff}. \tag{17}$$

The *principal wave types* are defined for $\theta = 0$ or for $\theta = \pi/2$.

1. Parallel propagation: $\mathbf{k} \parallel \mathbf{B}_0$.
   (a) $P = K_3 = 0$, plasma oscillations, described in Sec. 1.1;
   (b) $n_R^2 = R = K_1 + iK_2$, right-handed circularly polarized wave (R wave);
   (c) $n_L^2 = L = K_1 - iK_2$, left-handed circularly polarized wave (L wave),
2. Perpendicular propagation: $\mathbf{k} \perp \mathbf{B}_0$.
   (a) $n_O^2 = P = K_3$, ordinary wave (O wave) described in Sec. 1.2;
   (b) $n_X^2 = RL/S = (K_1^2 + K_2^2)/K_1$, extraordinary wave ($X$ wave), a transverse wave whose wave vector is perpendicular to both the magnetic and the electric field.

In ionospheric and space applications, the names for these waves sometimes vary, with the *R* wave called the ordinary wave and the *L* wave the extraordinary wave. At low frequencies, both the *R* wave and *L* wave are magnetohydrodynamic (MHD) waves, where both dispersion relations become $n^2 = 1 + c^2/V_A^2$ where V_A is the Alfvén speed given by $V_A^2 = B_0^2/\mu_0 n_i m_i$. The low-frequency *L* wave, which has a resonance at the ion cyclotron frequency, is sometimes called the torsional Alfvén wave since the magnetic field lines twist as the wave propagates. The *R* wave is often called the compressional Alfvén wave below and near the ion cyclotron frequency as the magnetic field lines alternately compress and expand, and is commonly called the whistler mode in the range $\omega_{ci} \ll \omega \ll \omega_{ce}$, and has a resonance at the electron cyclotron frequency. Above their high-frequency cutoffs, both the *L* wave and the *R* wave become simple electromagnetic waves with $n \rightarrow 1$ at very high frequencies. Plots of both the *R* wave and the *L* wave dispersion relations are given in Fig. 1 for a low-density case (and artificial mass ratio) to show the character of the cutoffs and resonances and show the range of variation of n^2 and its asymptotic limits. The *X* wave has resonances at the lower and upper hybrid resonance frequencies, given by

$$\omega_{LH}^2 = \omega_{ce}\omega_{ci}\left(\frac{\omega_{pe}^2 + \omega_{ce}\omega_{ci}}{\omega_{pe}^2 + \omega_{ce}^2}\right), \tag{18}$$

$$\omega_{UH}^2 = \omega_{pe}^2 + \omega_{ce}^2. \tag{19}$$

These are called *hybrid resonances* because they depend upon both the density (ω_{pe}) *and* the magnetic field (ω_{ce} and ω_{ci}). The upper hybrid resonance is always above ω_{ce}, and the lower hybrid resonance is always between the two cyclotron frequencies. A plot of the *X* wave dispersion relation is given in Fig. 2 and shows two cutoffs and resonances.

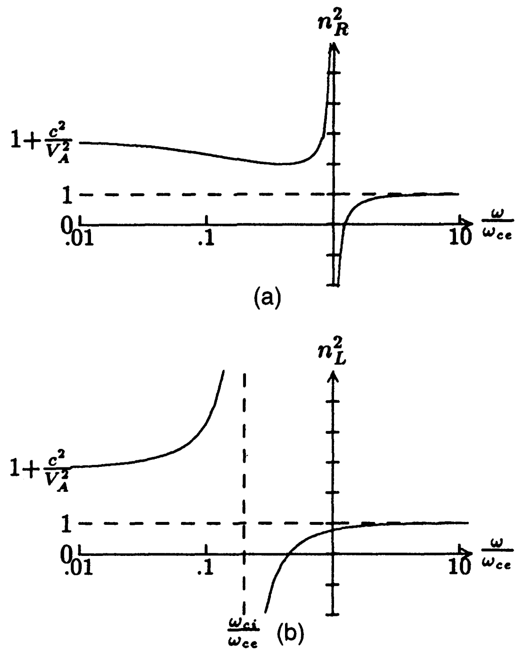

FIG. 1. Dispersion relations for (a) n_R^2 and (b) n_L^2 for $m_i/m_e = 5$, $\omega_{pe}^2/\omega_{ce}^2 = 0.3$.

2.2 The CMA Diagram

The regions of propagation and evanescence for even the principal wave types are nontrivial, and when intermediate angles are included, the picture becomes very complex. The Clemmow–Mullaly–Allis (CMA) diagram (Allis, 1959) is useful in determining which wave types are present in various density and magnetic-field regions, presenting both the number of propagating waves and the transitional boundaries where resonances and cutoffs occur. The boundaries in the CMA diagram are the resonances and cutoffs of the principal wave types, and in each region wave normal surfaces are shown where the radius of the figure is a topological sketch of the phase velocity vs angle, $v_p(\theta)$. If a wave propagates at all angles in some region, it is represented by a spheroid. The axes are effectively the magnetic-field

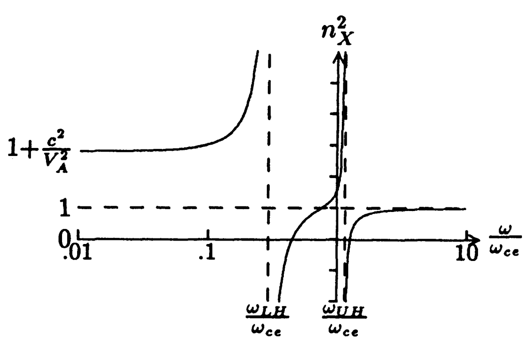

FIG. 2. Dispersion relation for the *X* wave.

strength ($\omega_{ce}/\omega \propto B_0$) vs the density ($\omega_{pe}^2/\omega^2 \propto n_e$). With $\theta = 0$ at the top of each wave normal surface, the CMA diagram is shown in Fig. 3 along with labels of the boundaries and wave types at $\theta = 0$ and $\theta = \pi/2$. If $P/S < 0$ in any bounded volume of the diagram, then there is a resonance at angle θ_r given by $\tan^2\theta_r = -P/S$. In such cases, there is a single lemniscoid in that region. The lightly dotted curve in Fig. 3, which corresponds to $RL = PS$, indicates where the X wave and the O wave cross [n^2 the same for both since $F = 0$ in Eq. (14)], but there is no resonance or cutoff on this surface. Figures 1 and 2 follow the heavy dotted trajectory from the upper right to the lower left.

2.3 Phase and Group Velocity

The wave normal surfaces represented topologically by the spheroids and lemniscoids of Fig. 3 are sometimes referred to as a "plasma pond," since a localized disturbance will exhibit waves propagating in either spheroids or lemniscoids. The surfaces display the phase velocity, however, which must be distinguished from the group velocity. Whereas the phase velocity is given by $v_p(\theta) = \omega/k(\theta)$, the group velocity is given by

$$\mathbf{v}_g = \nabla_k \omega = \left.\frac{\partial\omega}{\partial k}\right|_\theta \hat{e}_k + \frac{1}{k}\left.\frac{\partial\omega}{\partial\theta}\right|_k \hat{e}_\theta, \tag{20}$$

where $\hat{e}_k$ is a unit vector in the $\mathbf{k}$ direction, etc. The angle α between the phase and group velocities is given by

$$\tan\alpha = \left(\frac{1}{k}\left.\frac{\partial\omega}{\partial\theta}\right|_k\right)\left(\left.\frac{\partial\omega}{\partial k}\right|_\theta\right)^{-1} = -\frac{1}{k}\left.\frac{\partial k}{\partial\theta}\right|_\omega .$$

A good example of the effects of the group velocity is the guidance of the whistler wave, which is the R wave when well above the ion cyclotron frequency and well below the electron cyclotron frequency. In this case, the dispersion relation is approximately given by

$$\omega \simeq k^2c^2\omega_{ce}\cos\theta/\omega_{pe}^2, \tag{22}$$

from which $\tan\alpha = -\frac{1}{2}\tan\theta$ so that $\mathbf{v}_g$ always lies between $\mathbf{B}_0$ and $\mathbf{v}_p$. This is illustrated in Fig. 4(a) where the wave normal surface is two spheres joined at $\theta = \pi/2$, while the group velocity $v_g(\theta) \simeq kc^2\omega_{ce} \times \sqrt{1 + \cos^2\theta/\omega_{pe}^2}$ from Fig. 4(b) is a pair of separated spheres. The maximum deviation of the group velocity from the direction of

the magnetic field is seen to be $(\theta + \alpha)_{\max} = \tan^{-1}8^{-1/2} = 19.5°$.

2.4 Ray Tracing

When a plasma is slowly varying in space (or time), these simple expressions for group velocity may not suffice. If one expresses a dispersion relation in the form $D(\mathbf{k},\omega,\mathbf{r},t) = 0$, the direction of power flow may be determined by integrating along a ray, called *ray tracing*, governed by the equations (Weinberg, 1962)

$$\frac{d\mathbf{k}}{d\tau} = \nabla D, \tag{23}$$

$$\frac{d\mathbf{r}}{d\tau} = -\nabla_k D, \tag{24}$$

$$\frac{d\omega}{d\tau} = \frac{\partial D}{\partial t}, \tag{25}$$

where τ is a parameter along the ray given by $\partial D/\partial\omega = dt/d\tau$. The energy density evolves along the ray according to

$$\frac{dU}{dt} = -U\nabla\cdot\mathbf{v}_g - \tfrac{1}{2}\omega\epsilon_0\mathbf{E}^*\cdot\mathbf{K}^A\cdot\mathbf{E}, \tag{26}$$

where U is the energy density from the Hermitian portion of $\mathbf{K}$ and $\mathbf{v}_g = \nabla_k\omega$, so that the first term is related to focusing, and $\mathbf{K}^A$ is the anti-Hermitian portion of $\mathbf{K}$, and relates to dissipation.

2.5 Polarization

We define the terms right-handed and left-handed in terms of the rotation of the electric-field vector as a wave propagates parallel to the magnetic field. If the electric vector rotates clockwise as it propagates along the B-field direction, then this is a right-handed wave, and the left-handed wave rotates counterclockwise. To see what this implies, we consider a wave with complex E_x and E_y that represent a circularly polarized R wave by requiring

$$\begin{aligned}\mathrm{Re}(E_x) &= a\cos(-\omega t) = \mathrm{Re}[a\exp(-i\omega t)],\\ \mathrm{Re}(E_y) &= -a\sin(-\omega t) = \mathrm{Re}[ia\exp(-i\omega t)],\end{aligned} \tag{27}$$

from which it is clear that the measurable fields represented by Eq. (27) with real a rotate clockwise. Thus, it follows that the phases of the waves are given by

$$\begin{aligned}iE_x &= E_y, \quad R\text{ wave},\\ iE_x &= -E_y, \quad L\text{ wave}.\end{aligned} \tag{28}$$

In order to connect this result with plasma waves, we note that the y component of Eq. (9) leads to

$$\frac{iE_x}{E_y} = \frac{n^2 - S}{D} = \pm 1 \tag{29}$$

by letting $n^2 = R, L$. Even this labeling is not always consistent for $\theta \neq 0$, since if the angle given by $\sin^2\theta_c = P/S$ is a real angle, then $n^2 = S$ there and the polarization changes direction at that angle.

2.6 Electrostatic Waves

When the phase velocity of a wave is very slow, the wave magnetic field component is typically small and if neglected, the wave may be obtained from an electrostatic potential, so that $\mathbf{E} = -\nabla\phi = -i\mathbf{k}\phi$. This leads to the electrostatic dispersion relation

$$\mathbf{k}\cdot\mathbf{K}\cdot\mathbf{k} = 0. \tag{30}$$

In cold plasmas, this reduces to $k_\perp^2 K_1 +$

$k_z^2 K_3 = 0$. For parallel propagation, this requires $K_3 = P = 0$, and so plasma oscillations are an example of an electrostatic wave. The sufficient condition for the validity of the electrostatic approximation is simply that $n^2 \gg |K_{ij}|$ for all i and j, or that the index of refraction should be large compared to all of the dielectric tensor elements. The large value of n justifies their frequently being called slow waves, since $v_p \ll c$.

2.6.1 Resonance Cones If one excites a wave in a plasma from a point source, then the radiation pattern is generally not symmetric in space, especially in those regions of parameter space where the wave normal surfaces are lemniscoids, since waves do not even propagate in all directions. In fact, in plasmas that have resonance angles, the propagation is strongly influenced by the resonance and was shown (Kuehl, 1962) to give rise to resonance cones, so called because virtually all of the wave energy is propagated from the point source in cones with a fixed angle with respect to the magnetic field. To see how this occurs, we consider electrostatic waves near the lower hybrid resonance.

We begin with an oscillating point source described by $\rho(\mathbf{r},t) = \delta(\mathbf{r}) \exp(-i\omega t)$ so that the spatial Fourier transform of the source is given by $\rho(\mathbf{k}) = 1$. As long as the source extent is small compared to the distances where measurements are to be made, this provides an adequate description of the source. The Fourier transform of the resulting potential is given by Poisson's equation so that

$$\Phi(\mathbf{k}) = \rho(\mathbf{k})/\epsilon_0 D(k_\perp^2, k_z), \tag{31}$$

where $D(k_\perp^2, k_z) = \mathbf{k}\cdot\mathbf{K}\cdot\mathbf{k}$. In cylindrical coordinates in k space with the axis aligned with the magnetic field, the inverse Fourier transform gives

$$\varphi(\mathbf{r}) = \int_{-\infty}^{\infty} \frac{dk_z e^{ik_z z}}{4\pi^2\epsilon_0} \int_0^{\infty} \frac{k_\perp J_0(k_\perp \rho) dk_\perp}{D(k_\perp^2, k_z)}, \tag{32}$$

where ρ and z are in cylindrical coordinates. The integral over $k_\perp$ has poles at $k_{\perp 0} = k_z\sqrt{-K_3/K_1}$, resulting in

$$\varphi(\mathbf{r}) = \frac{i}{8\pi\epsilon_0 K_1} \int_{-\infty}^{\infty} dk_z e^{ik_z z} H_0^{(1)}(k_{\perp 0}\rho). \tag{33}$$

For large $|\rho|$, the integral becomes a delta function, evaluating the integrand at $\rho = z \times \tan\phi$. Now ϕ is the angle of the group velocity at resonance, and so the only disturbance far from the source occurs at this particular cone angle. Using lower hybrid waves as an example of this, the radiated energy far from the source is found only on cones whose angle is given by

$$\theta_c = \tan^{-1}\sqrt{-K_1/K_3}. \tag{34}$$

These cones are illustrated in Fig. 5 where the geometry is evident. Thermal effects tend to broaden the cone and generate thermal interference fringes just inside the resonance cone angle (Fisher and Gould, 1971).

2.7 Beams and Instabilities

If one adds a drifting plasma component or beam that is moving at uniform velocity v_0 parallel to the magnetic field, the dielectric tensor elements are modified so that

$$\begin{aligned} K_1 &= K_{10} + \frac{\omega_{pb}^2}{[\omega_{cb}^2 - (\omega - k_\parallel v_0)^2]}, \\ K_2 &= K_{20} - \frac{i\epsilon_b \omega_{pb}^2 \omega_{cb}(\omega - k_\parallel v_0)}{\omega^2[\omega_{cb}^2 - (\omega - k_\parallel v_0)^2]}, \\ K_3 &= K_{30} - \omega_{pb}^2/(\omega - k_\parallel v_0)^2. \end{aligned} \tag{35}$$

This additional term adds a source of free energy in the plasma and permits unstable plasma waves with complex roots. If k is assumed complex, there are decaying and amplifying waves, or if ω is taken complex, waves grow or decay in time everywhere. Which, in fact, occurs is not immediately ap-

parent without some criteria to distinguish them.

2.7.1 Convective and Absolute Instabilities The criteria for distinguishing the kinds of instabilities were first given by Sturrock (1958), but the form here is due to Briggs (1964). Waves are classified as *unstable* if for real k, ω has a positive imaginary part; a wave with complex k for real ω is called *amplifying* if it grows in space in the direction of the group velocity and *evanescent* if it decays in that direction. Furthermore, if a finite source leads to growth in time at *every* point in space, it is an *absolute* instability. Finally, a *convective* instability occurs if at a fixed point in space, a growing wave eventually decays in time as the disturbance "convects" away. These are related to amplifying waves.

For a general dispersion relation $D(\omega,k) = 0$, where a general wave is assumed to vary as $\exp(ikz - i\omega t)$, the criteria for distinguishing between amplifying and evanescent waves at a fixed real frequency ω_0 are determined by the motion of the roots of the dispersion relation as the imaginary part of ω is varied. To decide whether a given wave with a complex $k = k_r + ik_i$ for some real ω is amplifying or evanescent, determine whether or not k_i changes sign when the frequency takes on a large positive imaginary part. If it does, then the wave is amplifying; otherwise, it is an evanescent wave. This rule has a relatively simple interpretation based on the concept of a source that is growing in time exponentially. If it grows fast enough, *causality* requires that the wave decay away from the source uniformly. This means that the growth rate of an amplifying wave should *change sign* when the imaginary part of ω becomes large and positive, signifying a growing source.

An absolute instability is obtained whenever there is a double root of k for some complex ω in the upper-half ω plane for which the two merging roots come from different halves of the complex k plane (upper and lower) when ω has a large positive imaginary part. For this case, we can understand the criterion by considering a point source in space that is again growing faster than any instability so that the wave must decay away from the source from causality. When we consider the wave to the right ($z > 0$, k_+) along with the wave traveling to the left ($z < 0$, k_-), in general one has a discontinuity in matching either k or its derivative that is provided by the source. If, however, the increasing imaginary part of ω should cause the two values of $k_\pm$ to *coincide*, then the match at $z = 0$ can be accomplished without any source and this is a normal mode of the system, and if growing, then it is growing everywhere independent of the source.

These criteria for absolute and amplifying instabilities are for infinite systems and are not guaranteed for bounded systems.

2.7.2 Beam–Plasma Instability As a first example, we consider a 1-D problem with an electron beam passing through an unmagnetized plasma, so that the dispersion relation is given by

$$K_3 = 1 - \frac{\omega_p^2}{\omega^2} - \frac{\omega_{pb}^2}{(\omega - kv_0)^2} = 0. \tag{36}$$

The roots of this dispersion relation are

$$kv_0 = \omega(1 \pm \omega_{pb}/\sqrt{\omega^2 - \omega_p^2}), \tag{37}$$

and when $\omega < \omega_p$, the roots are complex and one lies above the real k axis and the other below. When ω has a large imaginary part, $|\omega| \to \infty$, and both roots are given by $k \sim (\omega \pm \omega_{pb})/v_0$, so that both roots are in the upper half plane. Since one had to cross, there is one amplifying wave. This is driven by the beam particles traveling close to the phase velocity which give up energy to the beam.

2.7.3 Two-Stream Instability Generalizing to two beams in opposite directions, the dispersion relation is

$$1 - \frac{\omega_p^2}{\omega^2} - \frac{\omega_{p1}^2}{(\omega - kv_1)^2} - \frac{\omega_{p2}^2}{(\omega + kv_2)^2} = 0. \tag{38}$$

if we let $\omega_{p1} = \omega_{p2} = \omega_0$ and $v_1 = v_2 = v_0$, some analytic results are possible. Defining $P = 1 - \omega_p^2/\omega^2$, the roots are

$$(kv_0)^2 = \omega^2 + \frac{\omega_0^2}{P} \pm \frac{\omega_0}{P}\sqrt{\omega_0^2 + 4P\omega^2}, \tag{39}$$

so there is a double root or saddle point where $\omega_0^2 = -4P\omega^2$ or $\omega^2 = \omega_p^2 - \omega_0^2/4$. For $\omega_p < \omega_0/2$, this leads to complex roots and an absolute instability. When we plot the locus of k^2 for pure imaginary ω in the complex k^2 plane, the saddle point lies on the real k^2 axis and branches off above and below the axis as in Fig. 6(a) for large ω_i and branches out along the real k^2 axis for small ω_i, ending with both roots at the origin. This means there are two symmetric saddle points, one with $k_r > 0$ and one with $k_r < 0$, and the branches for variable ω_i go either along the real k axis or above and below the axis, as shown in Fig. 6(b), which is the condition for the absolute instability.

3. WARM-PLASMA WAVES

When one goes beyond the cold-plasma model, effects of finite temperature may be inserted at several levels of approximation, from simply including a pressure term, or possibly by using higher moments of the Boltzmann equation, through kinetic-theory effects that may be nonrelativistic or relativistic. The first level of approximation is usually based either on one- or two-fluid models, which include MHD theory and indicate the direction that finite-temperature effects will take us from the cold-plasma model. The full kinetic-theory model, however, introduces both quantitatively and qualitatively different behavior, with a new class of waves and collisionless damping.

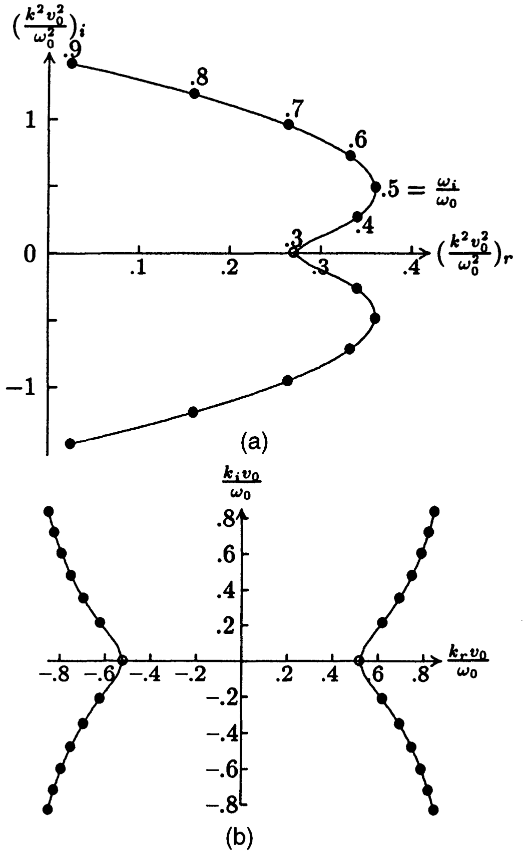

FIG. 6. Locus of (a) $k^2(\omega_i)$ in complex k^2 plane and (b) $k(\omega_i)$ in complex k plane (same points) from Eq. (39) for $\omega_p = 0.4\ \omega_0$.

3.1 Fluid Models

Fluid equations are based on moment expansions of the Boltzmann equation

$$\frac{\partial f}{\partial t} + \mathbf{v}\cdot\nabla f + \mathbf{a}\cdot\nabla_v f = \left.\frac{df}{dt}\right|_{\text{coll.}}, \tag{40}$$

where $\mathbf{a}$ is the acceleration due to electric and magnetic fields through the Lorentz force. If $\mathbf{u}$ is the mean velocity for a particular species, then the 0th moment of the Boltzmann equation, with the average density given by $n(\mathbf{r}) = \int f d^3v$, is

$$\frac{\partial n}{\partial t} + \nabla\cdot(n\mathbf{u}) = 0, \quad \text{Continuity equation.} \tag{41}$$

The corresponding first moment is

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u}\cdot\nabla)\mathbf{u} + \frac{\nabla\cdot\boldsymbol{\Psi}}{nm} - \frac{q}{m}(\mathbf{E} + \mathbf{u}\times\mathbf{B}) = 0, \tag{42}$$

where $\boldsymbol{\Psi}$ is the stress tensor. The evaluation of the stress tensor depends on even higher-moment equations, which introduce even higher-order terms. The method of solution is to truncate the hierarchy, in which case the simplest interpretation of $\boldsymbol{\Psi}$ is simply the pressure, which is obtained from an equation of state. Equation (42) represents the conservation of momentum while the continuity equation conserves particles.

3.1.1 Bohm–Gross Dispersion Relation

If we restrict ourselves to a one-dimensional problem, the higher moments are not so complicated; and if we examine the special case of plasma oscillations, where the magnetic field is not involved, then, assuming a Maxwellian distribution and truncating above the third moment, the dispersion relation for plasma oscillations is given by Eq. (2), which is called the Bohm–Gross dispersion relation (Bohm and Gross, 1949). Keeping terms through the fifth moment, the result is Eq. (3), so it is apparent that *the moment expansion is an expansion in the ratio of the thermal velocity to the phase velocity*. The Bohm–Gross dispersion relation resolves the ambiguity in cold-plasma theory where there was no phase or group velocity for plasma oscillations since k was not involved, and supports the notion that $P = 0$ in cold plasma is a cutoff rather than a resonance, since this dispersion relation describes a wave with a cutoff at ω_{pe} that propagates at the electron thermal speed for high frequencies.

3.1.2 Low-Frequency Dispersion Relation If we consider the linearized fluid equations for electrons and one species of ions along with the Maxwell equations, using the adiabatic equation of state so that the pressure $p_j = c_j^2\rho_j$ and c_j is the sound speed for species j given by $c_j^2 \equiv \gamma_j \kappa T_j/m_j$, then we may write the *low-frequency dispersion relation* (Stringer, 1963)

$$\left(1 - \frac{\omega^2}{k^2V_A^2} - \frac{\omega^2}{\omega_{ce}\omega_{ci}} + \frac{k^2c_s^2\sin^2\theta}{\omega^2 - k^2c_s^2}\right) \times \left(\cos^2\theta - \frac{\omega^2}{k^2V_A^2} - \frac{\omega^2}{\omega_{ce}\omega_{ci}}\right) = \frac{\omega^2\cos^2\theta}{\omega_{ci}^2}, \tag{43}$$

where θ is the angle between the direction of propagation and the static magnetic field and c_s is the acoustic speed given by $c_s^2 = (\gamma_e\kappa T_e + \gamma_i\kappa T_i)/(m_e + m_i)$.

3.1.3 MHD Region For the very low-frequency case, where $\omega \ll \omega_{ci}$, the right-hand side of the low-frequency dispersion relation may be neglected, along with $\omega^2/\omega_{ce}\omega_{ci}$, so that it reduces to the two separate factors,

$$1 - \frac{\omega^2}{k^2V_A^2} + \frac{k^2c_s^2\sin^2\theta}{\omega^2 - k^2c_s^2} = 0, \tag{44}$$

$$\cos^2\theta - \omega^2/k^2V_A^2 = 0. \tag{45}$$

Equation (45) gives the cold torsional-wave dispersion relation,

$$\omega^2 = k^2V_A^2\cos^2\theta, \tag{46}$$

which is independent of temperature. This is the torsional Alfvén wave, whose group velocity is parallel to the magnetic field.

Equation (44) leads to the quadratic

$$\omega^4 - k^2(V_A^2 + c_s^2)\omega^2 + k^4V_A^2c_s^2\cos^2\theta = 0, \tag{47}$$

with approximate roots (for $c_s \ll V_A$)

$$\omega^2 = k^2(V_A^2 + c_s^2\sin^2\theta) \tag{48}$$

and

$$\omega^2 = k^2c_s^2\cos^2\theta. \tag{49}$$

This last dispersion relation describes an acoustic wave whose phase velocity is equal to the acoustic speed and whose group velocity is parallel to the magnetic field but otherwise independent of the magnetic field.

The first root, from Eq. (48), is more interesting, since now the cold compressional wave is coupled to sound-wave terms. For this reason, this wave is often called the magnetoacoustic or magnetosonic wave since it is coupled to acoustic modes in the low-frequency limit. It is clear from the dispersion relation that the magnetoacoustic wave is equivalent to the cold-plasma compressional mode when $V_A \gg c_s$ and that the phase and group velocities are parallel in that limit; but when V_A is comparable to c_s, then the phase and group velocities are no longer parallel, since the acoustic-wave component of the dispersion relation tends to guide the wave away from the direction of the magnetic field. This same branch is thus partially guided *across* the field at very low frequencies if acoustic effects are important, isotropic if acoustic effects are negligible, and then at intermediate frequencies is guided *along* the field as the whistler wave, and carries a variety of names, depending on the approximation ($V_A \gg c_s$ or $V_A \ll c_s$), the frequency ($\omega \ll \omega_{ci}$ or $\omega_{ci} \ll \omega \ll \omega_{ce}$), and the angle ($R$ wave for $\theta = 0$, X wave for $\theta = \pi/2$ up to ω_{LH}).

In addition to the MHD region, there are numerous regions in parameter space that have distinctive characteristics, and the low-frequency dispersion relation couples these in a variety of transition regions. Unfortunately, most of these transitions occur in regions where the phase velocity is comparable to a thermal speed, and so the moment expansions upon which the analysis is based are unreliable in precisely those regions. This means that some solutions, and the transitions in particular, require a full kinetic treatment in order to obtain a proper description.

3.1.4 Collisions and Resistivity The effects of collisions on waves may be included relatively easily by adding a drag term in the momentum equation. For example, if Eq. (42) were for electrons (so that $\mathbf{u} \rightarrow \mathbf{v}_e$), then one would add a term $-\nu_{en}\mathbf{v}_e$ on the right for electron-neutral collisions. For the cold plasma, this kind of collision term modifies the dielectric tensor elements so that

$$\begin{aligned} K_1 &\equiv S = 1 - \sum_j \frac{\omega_{pj}^2(\omega + i\nu_j)}{\omega[(\omega + i\nu_j)^2 - \omega_{cj}^2]}, \\ iK_2 &\equiv D = \sum_j \frac{\epsilon_j \omega_{cj} \omega_{pj}^2}{\omega[(\omega + i\nu_j)^2 - \omega_{cj}^2)]}, \\ K_3 &\equiv P = 1 - \sum_j \frac{\omega_{pj}^2}{\omega(\omega + i\nu_j)}. \end{aligned} \tag{50}$$

For electron-ion collisions, the momentum gained by one species must be balanced by a corresponding loss for the other species, and this is generally incorporated through the introduction of plasma resistivity through a form of Ohm's law. The effective collision times from a one-fluid model with $\mathbf{u} = \mathbf{v}_e - \mathbf{v}_i$ are (Braginskii, 1965)

$$\begin{aligned} \tau_e &= \frac{3(2\pi)^{3/2}\sqrt{m_e}\,\epsilon_0^2(\kappa T_e)^{3/2}}{e^4 Z n_e \ln\Lambda} \\ &= \frac{3.4 \times 10^{11} T_e^{3/2}}{Z n_0 \ln\Lambda}, \end{aligned} \tag{51}$$

where the temperature is expressed in eV in the simplified expression with $n_e = n_0 = Zn_i$. The quantity Λ is approximately given by $\Lambda \simeq 9N_\mathrm{D}$ where N_D is the number of particles in a Debye sphere. The drag term is

$$\mathbf{R}u = -ne(\mathbf{j}_\parallel/\sigma_\parallel + \mathbf{j}_\perp/\sigma_\perp), \tag{52}$$

where the perpendicular and parallel conductivities are given by

$$\sigma_\perp = n_e e^2 \tau_e / m_e, \quad \sigma_\parallel = 1.96\sigma_\perp. \tag{53}$$

The inclusion of resistivity in the low-frequency dispersion relation, Eq. (43), modifies only the terms in $\omega^2/\omega_{ce}\omega_{ci}$, changing the first such term so that $\omega^2 \rightarrow \omega(\omega + i\nu_\perp)$ and the second so that $\omega^2 \rightarrow \omega(\omega + i\nu_\perp \cos^2\theta + i\nu_\parallel \sin^2\theta)$, where $\nu_\perp = ne^2/m_e\sigma_\perp$ and $\nu_\parallel = 0.51\nu_\perp$. The reason one ω is modified by collisions and the other not is that the first came from the Maxwell equations (not modified) and the other from the moment equations where collisions modify the time evolution of the distribution function.

3.1.5 Drift Waves Whenever there is a gradient in one of the equilibrium parameters, it generally leads to crossed electric and magnetic fields that allow the propagation of drift waves. The literature is extensive in the kinds of instabilities that may arise from these gradients (see Krall, 1968; Mikhailovskii, 1983). We will examine here only the basic principles and illustrate with an example. The literature is difficult to survey because there are examples of collisionless drift instabilities from a kinetic equation, there are collisional or dissipative drift instabilities from the fluid equations, and some use a mixture of both.

In order to see some of the nature of the problem without extensive analysis, we begin with a case of electrons and ions in the long-wavelength limit ($k^2\lambda_\mathrm{D}^2 \ll 1$ so that $n_e = n_i$) using the fluid equations and examine low-frequency electrostatic waves. If we neglect electron inertia ($m_e \rightarrow 0$) in the momentum equation, then we have the balance between the pressure gradient and the electric field as

$$e\frac{\partial\varphi}{\partial x} = \frac{\kappa T_e}{n_e}\frac{\partial n_e}{\partial x}, \tag{54}$$

with solution $n_e = \exp(e\varphi/\kappa T_e)$. The potential is assumed to vary as $\varphi \sim \exp(ik_y y - i\omega t)$, and the density as

$$n_i = n_e = n_0 \exp(e\varphi/\kappa T_e) \simeq n_0 + n_0 e\varphi/\kappa T_e. \tag{55}$$

The equation of motion for ions is

$$-i\omega m_i \mathbf{v}_i = e(\mathbf{E} + \mathbf{v}_i \times \mathbf{B}_0) \simeq 0, \tag{56}$$

since $\omega \ll \omega_{ci}$. Hence, $v_{ix} \simeq E_y/B_0 = -ik_y\varphi/B_0$. The ion continuity equation gives

$$-i\omega n_{1i} + v_{ix}\frac{dn_0}{dx} = 0, \tag{57}$$

and using the expressions for n_{1i} and v_{ix}, this may be solved for ω as

$$\omega = -\frac{k_y \kappa T_e}{eB_0}\frac{1}{n_0}\frac{dn_0}{dx} \equiv \omega_e^*. \tag{58}$$

Usually $n_0(x)$ decreases with increasing x, and so normally $\omega_e^* > 0$. The wave travels in the direction of $\nabla n_0 \times \mathbf{B}_0$ with phase velocity $c_s\rho_s/L_n$ where c_s is the ion-acoustic speed, $\rho_s = c_s/\omega_{ci}$ is like an ion Larmor radius, except that it depends on T_e rather than T_i, and L_n is the scale length of the density variation.

One way of thinking about the source of free energy for this instability is to realize that the density gradient tends to establish a radial electric field to balance the diffusion rates, and this radial field sets the plasma into rotation as a result of the $\mathbf{E} \times \mathbf{B}_0$ drift. In this case, a cylindrical plasma leads to waves rotating with an azimuthal mode number $k_y \simeq 2\pi m/r$, and so the waves may be localized about a radius where m is an integer. These drifting low-frequency waves are susceptible to a variety of instabilities.

3.1.6 Drift Resistive Instability For this example, we shall generalize somewhat the elementary analysis above, but still use the long-wavelength approximation and the electrostatic approximation, but with $\mathbf{E} = \mathbf{E}(x)\exp[i(k_y y + k_z z - \omega t)]$. This allows the wave to propagate parallel to the magnetic field in addition to its drift perpendicular to both the field and the gradient. Then using the fluid equation for electrons with collisions, and the electron continuity equation, the perturbed electron density is

$$\frac{n_e}{n_0} = \frac{e\varphi}{\kappa T_e}\frac{(1 - i\omega_e^* m_e \nu_{ei}/k_z^2\kappa T_e)}{(1 - i\omega m_e \nu_{ei}/k_z^2\kappa T_e)}. \tag{59}$$

For the ions, we assume $\omega \ll \omega_{ci}$ but keep first-order terms, so that along with the ion continuity equation, one finds

$$\frac{n_i}{n_0} = \frac{e\varphi}{\kappa T_e}\left(\frac{\omega_e^*}{\omega} + \frac{k_z^2 c_s^2}{\omega^2} - k_\perp^2\rho_s^2\right). \tag{60}$$

Equating Eq. (59) to Eq. (60) leads to the dispersion relation, which may be written as a quadratic,

$$\omega^2 + i\omega_s\left(1 + k_\perp^2\rho_s^2 - \frac{k_z^2 c_s^2}{\omega^2}\right)\omega - i\omega_e^*\omega_s = 0, \tag{61}$$

where

$$\omega_s = \frac{\omega_{ce}\omega_{ci}}{\nu_{ei}}\left(\frac{k_\perp^2}{k_z^2} - \frac{\omega_{ci}^2}{\omega^2}\right)^{-1}. \tag{62}$$

There is an unstable root whose maximum growth rate occurs when $\omega_e^* \simeq \omega_s(1 + k_\perp^2\rho_s^2 - k_z^2c_s^2/\omega^2)^2$, at which point

$$\omega = \frac{\omega_e^*(0.618 + 0.300i)}{1 + k_\perp^2\rho_s^2 - k_z^2c_s^2/\omega^2}. \tag{63}$$

This example exemplifies both the complexities and many approximations that are common to drift-type instabilities, and others based on temperature gradients, etc., are numerous.

3.2 Kinetic Models

Kinetic effects in plasma waves are included through the kinetic equation

$$\frac{\partial f_j}{\partial t} + \mathbf{v}\cdot\nabla f_j + \frac{q_j}{m_j}(\mathbf{E} + \mathbf{v} \times \mathbf{B})\cdot\nabla_v f_j = 0 \tag{64}$$

for each species, and the Maxwell equations, with

$$\rho = \sum_j q_j \int d^3v\, f_j, \tag{65}$$

$$\mathbf{J} = \sum_j q_j \int d^3v\, \mathbf{v} f_j \tag{66}$$

as the sources. This set, which neglects correlations, is commonly called the Vlasov equations. They form the basis for virtually all of kinetic theory except when correlations (or collisions) must be included.

3.2.1 Landau Damping The solution of the linearized set of equations without any magnetic field was first attempted using Fourier transforms in both time and space, resulting in a dispersion relation for plasma oscillations of the form

$$K_3 = 1 - \frac{\omega_{pi}^2}{k^2v_i^2}Z'\left(\frac{\omega}{kv_i}\right) - \frac{\omega_{pe}^2}{k^2v_e^2}Z'\left(\frac{\omega}{kv_e}\right), \tag{67}$$

where the prime denotes a derivative with respect to the argument, and the $v_j^2 = 2\kappa T_j/m_j$ are thermal velocities. The difficulty with this simple analysis was that in integrating over the velocity, it must be assumed that ω has a positive imaginary part in order to obtain the result above, while using the asymptotic expression for $Z(\zeta)$, one finds that ω has a negative imaginary part. Conversely, assuming a negative imaginary part to begin with, one finds a positive imaginary part, and so the method is not self-consistent. This difficulty was resolved by Landau who instead took Laplace transforms in time, assuming an initial perturbation at time 0+, and then the result above follows in a natural way, and the resulting damping is called Landau damping (Landau, 1946).

In the weak-damping limit ($v_p \gg v_e$), the dispersive solution for $\omega(k)$ gives the same result as the moment expansion, which to lowest nontrivial order gave the Bohm–Gross dispersion relation of Eq. (2). The corresponding Landau damping rate is given by

$$\omega_i = -\frac{\sqrt{\pi}\,\omega_{pe}^2\omega_r^2}{k^3 v_e^3}\exp\left(-\frac{\omega_r^2}{k^2 v_e^2}\right). \tag{68}$$

This damping is due to those particles in the distribution that travel near the phase velocity, and results in damping instead of growth because there are more traveling slightly slower than traveling faster, drawing energy from the wave as they gain or lose energy to stay with the wave.

3.2.2 Ion-Acoustic Wave In the example above, ion motions were neglected, since they are usually unimportant. In the cold-plasma limit this is because $m_e/m_i \ll 1$. Near the ion plasma frequency, however, it is possible to consider a case where the ions are cold ($v_i \ll v_p$), but the electrons are hot ($v_e \gg v_p$). When the electron and ion temperatures are comparable, there is generally no oscillation, since when one moves some of the ions to form a slight charge imbalance that would induce the ions to oscillate, the period is so slow that electrons, being so much more mobile, rush in to fill the charge imbalance before the ions can respond. When the electron temperature is much higher than the ion temperature, however, the electrons have too much momentum to slow down and fill in the potential depressions, and so some ion oscillations may occur.

Using the same dispersion relation for this case, but assuming $\zeta_i = \omega/kv_i \gg 1$, and $\zeta_e = \omega/kv_e \ll 1$, the dispersion relation becomes

$$1 + \frac{1 + i\sqrt{\pi}\zeta_e}{k^2\lambda_{\mathrm{D}}^2} = \frac{\omega_{pi}^2}{\omega^2}\left[1 - 2i\sqrt{\pi}\zeta_i^3\exp(-\zeta_i^2)\right]. \tag{69}$$

Setting the real and imaginary parts equal to zero separately, we obtain

$$\omega_r^2 = k^2c_s^2/(1 + k^2\lambda_{\mathrm{D}}^2) \tag{70}$$

and

$$\frac{\omega_i}{\omega_r} = -\sqrt{\pi}\zeta_i^3\left[\exp(-\zeta_i^2) + \frac{T_i v_i}{T_e v_e}\right], \tag{71}$$

where $\omega = \omega_r + i\omega_i$ and $c_s = \sqrt{\kappa T_e/m_i}$ is the ion-acoustic speed. We note that if $k\lambda_{\mathrm{D}} \ll 1$, then all waves will travel at the ion-acoustic speed. In order for the damping to be weak, there are constraints on both the electron and ion temperatures so that it requires $T_e \gg T_i$.

3.2.3 Hot-Plasma Dispersion Relation The derivation of the hot-plasma dispersion relation with a static magnetic field is nontrivial. Even if we restrict the results to isotropic Maxwellian distributions without any drifts, then all nine components of the dielectric tensor are nonzero, and if we again take $k_y = 0$, then the *changes* in the structure of the tensor relative to the cold-plasma dielectric tensor may be summarized by the relations

$$K_{yy} = K_1 + K_0, \tag{72}$$

$$K_{xz} = K_{zx} = K_4, \tag{73}$$

$$K_{yz} = -K_{zy} = -K_5, \tag{74}$$

where now $\zeta_{nj} = (\omega + n\omega_{cj})/k_z v_j$ in

$$K_0 = 2\sum_j \frac{\omega_{pj}^2 e^{-\lambda_j}}{\omega k_z v_j}\sum_{n=-\infty}^{\infty}\lambda_j(I_n - I_n')Z(\zeta_{nj}), \tag{75}$$

$$K_1 = 1 + \sum_j \frac{\omega_{pj}^2 e^{-\lambda_j}}{\omega k_z v_j}\sum_{n=-\infty}^{\infty}\frac{n^2 I_n}{\lambda_j}Z(\zeta_{nj}), \tag{76}$$

$$K_2 = i \sum_j \frac{\epsilon_j \omega_{pj}^2 e^{-\lambda_j}}{\omega k_z v_j} \sum_{n=-\infty}^{\infty} n(I_n - I_n')Z(\zeta_{nj}), \tag{77}$$

$$K_3 = 1 - \sum_j \frac{\omega_{pj}^2 e^{-\lambda_j}}{\omega k_z v_j} \sum_{n=-\infty}^{\infty} I_n \zeta_{nj} Z'(\zeta_{nj}), \tag{78}$$

$$K_4 = \sum_j \frac{k_\perp \omega_{pj}^2 e^{-\lambda_j}}{2k_z \omega \omega_{cj}} \sum_{n=-\infty}^{\infty} \frac{nI_n}{\lambda_j} Z'(\zeta_{nj}), \tag{79}$$

$$K_5 = i \sum_j \frac{k_\perp \epsilon_j \omega_{pj}^2 e^{-\lambda_j}}{2k_z \omega \omega_{cj}} \sum_{n=-\infty}^{\infty} (I_n - I_n')Z'(\zeta_{nj}), \tag{80}$$

where the I_n are modified Bessel functions of order n with argument $\lambda_j = \frac{1}{2}k_\perp^2 \rho_j^2$ where $\rho_j = v_j/\omega_{cj}$ is the Larmor radius, and the I_n' are derivatives with respect to the argument. Generally, $k_\perp^2 = k_x^2 + k_y^2$, but here we have taken $k_y = 0$, so that $k_\perp = k_x$.

The appearance of the parameter λ_j, which is effectively the square of the ratio of the Larmor radius to the perpendicular wavelength, adds an important new feature to the hot-plasma effects. When the wavelength is long (λ_j small), a gyrating particle sees no overall effect near integral multiples of the cyclotron frequency. When the lengths are comparable, however, the integrated effect about the orbit is not small, and significant dispersion is the result. There are thus two distinct kinds of parameters that affect the deviations from cold plasma, namely, the ratio v_j/v_p and λ_j.

Using these components, the hot-plasma dispersion relation may be written as

$$\begin{aligned}&[\gamma(\gamma - \kappa_0 + k_\perp^2) + \kappa_2^2]\kappa_3 \\ &\quad + k_\perp^2[(\gamma - \kappa_0 + k_\perp^2)\kappa_1 - \kappa_2^2] \\ &\quad = \kappa_4(\gamma - \kappa_0 + k_\perp^2)(2k_\perp k_z + \kappa_4) \\ &\quad - \kappa_5[\gamma\kappa_5 + 2\kappa_2(k_\perp k_z + \kappa_4)] = 0,\end{aligned} \tag{81}$$

where $\kappa_j \equiv (\omega^2/c^2)K_j$ and $\gamma = k_z^2 - \kappa_1$. Although the dielectric tensor elements are more complicated with $k_y \neq 0$, the dispersion relation is the same as long as $k_\perp$ is used. This dispersion relation and the more complicated dielectric tensor components introduce two new distinct effects: cyclotron damping and finite–Larmor-radius effects. The first is analogous to Landau damping, only one must be in a rotating reference frame with angular frequency $n\omega_{cj}$ to observe the similarity. The effects of finite Larmor radius are exhibited through $\lambda_j \neq 0$, since this parameter is the square of the ratio of the Larmor radius to the perpendicular wavelength.

3.2.4 Cyclotron Damping For parallel propagation, $k_\perp = \lambda_j = 0$, and the tensor elements simplify since the infinite sums reduce to either one or two terms. In addition, we find $K_0 = K_4 = K_5 = 0$, and so the dispersion relation reduces to

$$(\gamma^2 + \kappa_2^2)\kappa_3 = 0, \tag{82}$$

whose roots are $\kappa_3 = 0$ and $k_z^2 = \kappa_1 \pm i\kappa_2$. The first root is the plasma wave, which is unaffected by the magnetic field. The other two roots are the R wave and the L wave, whose dispersion relations reduce to

$$\begin{aligned}n_{R,L}^2 = 1 + \sum_j \frac{\omega_{pj}^2}{\omega k_z v_{lj}} \Bigg[&\left(\frac{1 \pm \epsilon_j}{2}\right)Z(\zeta_{1j}) \\ &+ \left(\frac{1 \mp \epsilon_j}{2}\right)Z(\zeta_{-1j})\Bigg].\end{aligned} \tag{83}$$

The structure of this dispersion relation confirms the general character we had observed with the cold-plasma waves except that now resonance has a different meaning. The R wave is here seen to be a function of $Z(\zeta_{1i})$ and $Z(\zeta_{-1e})$, and assuming that $\omega \gg k_z v_{lj}$, then there is virtually no ion damping associated with the R wave since $|\zeta_{1i}| \gg 1$ and the ion damping is exponentially small. Near the electron cyclotron resonance, however, $|\zeta_{-1e}| \simeq 0$, and in this limit $Z(\zeta_{-1e}) \simeq i\sqrt{\pi}$ so that there is no longer any resonance at the electron cyclotron frequency, but now there is strong damping. A little away from the resonance, assuming weak damping, $\omega_i \ll \omega_r$, the damping is approximately given by

$$\frac{\omega_i}{\omega_r} \sim -\frac{\sqrt{\pi}\omega_{pe}^2 \exp(-\zeta_{-1e}^2)}{\omega_r k_z v_e[2 + \omega_{pe}^2 \omega_{ce}/\omega_r(\omega_r - \omega_{ce})^2]}, \tag{84}$$

which indicates that the damping is exponentially small far from resonance, but as resonance approaches, the exponential term grows. The denominator also grows, suggesting a maximum damping rate, but this approximation fails near the resonance. For $|\zeta_{-1e}| \gg 1$, the damping is weak, and so the cold-plasma dispersion relation is relevant except near resonance.

3.2.5 Electrostatic Waves The effects of finite Larmor radius are very apparent for hot electrostatic waves. In the electrostatic limit, the dispersion relation reduces greatly in complexity, resulting in

$$k_\perp^2 K_1 + 2k_\perp k_z K_4 + k_z^2 K_3 = 0. \qquad (85)$$

Combining the terms in the expressions for K_1, K_3, and K_4, one obtains the hot-plasma electrostatic dispersion relation

$$1 + \sum_j \frac{e^{-\lambda_j}}{k^2\lambda_{Dj}^2} \sum_{n=-\infty}^{\infty} [1 + \zeta_{0j} Z(\zeta_{nj})] I_n(\lambda_j) = 0. \qquad (86)$$

An important special case is when $k_z \to 0$, in which case there is no damping at all and the dispersion relation reduces to

$$k_\perp^2 = \sum_j 2k_{Dj}^2 e^{-\lambda_j} \sum_{n=1}^{\infty} I_n(\lambda_j) \frac{n^2}{\nu_j^2 - n^2}, \qquad (87)$$

where $k_{Dj} = 1/\lambda_{Dj}$ is the Debye wave number and $\nu_j = \omega/\omega_{cj}$. This dispersion relation describes what are known as Bernstein waves and has a resonance at every harmonic of both ion and electron cyclotron frequencies, but the "strength" of the resonance indicated by $I_n(\lambda_j)$ becomes small for large n. We note that there is no absorption to damp out the wave at resonance. Within the framework of the collisionless theory outlined in this section, these resonances remain unresolved.

Examining the behavior for small λ_i (which means $\lambda_e \ll 1$ since $\lambda_e/\lambda_i = T_e m_e/T_i m_i \ll 1$), we approximate $I_n(\lambda) \simeq (\lambda/2)^n/n!$ and consider cold electrons. In this case, the dispersion relation can be approximated by

$$\nu = n - \frac{(n^2 - 1)\lambda_i^{n-1}}{2^n(n-1)![1 - (n^2 - 1)V_A^2/c^2]}, \qquad (88)$$

which indicates that Bernstein waves propagate just below each harmonic while the slope of the dispersion relation near the origin for λ_i is linear for $n = 2$, quadratic for $n = 3$, etc. This behavior changes above the lower hybrid resonance, where the wave propagates just above each harmonic. This behavior is illustrated in Fig. 7(a) below the lower hybrid resonance and in Fig. 7(b) above the resonance.

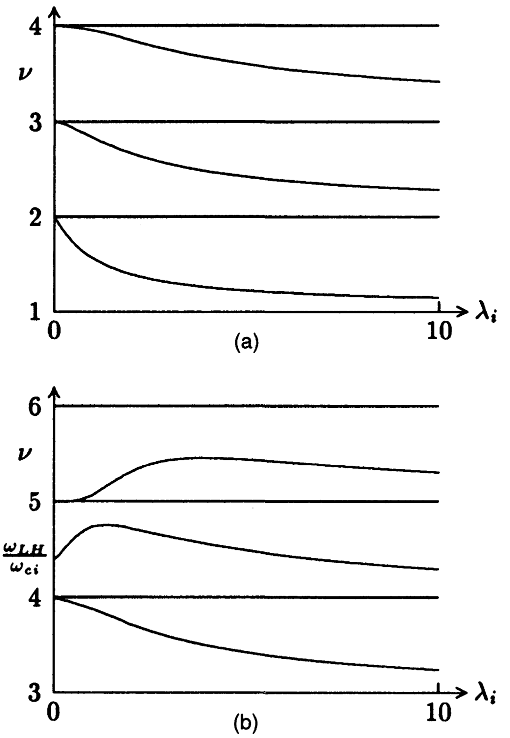

FIG. 7. Ion–Bernstein-wave dispersion relations. (a) High density ($\omega_{pe}^2/\omega_{ce}^2 = 10$). (b) Low density near ω_{LH} ($\omega_{pe}/\omega_{ce} = 0.1$).

There are additional warm-plasma effects when the plasma is relativistic, even if only weakly so. These effects are apparent when one examines the quantity $\zeta_n = (\omega - n\omega_c/\gamma)/k_\parallel v_j$ where γ is the relativistic factor. This argument appears as a constant in the nonrelativistic case, but when $\gamma = 1$ and $k_\parallel \to 0$, $\zeta_n \to \infty$ for any $\omega \neq n\omega_c$, but $\zeta_n \to 0/0$ when $\omega = n\omega_c$. With only weakly relativistic corrections, however, the numerator never vanishes, and there is collisionless damping even for $k_\parallel = 0$. In the weak relativistic limit, where $\mu = mc^2/\kappa T \gg 1$, the dominant dielectric tensor elements with $k_\parallel = 0$ are

$$K_1 = 1 - \frac{\omega_p^2}{\omega^2}\mu \sum_{n=1}^{\infty} \frac{n^2 I_n}{\lambda} \times [F_{n+3/2}(z_+) + F_{n+3/2}(z_-)], \qquad (89)$$

$$iK_2 = \frac{\omega_p^2}{\omega^2}\mu \sum_{n=1}^{\infty} n[I_n'[F_{n+3/2}(z_+) - F_{n+3/2}(z_-)] - I_n[F_{n+5/2}(z_+) - F_{n+5/2}(z_-)]], \qquad (90)$$

$$K_3 = 1 - \frac{\omega_p^2}{\omega^2}\mu\Bigl\{I_0F_{5/2}(\mu) + \sum_{n=1}^{\infty} I_n \times [F_{n+5/2}(z_+) + F_{n+5/2}(z_-)]\Bigr\}, \qquad (91)$$

where $z_\pm = \mu(\omega \pm n\omega_c)/\omega$. The weakly relativistic plasma dispersion function is related to the usual plasma dispersion function through the relation $i\sqrt{z}F_{1/2}(z) = Z(i\sqrt{z})$. The higher-order functions may be obtained from the recursion formula

$$(q - 1)F_q(z) = 1 - zF_{q-1}(z). \qquad (92)$$

From the tensor components above, the X-wave dispersion relation, written as

$$n^2 = 2RL/(R + L), \qquad (93)$$

may be written to first order in λ from the relations

$$R, L = 1 - \frac{\omega_p^2}{\omega^2}\mu[F_{5/2}(z_{\mp 1}) - \lambda F_{7/2}(z_{\mp 1}) + \lambda F_{7/2}(z_{\mp 2})]. \qquad (94)$$

For $z < 0$ (and small), the extraordinary wave will be damped, and this occurs for ω just below the fundamental or the harmonic. The maximum damping typically occurs for $z_n \simeq -\frac{7}{2}$, so that even with κT much less than 1% of the electron rest energy ($\mu > 1000$), nontrivial absorption can occur within a few percent of the cyclotron resonance or its harmonic. It is to be noted that this is with $n_\parallel = 0$ where the nonrelativistic theory indicated no damping at all.

4. PLASMA-FILLED WAVEGUIDE

4.1 Boundary Conditions

The usual boundary conditions encountered are either a conducting wall or a boundary between the plasma and either vacuum or a dielectric (such as glass). These boundary conditions are generally taken as abrupt, and we use jump conditions to relate the fields on opposite sides of the discontinuity. This is never precise, since real plasmas do not have sharp boundaries. In general, as the plasma approaches either a conductor or a dielectric, the density either falls gradually, dominated by a variety of transport phenomena such as electron and ion diffusion, ionization, and recombination, or it falls off rather abruptly, so that a large change occurs in a few Debye lengths. We restrict our attention primarily to waves whose wavelength is long compared to the thickness of the boundary layer (abrupt boundary). The simplest case is the conducting boundary because the condition in a cold plasma is that the tangential electric field must vanish at a perfect conductor. This may be written as

$$\mathbf{E}_t(a) = 0, \qquad (95)$$

where the conducting wall is at radius a (laboratory plasmas are more likely to be cylindrical than rectangular). The boundary conditions used at a plasma–vacuum interface, or at an interface between a plasma and an isotropic, insulating ideal dielectric (such as glass or vacuum), are the usual ideal-dielectric boundary conditions, and with $\hat{\mathbf{e}}_n$ as a unit vector normal to the surface, pointing out from the plasma, are

$$\hat{\mathbf{e}}_n \times (\mathbf{E}_v - \mathbf{E}_p) = 0, \qquad (96)$$

$$\hat{\mathbf{e}}_n \cdot (\mathbf{D}_v - \mathbf{D}_p) = 0, \qquad (97)$$

where we denote either vacuum or an isotropic dielectric by the subscript v. This is not a trivial boundary condition, since for a single wave in the plasma (incident plus reflected, or standing wave normal to the surface, characterized by a single value of $k_\perp$), the conditions Eqs. (96) and (97) imply that in general the vacuum transverse electric and transverse magnetic modes are coupled. The second wave is characterized by the same wave number parallel to the surface but distinct in $k_\perp$. The second value, which we shall denote $k_{\perp 2}$, is derived from the cold-plasma dispersion relation, which is quadratic in $k_\perp^2$, so that choosing $k_{\perp 1}$ or k_z determines the value of $k_{\perp 2}$. If $k_{\perp 1}^2 > 0$ (standing wave radially), the second root is typically evanescent radially, and so it is localized near the surface, in which case a surface wave is required to satisfy boundary conditions.

For electrostatic waves, we simply take the potential to be continuous at the boundary, along with Eq. (97). We note that in calculating the normal component of the displacement vector, the dielectric tensor elements are the ones given previously *only if the magnetic field is parallel to the interface and oriented in the z direction.* When the magnetic-field direction is oblique to the interface, then the usual dielectric tensor must be rotated, but this is rarely necessary, since plasma–vacuum interfaces are typically magnetic surfaces.

4.2 Unmagnetized Plasmas

When an electromagnetic wave scatters from a plasma column, it will generally excite plasma waves in the column, and whenever those plasma waves fit the plasma column so as to represent standing waves, the scattering amplitude exhibits plasma column resonances, called the *Tonks–Dattner resonances*, which were shown to have a dipole character (dominantly linear rather than radial). In addition to verifying the general representation of a plasma by a dielectric constant, the rather widely separated series of resonances also led to the verification of the Bohm–Gross dispersion relation of Eq. (2), which included the lowest-order thermal corrections to the cold unmagnetized plasma.

The plasma wave may be described by the electrostatic approximation, $\mathbf{E} = -\nabla\varphi$, where the potential satisfies Poisson's equation,

$$\nabla \cdot \epsilon \nabla \varphi = -\rho_{\text{ext}}. \tag{98}$$

Here, $\epsilon = \epsilon_0 K_3$ is the uniform plasma dielectric constant and the plasma is assumed to have no *external* charge, and so φ must satisfy Laplace's equation inside and outside the plasma column. Assuming no z dependence, the potentials inside and outside the plasma are

$$\varphi_i = \sum_{m=1}^{\infty} A_m r^m \sin m\theta, \tag{99}$$

$$\varphi_o = \sum_{m=1}^{\infty} B_m r^{-m} \sin m\theta + E_{in} r \sin\theta, \tag{100}$$

where E_{in} is the incident wave field amplitude. The values of A_m and B_m must be obtained by matching boundary conditions at the plasma surface at $r = a$,

$$K_3 \left.\frac{\partial \varphi_i}{\partial r}\right|_a = \left.\frac{\partial \varphi_o}{\partial r}\right|_a, \tag{101}$$

$$\varphi_i(a) = \varphi_o(a). \tag{102}$$

Using the orthogonality relations, these lead to the relations $A_1 = 2E_{in}/(1 + K_3)$ and $(1 + K_3)A_m = 0,\ m \geq 2$. The dominant mode ($A_1$) becomes large (resonant) as $1 + K_3 \to 0$ so that the resonant frequency is given by

$$\omega = \omega_p/\sqrt{2}. \tag{103}$$

The fact that the resonance occurs at $\omega_p/\sqrt{2}$ rather than at the plasma frequency is a consequence of the finite geometry and the cylindrical coordinate system. For a spherical plasma, the resonance occurs at $\omega = \omega_p/\sqrt{3}$.

The existence of such a resonance in the column leads to several conclusions. First, near the resonance, the amplitude of the electric field in the plasma will be large and hence the motions of the plasma particles will be correspondingly large. Secondly, these moving charges will radiate, or scatter the incident radiation. Finally, this scattering of radiation will lead to reflection, and so the reflection peak will correspond to the column resonance. It is generally the peak in the reflected power that is measured in experiments.

While this simple analysis was sufficient to describe the main resonance, which has the largest reflection coefficient, there appeared in the experiments a series of resonances that remained unexplained for many years. The multiplicity of resonances was shown to be due to thermal effects, and the wide spacing was shown to be due to the density variation across the plasma column (Parker *et al.*, 1964), so that an abrupt boundary model was inappropriate for this case.

One can also investigate electromagnetic waves in an unmagnetized plasma column where the waves are generally surface waves that propagate *along* the column. For a case where a plasma column of radius a is surrounded by vacuum, the dispersion relation is given by

$$1 - \frac{\omega_p^2}{\omega^2} = \frac{\tau a}{\tau_0 a} \frac{K_0'(\tau_0 a)}{K_0(\tau_0 a)} \frac{I_0(\tau a)}{I_0'(\tau a)}, \tag{104}$$

where $\tau_0^2 = k_z^2 - \omega^2/c^2$, $\tau^2 = \tau_0^2 + \omega_p^2/c^2$, and the I_0 and K_0 are the regular and irregular modified Bessel functions of order zero. In the limit as $k_z \rightarrow 0$, $\omega \rightarrow \omega_p/\sqrt{2}$, which is the Tonks–Dattner limit. In the high-density limit, the waves are surface waves and are called Trivelpiece–Gould modes (Trivelpiece and Gould, 1959).

4.3 Magnetized Plasmas

4.3.1 Wave Fields When one considers a cold magnetized plasma in a waveguide, the Maxwell wave equation is quadratic in $\nabla_\perp^2$ and may be written in the form

$$(\nabla_\perp^2 + k_{\perp 1}^2)(\nabla_\perp^2 + k_{\perp 2}^2)E_z = 0, \tag{105}$$

where the two values of $k_\perp^2$ are the quadratic pair of roots of the cold-plasma dispersion relation. Since B_z satisfies the same equation, $B_z \propto E_z$. The longitudinal field components may be written as

$$\begin{aligned} B_{zm} &= A_m[J_m(k_{\perp 1}r) + \tau_m J_m(k_{\perp 2}r)], \\ E_{zm} &= \frac{\omega\kappa_1 A_m}{k_z\kappa_2\kappa_3}[\beta_1 J_m(k_{\perp 1}r) + \tau_m\beta_2 J_m(k_{\perp 2}r)], \end{aligned} \tag{106}$$

where the common factor $\exp[i(k_z z + m\theta - \omega t)]$ is suppressed, and the other tangential electric-field component is

$$\begin{aligned} \frac{E_{\theta m}}{A_m} = &-\frac{m\omega}{r\kappa_2}\left[\delta_1 \frac{J_m(k_{\perp 1}r)}{k_{\perp 1}^2} + \tau_m\delta_2 \frac{J_m(k_{\perp 2}r)}{k_{\perp 2}^2}\right] \\ &- i\omega\left[\frac{J_m'(k_{\perp 1}r)}{k_{\perp 1}} + \tau_m \frac{J_m'(k_{\perp 2}r)}{k_{\perp 2}}\right], \end{aligned} \tag{107}$$

where $\beta_j = \gamma + k_{\perp j}^2 - \kappa_2^2/\kappa_1$ and $\delta_j = \gamma + k_{\perp j}^2$ for $j = 1, 2$ and $\gamma = k_z^2 - \kappa_1$.

The boundary conditions in this case are very simple when the plasma completely fills a conducting waveguide, since $\mathbf{E}_t(a) = 0$. This leads to the result

$$\begin{aligned} &\frac{im\delta_1}{k_{\perp 1}^2 a\kappa_2\beta_1} - \frac{1}{k_{\perp 1}\beta_1}\frac{J_m'(k_{\perp 1}a)}{J_m(k_{\perp 1}a)} \\ &\quad = \frac{im\delta_2}{k_{\perp 2}^2 a\kappa_2\beta_2} - \frac{1}{k_{\perp 2}\beta_2}\frac{J_m'(k_{\perp 2}a)}{J_m(k_{\perp 2}a)} \end{aligned} \tag{108}$$

4.3.2 MHD Approximation For frequencies well below the ion cyclotron frequency, κ_1 and κ_2 are approximately related as $\kappa_2 \simeq (\omega/\omega_{ci})\kappa_1 \rightarrow 0$ as $\omega/\omega_{ci} \rightarrow 0$, while $\kappa_1 \rightarrow \omega^2/V_A^2$, and so we can neglect κ_2. In this case, the dispersion relation [Eq. (81) with $\kappa_0 = \kappa_4 = \kappa_5 = 0$ since cold] can be factored into

$$(\gamma + k_\perp^2)(\gamma + k_\perp^2\kappa_1/\kappa_3). \tag{109}$$

Because the dispersion relation factors, the wave equation separates into two separate second-order equations, so that

$$d\nabla_\perp^2 B_z - i\omega B_z = 0, \tag{110}$$

$$q\nabla_\perp^2 E_z + \frac{i\kappa_3}{\omega}E_z = 0, \tag{111}$$

where $d = i\omega\gamma/(\gamma^2 + \kappa_2^2) \rightarrow i\omega/\gamma$, and $q = (\kappa_1\gamma - \kappa_2^2)/i\omega(\gamma^2 + \kappa_2^2) \rightarrow \kappa_1/i\omega\gamma$. The transverse-wave number from Eq. (110) is $k_\perp^2 = -\gamma$ so that $\gamma + k_\perp^2 = 0$ is the dispersion relation for this case. The waves are compressional and transverse electric modes, since there is no E_z component. The boundary condition is

$$E_\theta(a) \propto J_m'(k_\perp a) = 0, \tag{112}$$

so $k_\perp a = p_{m\nu}'$ where $p_{m\nu}$ and $p_{m\nu}'$ are the νth zeroes of the Bessel function of order m and its first derivative, respectively. The dispersion relation can then be written in the form

$$(k_z a)^2 = (\omega a/V_A)^2 - p_{m\nu}'^2, \tag{113}$$

where the approximation $K_1 \simeq \omega_{pi}^2/\omega_{ci}^2 = c^2/V_A^2$ has been used. This dispersion relation is identical to that of electromagnetic waves in an empty cylindrical waveguide except that the effective dielectric constant is $K_{\text{eff}} = c^2/V_A^2$. The cutoff frequencies are given by

$$\omega_{co} = k_\perp V_A = p_{m\nu}' V_A/a. \tag{114}$$

For circularly symmetric modes, $J_0'(x) = -J_1(x)$, and so $p_{0\nu}' = p_{1\nu} = 3.83, 7.01, 10.17, \ldots$, etc. For the lowest cutoff frequency, however, one must choose $m = \pm 1$, since the lowest root of $J_1'(x) = 0$ is $p_{11}' = 1.84$.

The other solution corresponds to Eq. (111), and so the waves are torsional and transverse magnetic modes (no B_z component) and the boundary condition is

$$E_z(a) \propto J_m(k_\perp a) = 0; \tag{115}$$

so $k_\perp a = p_{m\nu}$, and the dispersion relation is

$$k_z^2 \simeq \frac{\omega^2}{V_A^2}\left[1 + \left(\frac{p_{m\nu}c}{\omega_{pe}a}\right)^2\right] \tag{116}$$

if $\omega_{pi} \gg \omega_{ci}$. It should be noted that Eq. (113) has no cutoff, so that transverse magnetic modes propagate down to zero frequency. These waves are the slow Alfvén waves that exhibit the ion cyclotron resonance. Their absence of any waveguide cutoff is due to their torsional character and the fact that the group velocity is parallel to the waveguide, minimizing any wall interactions. It should be noted that near ω_{ci}, $k_\perp a \to p'_{m\nu}$, and so the MHD approximation fails in that range.

4.3.3 Loop Antenna (MHD) In the MHD case for the compressional mode, the response from a loop antenna in a waveguide is calculated by considering the jump in the magnetic field due to a current in the loop, which we take to be of radius b. This jump condition is

$$[B_r] = \mu_0 I \delta(r - b). \tag{117}$$

The dispersion relation from Eq. (113) may be written

$$k_{\parallel\nu}^2 = \omega^2/V_A^2 - k_{\perp\nu}^2. \tag{118}$$

The principal fields are B_r, B_z, and E_θ. In particular,

$$B_{r\nu} = -(ik_{\parallel\nu}/k_{\perp\nu})A_\nu J_1(k_{\perp\nu}r). \tag{119}$$

Then the jump condition gives

$$\begin{aligned}[B_r] &= -2\sum_\nu \frac{ik_{\parallel\nu}A_\nu}{k_{\perp\nu}} J_1(k_{\perp\nu}r) \\ &= \mu_0 I\delta(r - b).\end{aligned} \tag{120}$$

Using orthogonality relations for $J_1(k_{\perp\nu}r)$, the excitation coefficient is given by

$$A_\mu = \frac{i\mu_0 Ibk_{\perp\mu}}{k_{z\mu}a^2}\frac{J_1(k_{\perp\mu}b)}{J_0^2(k_{\perp\mu}a)}. \tag{121}$$

It is possible to adjust b to eliminate one radial mode, but in general there are an infinite number of modes.

The time dependence of the response for an impulse is obtained by an inverse Fourier transform in ω, with the result

$$B_z(r,z,t) = \frac{\mu_0 Ib}{a^2}\sum_\nu \frac{k_{\perp\nu}J_1(k_{\perp\nu}b)}{J_0^2(k_{\perp\nu}a)} J_0(k_{\perp\nu}r) \times \begin{cases} J_0(\omega_\nu\sqrt{t^2 - z^2/V_A^2}), & t > z/V_A, \\ 0, & t < z/V_A \end{cases}. \tag{122}$$

Each radial mode has similar time dependence, and the total B_z is the sum of such terms. We can understand the response by noting first that $v_g \leq V_A$ always, so that nothing can appear before the Alfvén transit time, $t = z/V_A$. Then the high frequencies appear first and give the sharp initial rise as illustrated in Fig. 8, and then, since $v_g \to 0$ as the frequency nears the cutoff frequency, the long-time behavior exhibits an oscillation that approaches the cutoff frequency since for large arguments, $J_0(\omega_\nu t) \sim \exp(i\omega_\nu t + i\phi)/\sqrt{\omega_\nu t}$. For realistic waveguides where there is some loss going down the guide, the higher modes damp more quickly and round off the sharp rise, and the long-time behavior is dominated by the cutoff frequency of the lowest mode. At higher frequencies, the group velocity of the higher-frequency components increases, and so the impulse response begins with a high-frequency oscillation, the maximum of the envelope arrives at the Alfvén transit time, and the final oscillation is the lowest cutoff frequency.

4.3.4 Electrostatic Case The electrostatic approximation can be obtained either by assuming a narrow waveguide (so that $k_\perp$ is very large) or by assuming that the wave

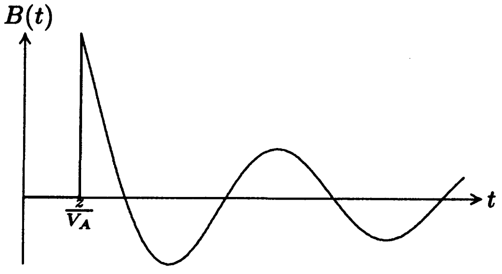

FIG. 8. Impulse response for a single radial mode for the compressional Alfvén wave.

is slow, but either case greatly simplifies the analysis. Assuming charge neutrality in a cold plasma, Poisson's equation becomes

$$\nabla \cdot \epsilon_0 \mathbf{K} \cdot \nabla \varphi_1 = 0, \tag{123}$$

with the cold magnetized-plasma dielectric tensor. Assuming a wavelike potential, i.e., $\varphi_1 = \varphi_1(\mathbf{r}) \exp(ik_z z - i\omega t)$, then Poisson's equation becomes

$$(K_1 \nabla_\perp^2 - K_3 k_z^2)\varphi_1 = 0, \tag{124}$$

where $\nabla_\perp^2 = \nabla^2 - \partial^2/\partial_z^2$. Solutions in cylindrical coordinates are

$$\varphi_1 = \sum_{m=0}^{\infty} A_m J_m(k_\perp r) \exp(ik_z z + im\theta - i\omega t), \tag{125}$$

with $k_\perp^2 = -k_z^2 K_3/K_1$. For a conducting waveguide, we require the tangential field to vanish at the wall at $r = a$; so we must have $J_m(k_\perp a) = 0$ and so $k_\perp a = p_{m\nu}$.

The electrostatic approximation is valid near the electron plasma frequency and the electron cyclotron frequency for sufficiently small a, and so we will neglect the ion motion in K_1 and K_3. The dispersion relation for the space charge waves is then given by

$$\left(\frac{p_{m\nu}}{k_z a}\right)^2 = -\frac{1 - \omega_{pe}^2/\omega^2}{1 + \omega_{pe}^2/(\omega_{ce}^2 - \omega^2)}. \tag{126}$$

The propagation is in two frequency bands, the upper one beginning at the upper hybrid resonance and propagating down to the greater of ω_{ce} or ω_{pe}, while the lower branch propagates from low frequency up to the lesser of ω_{ce} or ω_{pe}. As $B_0 \to 0$, both regions collapse, and no propagation is possible. With an additional vacuum or dielectric layer, however, propagation is again possible as surface waves (Trivelpiece and Gould, 1959).

5. EMISSION AND ABSORPTION

In order to estimate the absorption for a wave in a uniform plasma, one generally needs only to evaluate the imaginary part of k to find the damping rate. Near resonances, however, it is not this simple, since even weak inhomogeneities require a more detailed treatment that considers the possibility of tunneling through a finite resonance layer along with the possibilities of absorption and mode conversion. Mode conversion is the phenomenon of wave energy converting through a linear process from one wave type to another (such as a cold electromagnetic wave to a warm electrostatic wave). After all of the scattering coefficients, which quantify the transmission, reflection, and conversion coefficients, are determined, then the remainder is absorbed. The evaluation of these coefficients is described by mode-conversion theory, which also gives detailed solutions for the fields in the resonance layer as well as the power deposition profiles and the emission along each branch. These problems generally divide into two main classes, one where there is only a simple resonance (no nearby cutoff) with no transmission and one where there is a back-to-back cutoff and resonance with tunneling, where absorption effects may be either weak or strong.

5.1 Simple Resonance

An example of a simple resonance is the lower hybrid resonance, where the X mode approaches the resonance in an inhomogeneous plasma. In this case, the incident wave is totally mode converted from a cold wave to a warm electrostatic wave, and the eventual fate of the energy carried by the wave must be determined by following the wave (generally by ray tracing) until it is damped by electron Landau damping or high-harmonic ion cyclotron damping. This was demonstrated by Stix (1965) by converting the local dispersion relation near the resonance into a differential equation whose solution established the total conversion of wave energy.

5.2 Tunneling Layers

Tunneling layers are not so simple, but are more common, as they occur at every harmonic of the electron and ion cyclotron frequencies and at the two-ion hybrid resonance. This problem was first analyzed by Budden (1955) who treated a wave equation with a cutoff and resonance of the form

$$y'' + k_0^2(1 + x_0/x)y = 0, \tag{127}$$

which has a pole at the origin and a zero at $x = -x_0$, and k_0 is the asymptotic value of k. He showed that the amplitude transmission coefficient is given by $T = e^{-\eta}$, where $\eta = \frac{1}{2}\pi k_0 x_0$, and is the same from either side. He also demonstrated that the reflection coefficient $R = 0$ from the positive-x side, and $R = 1 - T^2$ from the opposite side. In neither case is energy conserved.

The more nearly complete solution includes warm-plasma effects, where cold-plasma waves typically couple to Bernstein modes, and the resonance is resolved. The form of the warm-plasma dispersion relation near $\omega \simeq 2\omega_{ci}$ is shown in Fig. 9, where three wave branches are identified and the tunneling layer where k^2 has an imaginary part is apparent. This dispersion relation may be cast into a differential equation of the form

$$y^{iv} + \lambda^2 z y'' + (\lambda^2 z + \gamma)y = 0, \qquad (128)$$

where $\lambda^2 > 0$ is a constant, the coordinate z is normalized so that the fast wave varies as $e^{\pm iz}$, and γ is a constant. Any fourth-order differential equation derived from a dispersion relation in k^2 with constant and linear coefficients can be cast into this form if the highest coefficient is constant. For the ion case, $\gamma > -1$ and the scattering coefficients are given in Table 1 with the upper signs, while for the electron case, $\gamma < -1$ and the dispersion relation is shown in Fig. 10, and the lower signs in the table are used. For all cases, the tunneling factor is $\eta = \pi|1 + \gamma|/2\lambda^2$ and $\epsilon \equiv 1 - e^{-2\eta}$. There is reciprocity for power between each branch, which means the fraction of incident power from any branch to any other branch is the same in either direction. The general analysis and many special results may be found in a review by Swanson (1985).

Table 1. Amplitude-scattering parameters for three branch problems without absorption.

Transmission	Reflection	Conversion
$T_1 = e^{-\eta}$	$R_1 = 0$	$C_{13} = \mp\epsilon$
$T_2 = e^{-\eta}$	$R_2 = -\epsilon$	$C_{23} = \mp e^{-\eta}\epsilon$
	$R_3 = -e^{-2\eta}$	$C_{31} = \mp 1,$
		$C_{32} = \mp e^{-\eta}$

5.3 Cyclotron Harmonics

5.3.1 Ion Cyclotron Case For ion cyclotron harmonics, without any absorption, the tunneling factor is given for the nth harmonic by

$$\eta = \frac{\pi}{4}\frac{\omega_{pi}L}{c}\frac{n_A^{2n+1}(n^2\beta_i/4)^{n-1}}{(n-1)![1/(n-1)+p^2]^2}, \qquad (129)$$

where $p = k_{\parallel}V_A/\omega$,

$$n_A^2 = \frac{[1/(n+1)-p^2][1/(n-1)+p^2]}{1/(n^2-1)+p^2}, \qquad (130)$$

and $\beta_i = 2\mu_0 n_i \kappa T_i/B_0^2$ if $\mathbf{B}\cdot\nabla B = 0$ with $B = B_0(1 + x/L)$ so that x (which is proportional to the dimensionless z) is in the direction of increasing magnetic field. From Fig. 9 and Table 1, we conclude that there is no reflec-

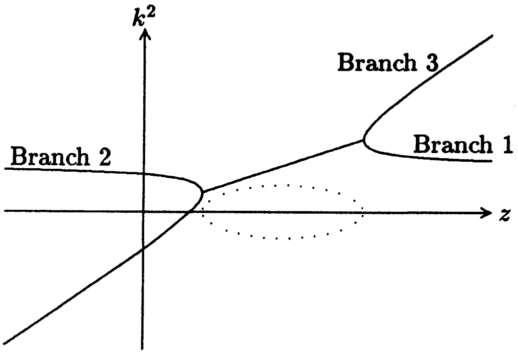

FIG. 9. Dispersion relation for tunneling equation for $\gamma > -1$.

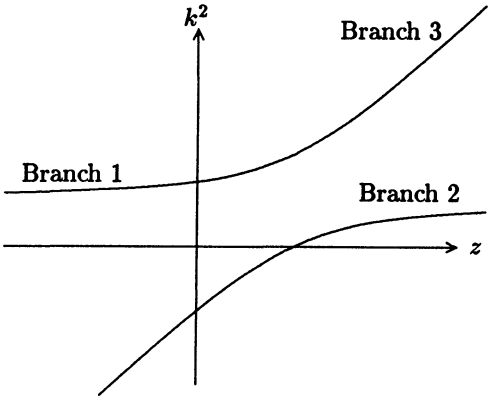

FIG. 10. Dispersion relation for tunneling equation for $\gamma < -1$.

tion from the high-magnetic-field side and transmission is symmetric, but not absorption, since the absorbed fractions on each branch are given by

$$A_1 = 1 - e^{-2\eta} - |C_{13}|^2/\epsilon, \tag{131}$$

$$A_2 = 1 - e^{-2\eta} - |R_2|^2 - |C_{23}|^2\epsilon, \tag{132}$$

$$A_3 = 1 - |R_3|^2 - \varepsilon|C_{31}|^2 - \varepsilon|C_{32}|^2, \tag{133}$$

where in this case, absorption is included in the reflection and conversion coefficients. With $p = 0$, there is no absorption, and Table 1 applies. Even with absorption, the transmission coefficient is unchanged, and there is still no reflection from the high-field side. The other coefficients, however, are reduced by absorption, so that, for example, numerical analysis shows that $R_2 \simeq R_{20}e^{-\kappa^2}$ where $\kappa = n_{\mathrm{A}}\sqrt{\beta_i}k_{\|}L$. The conversion coefficients also become exponentially small with strong absorption, with C_{23} falling much faster than C_{13}.

5.3.2 Electron Cyclotron Case For the second harmonic of the electron cyclotron frequency, $\gamma < -1$ and the tunneling factor for the X mode is given by

$$\eta = \frac{\pi}{4}\frac{\omega_{ce}L}{c}\frac{n_{\perp}^5}{(1 - n_{\|}^2 - \alpha_e/2)^2}\beta_e, \tag{134}$$

where $\alpha_e \equiv \omega_{pe}^2/\omega_{ce}^2$, $\beta_e = 2\mu_0 n_e \kappa T_e/B_0^2$, and

$$n_{\perp}^2 = \frac{(1 - n_{\|}^2 - \alpha_e/2)(1 - n_{\|}^2 - \alpha_e/6)}{(1 - n_{\|}^2 - \alpha_e/3)}. \tag{135}$$

There is also mode conversion for the O mode at the fundamental of the same order such that the tunneling factor is

$$\eta = \tfrac{1}{8}\pi(\omega_{ce}L/c)n_{\perp}\beta_e. \tag{136}$$

For the electron cyclotron cases, $z \propto -x$ so that the slow wave always propagates on the positive-z side. This means that the branch labels for the fast (cold plasma) modes are reversed and again there is no reflection from the high-magnetic-field side. The expressions above include $n_{\|} \neq 0$, where in general there is damping for either relativistic or nonrelativistic cases, but the relativistic absorption is always so much stronger that when considering the effects of absorption the relativistic analysis is nearly always needed. In this case, there is absorption even with $n_{\|} = 0$, and the expressions in Table 1 are never exact, except for the transmission coefficient, and $R_2 \simeq R_{20}\exp(-\frac{7}{2}\kappa^2)$, with $\kappa = \omega L n_{\perp}/\mu c$.

5.4 Cyclotron Emission

From Kirchhoff's law, there is an intimate relationship between emission and absorption. For the emission at cyclotron harmonics, one may assume that there is incident radiation on each branch of Fig. 9 or Fig. 10 of magnitude I_k and emission along each branch of E_k, $k = 1, 2, 3$. For steady state, the incoming and outgoing power must balance on each branch, and if the plasma and walls are assumed to be in thermal equilibrium, then $I_1 = I_2 = I_3 = I_{BB}$, where in the classical limit of $\kappa T \gg \hbar\omega$, $I_{BB} = \omega^2\kappa T/8\pi^3c^2$, with the result

$$E_k = A_k I_{BB}, \tag{137}$$

which is called the *generalized Kirchhoff's law* (Swanson and Shvets, 1992). If the walls are removed to infinity, then this is a local result and independent of the walls. This result differs from some classical calculations that describe emission in terms of the optical depth and the opacity such that

$$E = (1 - e^{-\tau})/I_{BB}, \tag{138}$$

where the optical depth is given by

$$\tau = 2\int \mathrm{Im}k(s)ds, \tag{139}$$

and the opacity is given by $1 - e^{-\tau}$. These analyses were based on the assumption that $k(s)$ is slowly varying, which is valid only in the limit when absorption is very strong so that both reflection and mode conversion are unimportant. The optical depth from Eq. (139) is equivalent to $\tau = 2\eta$, which in fact is determined entirely from the asymptotic parameters λ^2 and γ and is unrelated to absorption in any way. For the electron cyclotron case, we almost recover the classical formula, however, by considering that the emission along branch 3, which is typically the strongest-emitting branch, is totally absorbed close to the resonant layer via either

Landau or cyclotron damping. If a totally absorbing layer is close by, then it is also a blackbody emitting layer, which means there is an incident slow wave that is partially mode converted back into the fast waves, and from the reciprocity relations, this exactly cancels the converted-wave contribution to the absorption, with the result that for branches 1 and 2, which are the only branches that propagate out of the plasma, we have

$$E_1' = (1 - e^{-2\eta})I_{BB}, \tag{140}$$

$$E_2' = (1 - e^{-2\eta} - |R_2|^2)I_{BB}, \tag{141}$$

where the prime denotes the inclusion of both the direct and indirect emission. The result in Eq. (140) is exactly the classical result, and so the emission from the high–magnetic-field side follows the classical opacity formula, but the emission on the low–magnetic-field side is invariably less except in the limit of strong absorption where $R_2 \to 0$. From these arguments, one must redefine opacity.

For ion cyclotron emission, the absorption of the slow wave may occur a considerable distance from the cyclotron layer, so that the indirect emission may be from a region of different temperature and the cancellation of the mode-converted term is no longer exact, and the more general expressions for the A_k must be used. There is also the probability that plasma instabilities may excite a slow wave that will mode convert and mix with the thermal emission, and so the interpretation of ion cyclotron emission is more complicated.

6. NONLINEAR WAVES

There are a variety of nonlinear effects in plasmas that imply that the plasma is changed by the wave as it passes through the medium, and this can modify the wave propagation as well as produce whole new classes of phenomena. Examples are the coupling of waves of different frequencies and wave numbers, the production of very localized disturbances, and, in the strongly nonlinear limit, plasma turbulence. At the lowest level of nonlinearity, the change in the distribution function due to a finite-amplitude wave is the first effect, and the description of the effects of such a modification is called weak-turbulence theory.

6.1 Weak Turbulence

For some externally excited waves, where the wave amplitude can be maintained low, the neglect of finite-amplitude effects is often adequate, but for unstable waves, where the linear theory indicates wave-amplitude growth, the amplitude will eventually become large enough to affect the zero-order distribution function and couple the primary wave to other waves. When this leads to a large number of finite-amplitude waves, or a broad spectrum of waves, the plasma has become turbulent and nonlinear effects may dominate.

In hydrodynamic theory, the turbulent state is particularly difficult because the various nonlinear couplings are characteristically strong, so that it is difficult to isolate the various nonlinear couplings. In a plasma, however, this is frequently not the case, since the nonlinearly induced waves are frequently excited with small amplitudes, and unless these waves are also unstable, we may have a case of *weak turbulence*. As a first approximation, then, we may consider the different modes to be independent, and then add the coupling at various levels and focus our attention on one phenomenon at a time.

In the first approximation, the nonlinear coupling coefficients between various linear modes change slowly in time, and this is the domain of weak-turbulence theory. The fundamental smallness parameter in this expansion is the ratio of the wave energy density to the plasma energy density. More complete treatments are given elsewhere (Davidson, 1972; Galeev and Sagdeev, 1983).

The weak-turbulence theory is generally broken into three types of interactions:

1. *Quasilinear wave–particle interactions.* This is generally a resonant wave–particle process where $\omega = \mathbf{k}\cdot\mathbf{v}$ without any magnetic field, or where $\omega - n\omega_c = k_z v_z$ in a magnetic field. This interaction is due to a group of particles that remain in phase with the wave over many cycles and have time to exchange energy with the wave, resulting in slow changes in the distribution function that may be attributed to a

diffusion process called quasilinear diffusion. Because of the resonant nature of the interaction, this is a kinetic process, and gives rise to phenomena such as plateau formation on the distribution function, and general distortions of the distribution function such as tail formation.

2. *Nonlinear wave–wave interactions.* This process is resonant among the waves such that

$$\sum_i \omega_i = 0, \quad \sum_i \mathbf{k}_i = 0, \tag{142}$$

where ω_i and $\mathbf{k}_i$ are the frequencies and wave vectors of the participating waves. For this case, there are no particle resonances involved, and so a fluid approach may suffice. One of the most important examples of this kind of interaction is the class of parametric instabilities where two waves beat together to interact with a third, and above a certain threshold, the interaction goes unstable.
3. *Nonlinear wave–particle–wave interactions.* This process is also resonant, but here the particles keep constant phase relative to the beat frequency of two waves, so that the resonance condition is $\omega_1 - \omega_2 = (\mathbf{k}_1 - \mathbf{k}_2)\cdot\mathbf{v}$. This process is a kinetic process, and gives rise to phenomena such as plasma-wave echoes.

All of these resonance conditions can be viewed as arising from the conservation of energy and momentum, and so it will not be surprising when we find these conservation laws built into the various nonlinear formalisms. There are also quantum analogs to each of these three processes, but the quantum approach is generally much more complicated than a direct perturbation expansion.

6.1.1 1-D Theory Quasilinear theory was developed to treat weak turbulence observed in nonequilibrium plasmas. Because of the non-Maxwellian nature of a turbulent plasma, a spectrum of electromagnetic waves is generated from local charge separations or particle currents. This spectrum of waves, known as fluctuations, can then interact with the plasma through collisionless damping processes. On a short enough time scale, such that $t \ll \tau_b = \sqrt{m/ek^2\varphi_0}$, where τ_b is the bounce time for a particle in the electrostatic potential well of the wave, the linear Landau theory is adequate. However, the kinetic energy gain of the particles is proportional to the slope of the zero-order distribution function, $\partial f_0/\partial v|_{v=v_p}$. This implies that the damping or growth rate of the wave is independent of time even on the longer time scale over which the first-order distribution function changes, since the zero-order distribution is unaffected by the growth of the first-order distribution function. At some time, this clearly fails to describe the physics of wave–particle interactions if the first-order distribution function grows to be a non-negligible perturbation on the zero-order distribution.

It is the purpose of quasilinear theory to address the time evolution of the zero-order distribution function f_0. Moreover, this theory conserves energy and momentum between the wave and the particle distribution function. Another useful aspect of quasilinear theory is the interaction of the particles with an externally imposed wave such as in wave heating of a plasma or driving a macroscopic current in a plasma with waves. We should be cautious in applying these results, since these wave damping or wave growth processes are noncollisional so that the final state of the distribution function will not be Maxwellian. The treatment of only one nonlinear effect at a time for a non-Maxwellian distribution may occasionally lead to a serious error, especially as the amplitude grows, since somewhere one crosses the boundary from weak turbulence to strong turbulence. One rather surprising experimental observation is that the quasilinear description of the wave–particle interaction is quite good even for fairly large-amplitude waves.

For simplicity, we first restrict our discussion to the case of an unmagnetized plasma and develop the more general case later. This will enable us to bring out the physical processes more clearly without the mathematical complexity added by the magnetic field. Furthermore, the 1-D problem will be applicable to wave–particle interactions along a magnetic field where the Lorentz force is negligible.

The basic procedure of developing the 1-D quasilinear equations is the same as the treatment of the linear Landau case given in Sec. 3. Here, however, the quasilinear approximation implies that the distribution function is allowed to evolve nonlinearly while the wave is calculated using the linear method of Sec. 3. The distribution function is assumed to be locally uniform in space but to approach zero as one tends toward infinity, or $f(x \to \pm\infty, v, t) = 0$. We again assume there are no zero-order electric or magnetic fields and use the Vlasov equations for electrons only (assuming a uniform, stationary ion background to cancel all zero-order electric fields). Thus, we have

$$\frac{\partial f}{\partial t} + v\frac{\partial f}{\partial x} - \frac{e}{m_e}E\frac{\partial f}{\partial v} = 0, \tag{143}$$

where the distribution function is assumed to have the properties

$$f(x,v,t) = f_0(v,t) + f_1(x,v,t), \tag{144}$$

$$f_1(x,v,t) = \int_{-\infty}^{\infty}\frac{dk}{2\pi}\tilde{f}_k(k,v,t)e^{ikx}, \tag{145}$$

$$E(x,t) = \int_{-\infty}^{\infty}\frac{dq}{2\pi}\tilde{E}_q(q,t)e^{iqx}, \tag{146}$$

where now the zero-order distribution function depends on time and the tilde denotes the Fourier-transformed quantity. We will denote the average over space by

$$\langle f\rangle = \lim_{L\to\infty}\frac{1}{L}\int_{-L/2}^{L/2} f\,dx, \tag{147}$$

and so the first-order perturbations average to zero so that $\langle f\rangle = f_0(v,t)$ and $\langle E\rangle = 0$. We note that the average of the second term of Eq. (143) is eliminated by the boundary condition since $f(x \to \pm\infty) = 0$, and so we have a nonlinear equation for the time evolution of the zero-order distribution function from averaging Eq. (143):

$$\frac{\partial}{\partial t}f_0(v,t) = \frac{e}{m_e}\frac{\partial}{\partial v}\langle Ef_1\rangle. \tag{148}$$

Integrating over the space coordinate first and over q, we have nothing unless $q = -k$ so that

$$\langle Ef_1\rangle = \frac{1}{L_\infty}\int_{-\infty}^{\infty}\frac{dk}{2\pi}\tilde{f}_k(t)\tilde{E}_{-k}(t), \tag{149}$$

where we have introduced the abbreviated notation $\lim_{L\to\infty}1/L \equiv 1/L_\infty$.

From taking Fourier transforms of the kinetic equation, Eq. (64), in both space and time, the linear solution for $\tilde{f}_k$ is

$$\tilde{f}_k(v,t) = \frac{ie\tilde{E}_k}{m_e(\omega - kv)}\frac{\partial f_0}{\partial v}, \tag{150}$$

and so f_0 evolves as

$$\frac{\partial f_0}{\partial t} = \frac{ie^2}{m_e^2}\frac{\partial}{\partial v}\frac{1}{L_\infty}\int_{-\infty}^{\infty}\frac{dk}{2\pi}\frac{\tilde{E}_k\tilde{E}_{-k}}{(\omega - kv)}\frac{\partial f_0}{\partial v}. \tag{151}$$

The form of Eq. (151) is that of a diffusion equation with the spatial coordinate replaced by the velocity, or

$$\frac{\partial f_0}{\partial t} = \frac{\partial}{\partial v}D\frac{\partial}{\partial v}f_0, \tag{152}$$

where

$$D = \frac{e^2}{m_e^2 L_\infty}\int_{-\infty}^{\infty}\frac{dk}{2\pi}\left[i\mathfrak{p}\left(\frac{\tilde{E}_k\tilde{E}_{-k}}{\omega - kv}\right) + \pi\delta(\omega - kv)\tilde{E}_k\tilde{E}_{-k}\right], \tag{153}$$

where $\mathfrak{p}$ denotes the principal part of the integral. The two terms in Eq. (153) contribute differently to the wave–particle interaction. Since the principal part does not involve the particle with velocity $v = \omega/k$, it is nonresonant and has only a weak effect, but this effect is felt over the entire distribution function. The resonant term affects the distribution in the immediate neighborhood of the resonant particles, and if the distribution function is unstable, it tends to modify the distribution function toward a stable configuration, at which time it becomes unimportant. Then the nonresonant term dominates and gradually modifies the remaining distribution function to smooth it out. The $\tilde{E}_k\tilde{E}_{-k}$ terms indicate the nonlinear nature of the quasilinear diffusion coefficient, which depends on the wave energy density.

A particular example of these effects is given in Fig. 11 where an originally stable distribution has a gentle (broad) bump on the tail added as a result of a beam. Wherever $\partial f_0/\partial v > 0$, the distribution is unstable, and the wave amplitude grows rapidly. In the resonant region where the distribution is unstable, resonant velocity diffusion quickly flattens the distribution into the plateau re-

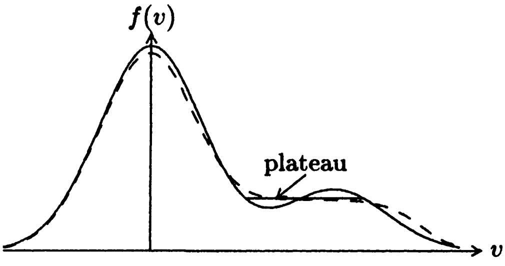

FIG. 11. Distribution function showing effects of quasilinear diffusion. The original distribution (solid) shows an unstable bump on the tail. The straight line shows the plateau that forms quickly through resonant diffusion. The nonresonant diffusion then modifies the entire distribution (dashed).

gime, as shown, and then the nonresonant diffusion begins to thermalize the entire distribution, passing through stages like that shown in the dashed curve.

6.2 Parametric Instabilities

Parametric instabilities are not unique to plasmas, as they relate to any oscillatory system where one of the parameters (hence the term parametric) is modulated at an appropriate frequency. A simple system is that of a child's swing, whose period depends on the length of the swing from its support, and the parametric instability occurs when the child lengthens or shortens the effective length once each period. This modulation at the natural frequency leads to growth of the fundamental oscillation, through what is commonly called "pumping."

Parametric instabilities in plasmas, including magnetized and unmagnetized plasmas, inhomogeneous and uniform plasmas, for linear and nonlinear electrostatic and electromagnetic waves, have been reviewed extensively (Kaw *et al.*, 1976). This section is intended to be an introduction to some of these topics in order to establish the fundamentals of parametric instabilities with a few examples, and as such abstracts some of the topics from this review.

Quite generally, parametric excitations require a minimal set of common characteristics:

1. *Matching condition:* The modulation and the natural oscillation should satisfy a phase-matching condition, such as $\omega T = n\pi$, $n = 1, 2, \ldots$, where ω is the natural frequency and T is the period of the modulation.
2. *Threshold:* Instability or amplification occurs only when the amplitude of the modulation exceeds a critical value.
3. *Frequency locking:* The frequencies of the amplified oscillations are determined by the modulation frequency rather than the natural frequency. For examples with $n = 1$, amplification is at frequency π/T (the natural frequency), but for $n = 2$, amplification occurs at $2\pi/T$ (the natural frequency again) *and* at zero frequency.

The matching and frequency-locking conditions follow from the intrinsic nonlinearity of the multiple-frequency system, and can be viewed either as coming from conservation of energy and momentum or as coming from the resonance conditions of the weak-turbulence analysis such that

$$\omega_0 = \omega_i + \omega_s, \tag{154}$$

$$\mathbf{k}_0 = \mathbf{k}_i + \mathbf{k}_s, \tag{155}$$

where the subscripts 0, i, and s stand for pump, idler, and signal, respectively. The instability occurs when the pump exceeds a certain threshold and the idler and signal waves grow. In general, we assume that the idler and signal represent waves that satisfy a dispersion relation in a plasma and are weakly damped modes, but this is not a strict requirement. When one of the waves is highly damped, we call it a quasimode, and numerous important applications involve quasimodes. From the nonlinear nature of the coupling, it is apparent that energy can be drawn from the pump wave and diverted to the idler and signal waves, or daughter waves. This process can become so efficient that as a pump wave propagates, it loses energy to the daughter waves until it is depleted to the extent that it falls below threshold. Among the various effects that limit this efficiency of coupling are the following: finite-wavelength effects, where the phase-matching conditions cannot be satisfied everywhere; finite pump extent, where the daughter waves grow only to a finite value because they propagate beyond the extent of the pump; and nonlinear effects, where saturation may occur due to quasilinear effects changing the decay and amplification rates, or to nonlinear frequency shifts that modify the matching condition.

In order to sort out this somewhat bewildering array of possible effects, we will examine one model that illustrates the fundamental phenomenon and then apply the principles thus discovered to a few specific plasma problems.

6.2.1 Coupled-Mode Case As plasmas are characterized by many natural frequencies, we shall choose as an example a case where two of the natural frequencies are far apart, with the pump frequency close to the higher frequency. When the sum of the two natural frequencies nearly equals the pump frequency, then both damped and locked excitations may be excited.

When the pump has a finite wavelength, the natural oscillations are described by $\mathcal{L}_s x_s = 0$ for $s = 1, 2$, where

$$\mathcal{L}_s \equiv \frac{d^2}{dt^2} + 2\gamma_s \frac{d}{dt} + (\omega_s^2 + \gamma_s^2), \tag{156}$$

where we assume that the frequencies ω_s and damping rates γ_s are both constant. We choose to denote the lower frequency as ω_1. The pump field is described by $Z(\mathbf{r},t) = 2\epsilon \times \cos(\mathbf{k}_0 \cdot \mathbf{r}\omega_0 t)$, with ϵ constant. This pump field couples $x_1(\mathbf{r},t)$ and $x_2(\mathbf{r},t)$ through the nonlinear interaction. The assumed coupling is of the form

$$\mathcal{L}_1 x_1(\mathbf{r},t) = \lambda_1 Z(\mathbf{r},t) x_2(\mathbf{r},t), \tag{157}$$

$$\mathcal{L}_2 x_2(\mathbf{r},t) = \lambda_2 Z(\mathbf{r},t) x_1(\mathbf{r},t), \tag{158}$$

where the λ_s are constants. We can imagine the pump and the high-frequency wave producing a modulation at their beat frequency, and if this forced oscillation resonates with the low frequency, then we expect a resonant energy transfer when $\omega_0 \simeq \omega_1 + \omega_2$. From the Fourier transforms of the coupled equations in space and time, the coupled equations take the form

$$\begin{aligned} D_1(\omega,\mathbf{k})\tilde{x}_1(\omega,\mathbf{k}) = \epsilon\lambda_1[&\tilde{x}_2(\omega + \omega_0,\mathbf{k} + \mathbf{k}_0) \\ &+ \tilde{x}_2(\omega - \omega_0,\mathbf{k} - \mathbf{k}_0)], \end{aligned} \tag{159}$$

$$\begin{aligned} &D_2(\omega \pm \omega_0,\mathbf{k} \pm \mathbf{k}_0)\tilde{x}_2(\omega \pm \omega_0,\mathbf{k} \pm \mathbf{k}_0) \\ &\quad = \epsilon\lambda_2\tilde{x}_1(\omega,\mathbf{k}), \end{aligned} \tag{160}$$

from which we obtain the dispersion relation

$$\begin{aligned} 1 = \frac{\epsilon^2\lambda_1\lambda_2}{D_1(\omega,\mathbf{k})} &\left[\frac{1}{D_2(\omega + \omega_0,\mathbf{k} + \mathbf{k}_0)}\right. \\ &\left. + \frac{1}{D_2(\omega - \omega_0,\mathbf{k} - \mathbf{k}_0)}\right], \end{aligned} \tag{161}$$

where the $D_s(\omega,\mathbf{k})$ are the dispersion relations from the Fourier transform of Eq. (156) associated with the linear waves. Defining $\omega \equiv \omega_r + i\gamma$ and separating the real and imaginary parts, we obtain

$$\begin{aligned} &\omega_r(\gamma + \gamma_1)[\Delta^2 - (\omega_r - \mu)^2 + (\gamma + \gamma_2)^2] \\ &\quad = (\omega_r - \mu)(\gamma + \gamma_2)[\omega_r^2 - \omega_1^2 - (\gamma + \gamma_1)^2], \end{aligned} \tag{162}$$

$$\begin{aligned} \frac{\Delta\kappa}{\langle\omega_2\rangle} &= \omega_r(\omega_r - \mu)(\gamma + \gamma_1)(\gamma + \gamma_2) \\ &\quad \times \left\{4 + \frac{[\omega_r^2 - \omega_1^2 - (\gamma + \gamma_1)^2]^2}{\omega_r^2(\gamma + \gamma_1)^2}\right\}, \end{aligned} \tag{163}$$

where

$$\mu = \tfrac{1}{2}[\omega_2(\mathbf{k} + \mathbf{k}_0) - \omega_2(\mathbf{k} - \mathbf{k}_0)], \tag{164}$$

$$\Delta = \omega_0 - \langle\omega_2\rangle, \tag{165}$$

$$\langle\omega_2\rangle = \tfrac{1}{2}[\omega_2(\mathbf{k} + \mathbf{k}_0) + \omega_2(\mathbf{k} - \mathbf{k}_0)], \tag{166}$$

and $\kappa = \epsilon^2\lambda_1\lambda_2 > 0$. There are three distinct roots for ω_r with $\mu > 0$: mode I with $\omega_r > \mu$, mode II with $\mu > \omega_r > 0$, and mode III with $\omega_r < 0$. Since $\kappa > 0$, Eq. (163) indicates that both mode I and mode III occur when $\Delta > 0$, and mode II corresponds to $\Delta < 0$. The uniform-pump case ($\mu = 0$) shows that mode II is a purely growing mode and the other two are decay–type modes. For this case with $\mu \neq 0$, however, there is no purely growing mode. Secondly, when $\mu > \omega_1$, then the frequency of mode I becomes nonresonant and we have a quasimode. For $\mu \neq 0$, the threshold can be substantially reduced for $\omega_r \sim \omega_1$, and the growth rate well above threshold can be significantly increased. For the resonant decay case, when $D_1(\omega,k) \simeq 0$, then the growth rate and threshold are given by

$$\gamma = \tfrac{1}{2}[-(\gamma_1 + \gamma_2) + \sqrt{(\gamma_1 - \gamma_2)^2 + \kappa/\omega_r\langle\omega_2\rangle}] \tag{167}$$

and

$$\kappa_0 = 4\omega_r\langle\omega_2\rangle\gamma_1\gamma_2. \tag{168}$$

6.2.2 Unmagnetized Plasma In the unmagnetized plasma, the principal waves are the ordinary wave, where the dispersion relation describing *photons* is

$$D(\omega,k) = \omega_{pe}^2 + k^2c^2 - (\omega - i\nu_e)^2, \tag{169}$$

where ν_e is the collision frequency; the plasma wave from Eq. (2), which may be written as

$$D(\omega,k) = \omega_{pe}^2 + \tfrac{3}{2}k^2v_e^2 - (\omega - i\gamma_p)^2, \tag{170}$$

which describe what are called *plasmons*, where

$$\gamma_p = \sqrt{\frac{\pi}{8}}\frac{\omega_{pe}}{k^3\lambda_D^3}\exp\left[-\frac{1}{2k^2\lambda_D^2} - \frac{3}{2}\right]; \tag{171}$$

and the ion-acoustic wave from Eq. (69), written as

$$D(\omega,k) = \frac{k^2c_s^2}{1 + k^2\lambda_D^2} - (\omega - i\gamma_a)^2, \tag{172}$$

which describe what are called *phonons*, where $k\lambda_D \ll 1$ and

$$\gamma_a = \sqrt{\frac{\pi}{8}}\left[\sqrt{\frac{m_e}{m_i}} + \left(\frac{T_e}{T_i}\right)^{3/2}\exp\left(-\frac{T_e}{2T_i}\right)\right] + \nu_i, \tag{173}$$

which includes a collisional term.

6.2.2.1 Case 1—The Pump Is a Plasma Wave. For this case, ω_0 satisfies Eq. (170) with wave vector $\mathbf{k}_0$. If $\mathbf{k} \parallel \mathbf{k}_0$, then

$$\mu \simeq \frac{3kk_0v_e^2}{2\omega_0}, \quad \Delta \simeq -\frac{3k^2v_e^2}{4\omega_0}. \tag{174}$$

With $\Delta < 0$, this is mode II where $\mu > \omega_r > 0$. We note two special cases:

1. When $\mu \gg \omega_1 \simeq \omega_r$, then Eq. (162) requires that $\Delta^2 \sim \mu^2$ so that $k \sim 2k_0 \sim 2(k - k_0)$. In this case, a plasmon has decayed into another plasmon [ω_2 from Eq. (170)] and a phonon [ω_1 from Eq. (172)]. This is an example where an electron plasma wave is *backscattered* by an ion wave since $k_0 - k \sim -k_0$.
2. Another limiting case is when $\mu \simeq \omega_1 \simeq \omega_r$, in which case Eq. (162) leads to $\Delta^2 \sim 0$, so k^2 must be small. In this limit, $k_0 \pm k \sim k_0$, so this case represents *forward scattering*.

6.2.2.2 Case 2—The Pump Is an Electromagnetic Wave. Here we note four cases:

1. When the pump frequency is just above the plasma frequency, it may decay into a plasmon (ω_2) and a phonon ($\omega_1 = \omega_0 - \omega_2 \ll \omega_0$). Since all three waves are different (photon → plasmon + phonon), this is a decay process that damps the pump.
2. Instead of decaying into a plasmon and a phonon when the pump frequency is just above the plasma frequency, it can also decay into another photon (a scattered electromagnetic wave) and a phonon. This is called *Brillouin scattering*.
3. When the pump frequency is higher such that $\omega_0 > 2\omega_p$, then it may decay into another photon (a scattered electromagnetic wave) and a plasmon. This type of scattering is called *Raman scattering*.
4. For the special case of $\omega_0 = 2\omega_p$, the photon may decay into two plasmons.

A number of these cases with an electromagnetic wave pump can be summarized by a few general relations if we take the driven-wave amplitude to be

$$\mathbf{E}_0^{\mp} = E_0\hat{e}_0\exp[\pm i(\mathbf{k}_0\cdot\mathbf{r} - \omega_0 t)], \tag{175}$$

so that the corresponding electron velocity is $\mathbf{v}_0 = \mathbf{v}_0^+ + \mathbf{v}_0^-$ where $\mathbf{v}_0^{\pm} = \mp ie\mathbf{E}_0^{\pm}/m_e\omega_0$. This driven velocity of the electrons times the density fluctuation of a daughter wave generates a current density that drives waves at the sum and difference frequencies of the velocity and density fluctuations. The dispersion relation then takes the form

$$\mathbf{E}^{\pm}\cdot\mathbf{E}_0^{\mp} = \frac{\omega_{pe}^2\tilde{n}_e(\omega,\mathbf{k})}{k_{\pm}^2 n_0} \times \left(\frac{(\mathbf{k}_{\pm}\times\mathbf{E}_0^{\mp})^2}{D_{2t}^{\pm}} - \frac{(\mathbf{k}_{\pm}\cdot\mathbf{E}_0^{\mp})^2}{D_{2l}^{\pm}}\right), \tag{176}$$

where D_{2t} and D_{2l} are the transverse (photon) and longitudinal (plasmon) dispersion functions given by

$$D_{2t}^{\pm} = k_{\pm}^2 c^2 - \omega_{\pm} K_1(\omega_{\pm}, \mathbf{k}_{\pm}), \tag{177}$$

$$D_{2l}^{\pm} = -\omega_{\pm} K_3(\omega_{\pm}, \mathbf{k}_{\pm}). \tag{178}$$

By introducing the wave coupling through the ponderomotive force, the dispersion relation can be put into the form of Eq. (161) where D_1 is given by

$$D_1(\omega,\mathbf{k})\tilde{n}_e(\omega,\mathbf{k}) = -\frac{\omega_{pe}^2 k^2 \epsilon_0}{m_e \omega_0^2} f(\mathbf{E},\mathbf{E}_0) \tag{179}$$

or

$$D_1(\omega,\mathbf{k})\tilde{n}_e(\omega,\mathbf{k}) = -\frac{\omega_{pi}^2 k^2 \epsilon_0 f(\mathbf{E},\mathbf{E}_0)}{m_e \omega_0^2 (1 + k^2 \lambda_{\mathrm{D}}^2)}, \tag{180}$$

where $f(\mathbf{E},\mathbf{E}_0) = (\mathbf{E}_0^+ \cdot \mathbf{E}^- + \mathbf{E}_0^- \cdot \mathbf{E}^+)$, which represent a plasmon or a phonon, respectively. From these results and Eq. (176), we find that the threshold parameters for several cases may be expressed in terms of $\mathbf{v}_0 = e\mathbf{E}_0/m_e\omega_0$ as in Table 2.

6.2.3 Brillouin Scattering For this case, D_2 is a photon dispersion function and D_1 is a phonon dispersion function, so that

$$\kappa = (k/k_{\pm})^2 \omega_{pi}^2 (\mathbf{k}^- \times \mathbf{v}_0)^2/(1 + k^2\lambda_{\mathrm{D}}^2), \tag{181}$$

since $\mathbf{k} \sim 2\mathbf{k}_0$, making $\mathbf{k}^-$ the resonant mode. In the resonant scattering case, $\omega \simeq \omega_1$, and so the threshold condition from Eq. (163) or Eq. (168) with $\gamma = 0$ is

$$k^2 v_0^2 \sin^2\theta \simeq \frac{4\gamma_a \gamma_2 \omega_1 \omega_0}{\omega_{pi}^2}(1 + k^2\lambda_{\mathrm{D}}^2), \tag{182}$$

where θ is related to the angle between $\mathbf{k}_-$ and $\mathbf{v}_0$. The corresponding growth rate just above threshold from Eq. (167) is

$$\gamma = -\gamma_2 + \frac{\omega_{pi}^2 k^2 v_0^2 \sin^2\theta}{4\omega_1\omega_0\gamma_a(1 + k^2\lambda_{\mathrm{D}}^2)}, \tag{183}$$

for $\gamma \gg \gamma_2 \sim \nu_e$.

6.2.4 Raman Scattering In this example, a photon is scattered off a plasmon rather than a phonon. Hence, D_1 represents a plasma wave from Eq. (170), and D_2 an electromagnetic wave from Eq. (169). Again for this case, $k - k_0$ is the resonant root, so that $\kappa = (k/k_-)^2\omega_{pe}^2(\mathbf{k}_- \times \mathbf{v}_0)^2 = k^2 v_0^2 \omega_{pe}^2 \times \sin^2\theta'$ from Table 2 where θ' again represents an angle between $\mathbf{k}$ and $\mathbf{v}_0$. The threshold is then given by Eq. (168) as

$$k^2 v_0^2 \sin^2\theta' = 4\gamma_p \gamma_2 \langle\omega_2\rangle/\omega_{pe}, \tag{184}$$

and the minimum threshold is for $k \sim 2k_0$ (backscattering) and $\theta' = \pi/2$, when $k_0^2 v_0^2 = \gamma_p\gamma_2\langle\omega_2\rangle/\omega_{pe}$. The gain just above threshold from Eq. (167) (resonant case) is

$$\gamma = -\gamma_2 + \frac{\omega_{pe} k^2 v_0^2 \sin^2\theta'}{4\langle\omega_2\rangle\gamma_p}. \tag{185}$$

6.3 Shock Waves

Shock waves are characteristic of a medium when the wave amplitude gets large enough to begin to modify the medium to the extent that the velocity of the wave is affected. Typically, a shock is related to a sound speed, and in a plasma, a classic example is the ion-acoustic shock wave (or solitary wave). It is assumed in the analysis that the wave shape is stationary in the frame moving with the wave, though not sinusoidal, as one usually assumes a single wave front so that far from the front, all derivatives vanish.

We shall assume the ions to be cold, but the electrons will have a finite temperature. We begin with the fluid equations of continuity and momentum,

Table 2. Threshold parameter κ for several combinations of daughter waves for an electromagnetic pump wave.

Case	D_1	D_2	κ
3 Raman	plasmon	photon	$k^2\omega_{pe}^2(\mathbf{k}_{\pm} \times \mathbf{v}_0)^2/k_{\pm}^2$
2 Brillouin	phonon	photon	$k^2\omega_{pi}^2(\mathbf{k}_{\pm} \times \mathbf{v}_0)^2/(1 + k^2\lambda_{\mathrm{De}}^2)k_{\pm}^2$
4 decay	plasmon	plasmon	$k^2\omega_{pe}^2(\mathbf{k}_{\pm} \cdot \mathbf{v}_0)^2/k_{\pm}^2$
1 decay	phonon	plasmon	$k^2\omega_{pi}^2(\mathbf{k}_{\pm} \cdot \mathbf{v}_0)^2/(1 + k^2\lambda_{\mathrm{De}}^2)k_{\pm}^2$

$$\frac{\partial n}{\partial t} + \frac{\partial}{\partial z} nv = 0, \tag{186}$$

$$\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial z} = -\frac{q}{m}\frac{\partial \varphi}{\partial z} - \frac{1}{nm}\frac{\partial p}{\partial z}, \tag{187}$$

and Poisson's equation,

$$\frac{\partial^2 \varphi}{\partial z^2} = -\frac{e}{\epsilon_0}(n_i - n_e). \tag{188}$$

For electrons, m_e is taken to be so small that we can neglect the left-hand side of the momentum equation, and then letting $p_e = n_e \kappa T_e$, we obtain

$$n_e = n_0 \exp(e\varphi/\kappa T_e). \tag{189}$$

Assuming now a wavelike solution so that all functions may be written as functions of $\xi = z - Ut$, then $\partial/\partial t \to -U\partial/\partial\xi$ and $\partial/\partial z \to \partial/\partial\xi$, so that the continuity and momentum equations for ions become ordinary differential equations with solution

$$n_i = n_0/\sqrt{1 - 2e\varphi/m_i U^2}. \tag{190}$$

Then Poisson's equation may be written as

$$\frac{d^2\varphi}{d\xi^2} = \eta\frac{d}{d\varphi}\eta = \frac{d}{d\varphi}\left(\frac{\eta^2}{2}\right), \tag{191}$$

with the change of variable $\eta = d\varphi/d\xi$, and the solution is

$$\frac{\eta^2}{2} = \frac{n_0}{\epsilon_0}\left\{m_i U^2\left(\sqrt{1 - \frac{2e\varphi}{m_i U^2}} - 1\right)\right.$$
$$\left. + \kappa T_e\left[\exp\left(\frac{e\varphi}{\kappa T_e}\right) - 1\right]\right\}, \tag{192}$$

where the constant terms are chosen so that $\eta \to 0$ as $\varphi \to 0$. Now solitary-wave solutions do not exist for all values of φ and U. It is clear from Eq. (192) that $e\varphi \leq m_i U^2/2$ for a meaningful solution.

If we consider $v(\varphi) = -\eta^2/2$ to be a "pseudopotential" with φ the "coordinate" and ξ the "time," then Eq. (191) has the form of an equation of motion for a particle moving in a "pseudopotential well,"

$$\frac{d^2\varphi}{d\xi^2} = -\frac{dv(\varphi)}{d\varphi}, \tag{193}$$

and we need a potential well for $v(\varphi)$ with two zero crossings for a "bound" (localized) solution. From Eq. (192) we have $v(\varphi) = 0$ at $\varphi = 0$, and so we require another zero crossing for a solitary wave. Using the parameter $\alpha \equiv U^2/c_s^2$ with $c_s^2 = \kappa T_e/m_i$, then for $\alpha < 1$, v increases monotonically with φ, so that there is no second zero crossing. For $\alpha_c > \alpha > 1$ with $\alpha_c = 2.51$, there is a well with two zero crossings, while for $\alpha > \alpha_c$ there is a well but without a second zero. Thus there exist solitary-wave solutions of this type only for Mach numbers $1 < \mathcal{M} < \sqrt{\alpha_c}$ where the Mach number is defined as $\mathcal{M} = U/c_s$ and c_s is the ion-acoustic speed.

6.4 Solitons

In describing shock waves or solitary waves, it is assumed that the wave shape is stationary in the wave frame, but this is not always true in practice. A subclass of solitary waves does have a special kind of stability in the shape and also describes the interactions of two or more individual localized waves that survive collisions with one another, and these are called *solitons*. In this section, we describe only two general types of solitons, although many others are known.

6.4.1 The Korteweg–de Vries (KdV) Equation Although there are many different nonlinear partial differential equations (PDEs) that give rise to solitons, there is one soliton equation that is generic to many different kinds of waves. The Korteweg–de Vries equation, which was shown in 1896 to describe shallow-water waves, provided the key to solving nonlinear PDEs by the method of inverse scattering. The general form of the KdV equation is

$$u_\tau + auu_\xi + bu_{\xi\xi\xi} = 0, \tag{194}$$

where a and b are constants (the classical form has $a = \pm 6$ and $b = 1$) and the subscripts denote partial derivatives. The nonlinearity is evident from the middle term. We may note that the first two terms typically come from the first two terms of the momentum equation so that τ and ξ usually represent normalized time and space variables, respectively. The third term of Eq. (194) is a dispersive term, and we motivate its form and indicate its generality by examining the form of a very simple dispersion relation.

Neglecting damping, the simple dispersion relation for the ion-acoustic wave is given by Eq. (69), which we may write as

$$\omega = \pm kc_s(1 - k^2\lambda_D^2/2 + \cdots), \tag{195}$$

which to the order indicated is representative in form of the dispersion relations of a great many waves that are characterized by a constant phase velocity in the long-wavelength limit and some dispersion. Neglecting the higher-order terms, we can identify the term on the left as coming from $\partial/\partial t$, and the first term on the right as coming from $\partial/\partial x$ [with the characteristic speed being amplitude dependent if we compare term by term with Eq. (194)]. The second term on the right is proportional to k^3, and so it represents a third-order spatial derivative as we find in the KdV equation. The importance of this dispersive term must not be underestimated, since if it were neglected in Eq. (194), then the peak amplitude would grow and speed up, eventually leading to wave breaking where the peak overtakes the trough, and the wave becomes multiple valued. The dispersive term limits this growth, and the tradeoff between the tendency to peak from the nonlinear term and the tendency to spread due to the dispersive term leads to the stable character of solitons.

The single-soliton solution of Eq. (194) may be simply found by assuming that a stationary solution exists in some rest frame moving at velocity U. Assuming then that $u = u(\xi - U\tau)$ leads to an ordinary differential equation, and the boundary conditions that $\lim_{|\xi|\to\infty} u = 0$ along with all its derivatives, allows the solution to be found.

6.4.2 Ion-Acoustic Solitons It has been shown that ion-acoustic waves may be KdV solitons (Washimi and Taniuti, 1966) beginning with the same equations as in Sec. 6.3. Using the normalized variables $n = n_i/n_0$, $u = v_i/c_s$, $x = z/\lambda_D$, $\tau = c_st/\lambda_D$, and $\Phi = e\varphi/\kappa T_e$, along with the variables $\eta = \omega(x - \tau)$, $\xi = \omega^3 x$, and a smallness parameter $\epsilon = \omega^2$, and expanding in the parameter ϵ, one obtains to first order

$$\frac{\partial n^{(1)}}{\partial \eta} = \frac{\partial u^{(1)}}{\partial \eta} = \frac{\partial \Phi^{(1)}}{\partial \eta}, \tag{196}$$

which leads to $n^{(1)} = u^{(1)} = \Phi^{(1)} \equiv \phi$. To second order, the result leads to

$$\phi_\xi + \phi\phi_\eta + \tfrac{1}{2}\phi_{\eta\eta\eta} = 0, \tag{197}$$

which is the Korteweg–de Vries (KdV) equation with $a = 1$ and $b = \frac{1}{2}$.

The KdV equation is more than an ordinary solitary-wave equation, since it has been proved that individual solitary waves survive collisions, and hence these are called solitons to indicate their particlelike behavior. The KdV equation and other soliton equations may be solved by the method of inverse scattering, which is a method of solving the nonlinear partial differential equations for *arbitrary initial conditions* by *linear* methods. The solution via inverse scattering for the KdV equation is discussed by many authors (e.g., see Drazin and Johnson, 1989). Through this formalism, it has been possible to show that the solitary waves are indeed *normal modes* and that arbitrary perturbations invariably relax to these solitary waves and the remainder "radiates" away. Analytic N-soliton solutions are also known, and there are an infinite number of conservation laws associated with the KdV equation and other soliton equations. The one-soliton solution of Eq. (197) is given by

$$\phi = A\,\mathrm{sech}^2[k(\eta - U\xi)], \tag{198}$$

and in terms of the original variables, the result is $\Phi = \Phi_m\,\mathrm{sech}^2[K(x - vt)]$ with $v = c_s/(1 - \Phi_m/3)$, $K = \sqrt{\Phi_m/6}(1 - \Phi_m/3)/\lambda_D$.

6.4.3 Alfvén-Wave Solitons In addition to ion-acoustic solitons, which have been experimentally observed to survive collisions, nonlinear Alfvén waves also are characterized by the KdV equation. This is because they propagate near the Alfvén speed at low frequency and long wavelength and begin to show dispersion at higher frequencies. Both fast and slow Alfvén waves have been shown to satisfy the KdV equation.

6.4.4 Nonlinear Schrödinger Equation The nonlinear Schrödinger equation describes a nonlinear wave where the wave amplitude is large enough to modify the dispersion relation by changing the parameters of the medium. Its solution is an envelope soliton where the wave-packet envelope has the soliton character where the medium is modified, and the complex phase term propagates at the wave phase velocity.

We begin with the assumption of a plane wave of the form $A \exp(i\mathbf{k}\cdot\mathbf{r} - i\omega t)$ + c.c. and a nonlinear dispersion relation

$$D(\omega,\mathbf{k},|A|^2) = 0, \tag{199}$$

where it has been assumed that the nonlinearity depends on the amplitude of the wave and not on the phase. This kind of nonlinearity is quite typical of the ponderomotive force. We also presume that the medium is homogeneous and isotropic in the absence of the wave, so that D and A are scalar quantities. We assume that the nonlinear effects will result in a slow modulation of the wave amplitude about an average amplitude A_0, and so we expand ω and $\mathbf{k}$, which represent the time and space differential operators, about the fast-variation values, so that Eq. (199) becomes a differential equation for the slowly varying amplitude,

$$D\left[\omega + i\frac{\partial}{\partial t}, \mathbf{k} - i\nabla, |A(\mathbf{r},t)|^2\right] A = 0. \tag{200}$$

Assuming $|A|^2 - |A_0|^2 \ll |A_0|^2$, then this may be written as the 3-D nonlinear Schrödinger equation

$$i\frac{\partial A}{\partial t} + \mathbf{P}\colon \nabla_\xi^2 A + Q(|A|^2 - |A_0|^2)A = 0, \tag{201}$$

where we have shifted to the wave frame moving with the group velocity, so that $\xi = \mathbf{r} - \mathbf{v}_g t$, and

$$\mathbf{P} = \tfrac{1}{2}\frac{\partial \mathbf{v}_g}{\partial \mathbf{k}} = \tfrac{1}{2}\frac{\partial^2 \omega}{\partial \mathbf{k}\partial \mathbf{k}}, \tag{202}$$

$$Q = \frac{\partial D}{\partial |A_0|^2}\left(\frac{\partial D}{\partial \omega}\right) = -\frac{\partial \omega}{\partial |A_0|^2}. \tag{203}$$

We can see that Q represents the nonlinear frequency shift due to the finite wave amplitude. We note a difficulty with names at this point, since the 1-D version of Eq. (201),

$$i\frac{\partial A}{\partial t} + P\frac{\partial^2 A}{\partial \xi^2} + Q(|A|^2 - |A_0|^2)A = 0, \tag{204}$$

is commonly called the nonlinear Schrödinger equation, but only the special case with $A_0 = 0$ is a soliton equation that goes by the same name. With $A_0 \neq 0$, Eq. (201) is generally unstable with the maximum growth rate

$$\gamma_{\max} = Q|A_0|^2. \tag{205}$$

The implication of this linear instability is that there exists a range where the wave amplitude will grow. This leads to a collapse where the amplitude will grow until all of the plasma has been expelled as a result of the ponderomotive force, resulting in a density cavity, or *caviton*. For a driven wave, then, it is expected that the wave will collapse, but the severe modification of the plasma may decouple the driven pump wave, so that effectively $A_0 \to 0$, in which case the equation becomes the soliton equation that is stable. These general characteristics are borne out in numerical simulations and experiments.

6.4.5 General Wave Collapse In addition to the caviton collapse above, it has been shown quite generally that in higher dimensional systems, i.e., with either cylindrical or spherical symmetry, where the nonlinear Schrödinger equation assumes the form

$$iu_t + \frac{\partial^2 u}{\partial r^2} + \frac{d-1}{r}\frac{\partial u}{\partial r} + |u|^s u = 0, \tag{206}$$

where d is the dimension and s indicates the degree of nonlinearity, the solutions are stable for $sd < 4$, but unstable for $sd \geq 4$ (Shvets, 1993). In each unstable case, the volume collapses to zero in a finite time, and the classification depends on the assumption of some absorption. For $sd = 4$, the collapse is called *strong*, as the energy absorbed is virtually independent of the absorption strength. For $4 < sd < 2s + 2$, the collapse is called *weak*, since the energy absorbed tends toward zero along with the absorption coefficient. On the other hand, for $sd \geq 2s + 2$, the collapse is *superstrong*, as the presence of absorption slows the collapse as the volume continues to absorb energy from the surrounding medium. Important examples are plasma-wave collapse, both with and without a magnetic field, and lower-hybrid wave collapse, both of which have been shown to convert wave energy to energetic particles as they generate strong turbulence.

GLOSSARY

Absolute Instability: An instability that grows in time everywhere in space.

Alfvén Waves: Waves whose velocity is proportional to the magnetic field strength. The torsional Alfvén wave is strongly guided along the field, while the compressional Alfvén wave is nearly isotropic.

Bernstein Wave: An electrostatic wave that propagates perpendicular to the magnetic field in bands between harmonics of the ion and electron cyclotron frequencies.

Convective Instability: An instability that grows in time in the local rest frame but that decays in time in some rest frame.

Cutoff: Any case where the index of refraction vanishes. In bounded plasmas, cutoff is when the index of refraction along the guide vanishes.

Electrostatic Wave: Any wave where the wave magnetic-field component is negligible. A sufficient condition is that the index of refraction be large compared with any of the dielectric tensor components.

Extraordinary Wave: A wave whose direction and wave electric field are both perpendicular to the magnetic field.

Ion-Acoustic Wave: An ordinary wave propagating close to the ion plasma frequency, whose speed is given by $c_s = \sqrt{\kappa T_e/m_i}$. Requires $T_e \gg T_i$.

Landau Damping: Collisionless damping due to phase mixing of particles traveling near the phase velocity of the electrostatic wave. In a rotating frame, accounts also for collisionless cyclotron damping.

Lower-Hybrid Resonance: A plasma resonance for waves propagating perpendicular to the magnetic field, which lies between the ion and electron cyclotron frequencies.

Mode Conversion: That process near a cold-plasma or cyclotron harmonic resonance that when resolved by thermal effects leads to energy being converted linearly to a warm-plasma wave. Frequently associated with tunneling, reflection, and absorption.

Ordinary Wave: A plasma wave propagating perpendicular to the magnetic field whose electric-field component is parallel to the magnetic field.

Parametric Instability: A nonlinear instability where several waves are coupled together so that one large-amplitude wave (pump wave) gives rise to daughter waves at different frequencies.

Quasilinear Diffusion: The diffusion in velocity space due to the weakly nonlinear effect of plasma waves on the particle distribution function.

Resonance: Any frequency where the index of refraction is unbounded. Cold-plasma resonances are typically resolved by warm-plasma effects.

Shock Waves: Large-amplitude waves characterized by a solitary wave as opposed to a wave train. Characteristically, the speed of a shock wave is amplitude dependent.

Solitons: A special subclass of nonlinear solitary waves whose shapes are unaffected by collisions with one another.

Upper-Hybrid Resonance: A plasma resonance for waves propagating perpendicular to the magnetic field, which lies above both the electron cyclotron and the electron plasma frequencies.

Weak Turbulence: The condition when a nonequilibrium velocity distribution leads to a narrow to modest spectrum of weak instabilities.

Whistler Wave: The right-handed wave well above the ion cyclotron frequency and well below the electron cyclotron frequency.

INTRODUCTION

Earthquakes, volcanoes, active faults, and mountains tend to occur in long, linear belts on the Earth's surface, bounding large regions that are relatively quiescent. The theory of plate tectonics views the quiescent regions as rigid "plates" and these deformational features, located at the boundaries between the plates, as the inevitable consequences of relative motion among the plates. Since the plates are confined to the surface of a spherical Earth, their relative motion is geometrically constrained. The great power of plate-tectonic theory lies in its ability to

provide testable kinematic predictions regarding the expected direction and rate of motion at the boundaries between the plates. In addition, it provides a framework for interpreting past geological events in terms of plate-tectonic processes observable today.

Section 1 of this article describes the geometrical aspects of motion of rigid plates on a sphere, and presents rates and directions of motion between major plates, as determined from the relevant data. Section 2 describes the differences between continental and oceanic parts of plates, constraints on plate thickness, and the vertical variations of temperature and strength within the plates. Section 3 describes the elastic behavior of plates, isostasy, and rebound due to viscous flow beneath the plates. Section 4 discusses plate motions as an indication of processes at greater depths in the earth. Finally, Sec. 5 discusses some of the limitations of plate-tectonic theory.

1. GENERAL THEORY OF PLATE TECTONICS

1.1 History

Plate tectonics is the unifying theory that the Earth's outermost solid layer is composed of a number of rigid plates, moving relative to one another; all tectonic activity on the Earth's surface results from interactions among these plates. These plates form the outer rigid layer of the Earth, called the "lithosphere," which reaches a maximum thickness of perhaps 100–150 km. The lithosphere overlies a less rigid layer, the "asthenosphere," so that plates can be envisioned as thin spherical caps floating on top of a region of less viscous material. Fourteen major lithospheric plates exist at present (Fig. 1); the number and size of these plates has varied with time. The relative motion of these plates follows the behavior that might be ex-

pected of rigid caps on the surface of a sphere. Under the theory of plate tectonics, the deformation at the Earth's surface is primarily confined to the boundaries between the plates.

Plate-tectonic theory was first proposed in the mid-1960s on the basis of an accumulated body of geophysical observations collected since the Second World War (see MARINE GEOPHYSICS). These observations included, first, a knowledge of the relief of the ocean floor, including belts of undersea mountains ("midocean ridges") that encircled the globe and corresponded to bands of seismic activity; trenches along continental margins or island arcs; and long undersea escarpments (fracture zones) across which the ridges were offset. Second, bands of positive and negative magnetic anomalies had been found in the oceans, forming symmetric patterns about these ridges; it was discovered that the Earth's magnetic field has changed polarity randomly in the past; and it was discovered that molten rock (lava), as it cools, can acquire a permanent thermal remanent magnetization parallel to the extant direction of the Earth's magnetic field. A key element was the hypothesis of Dietz and Hess that new oceanic crust was forming at the midocean ridges by a process of "seafloor spreading," whereby the two halves of the ocean basin were moving apart, and new molten rock was filling the gap and cooling. Under this theory, the earthquakes occurring along the ridges were due to divergent motions at the plate boundary, and the oceanic material was carried laterally by mantle convection currents until it was thrust back down into the mantle at trenches. Additional support for this model came from the work of Vine and Matthews (1963–1965) who proposed that this new seafloor could then become alternately normally or reversely magnetized according to the direction of the Earth's field at the time the rock was cooling. Continued seafloor spreading would form a linear pattern of magnetic anomalies symmetric about the ridge crest, much as observed. Both the age of the seafloor and the maximum age of the sediments deposited on it should increase with distance from the spreading center; and the magnetic anomaly patterns in the various oceans, once corrected for differences in rate of seafloor spreading, should give a single history of magnetic-field reversals.

The basic framework of plate-tectonics theory was confirmed in 1967–1968 by several lines of observation. Drilling results from the South Atlantic ocean showed that the age of the oldest sediments on the seafloor increased in both directions away from the ridge crest. Observations of the slip directions during earthquakes on the midocean ridge system showed directions of separation and lateral motion consistent with plate-tectonic theory. The age constraints on the seafloor, combined with the pattern of magnetic reversals observed in marine magnetic anomalies, were used to calibrate a "magnetic reversal time scale" with the basic reversal history still in use today. Anomalies numbered from Chron 1, at the present ridge crest, back to Chron 33, 84 Ma ago, correspond to a period of frequent polarity changes (the "Cretaceous-Tertiary-Quaternary Mixed Superchron"); from ~120 to 84 Ma ago was a period of constant magnetic polarity known as the "Cretaceous Normal Superchron"; before 120 Ma ago was an earlier period of mixed-polarity intervals.

The theory of plate tectonics also provided a kinematic framework for explaining earlier geological observations that had prompted Wegener's theory of "continental drift" in the early part of the twentieth century—that is, that continents with apparent similarities of rock deposits, fossils, and structural evolution, were once adjacent and are now widely separated by ocean basins because they have "drifted" apart.

1.2 Types of Plate Boundaries

Plate boundaries are divided into three basic types: divergent, convergent, and transcurrent (or strike-slip) (Fig. 2). The nature of the boundary depends on its orientation with respect to the direction of relative motion of the two plates. Divergent boundaries are midocean ridges, or "spreading centers," where two plates are moving apart. They can also be "back-arc basins," which represent divergent motion between smaller plates near a convergent boundary. In these regions, "seafloor spreading" occurs: upwelling of asthenosphere in the zone between the plates produces volcanism, which creates new seafloor in the zone between the plates, ultimately adding area to the lithospheric plates on each side. (This growth in plate

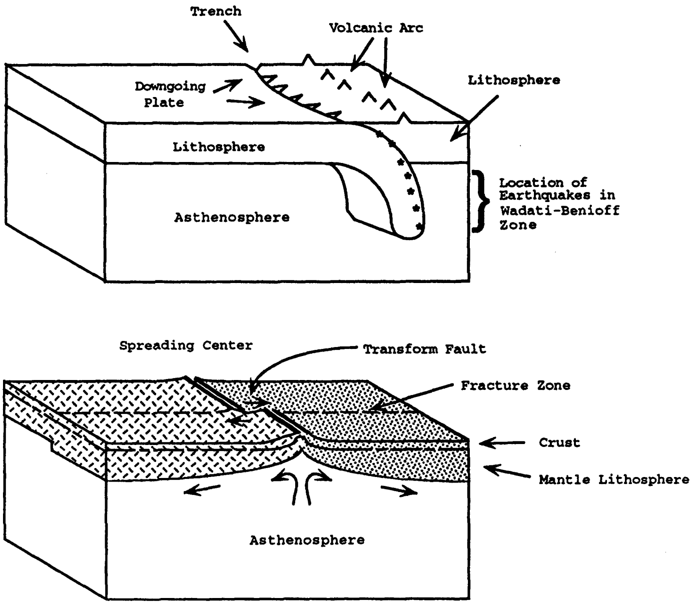

FIG. 2. Block diagrams illustrating the three types of plate boundaries: divergence at oceanic spreading centers (double line), convergence at trenches (line with teeth on upper plate) and earthquakes along the subduction zone, and lateral motion along transform faults (single line). Note that the thickness of the oceanic plate increases with age as a result of cooling and underplating of mantle material to the base of the plate (see Sec. 2.2.1).

area must be compensated by a decrease in plate area at convergent zones elsewhere on Earth, so that a constant surface area is maintained.) Such zones often originate during breakup of continental plates, and are preceded by continental extension. Thus, at very young divergent boundaries such as the Red Sea or the Gulf of California, a narrow rift system containing true seafloor spreading structures is seen to pass gradually into a broader rift system still dominated by continental extensional processes.

At transcurrent boundaries, two plates slide past one another without the creation or destruction of plate area, along fault zones known as "transform faults." Oceanic transform faults are linear bathymetric lows separating the ends of two different segments of spreading ridge and marking a discontinuity in the pattern of seafloor magnetic anomalies. The inactive trace of a transform fault is called a "fracture zone"; the magnetic anomaly discontinuity is still recognizable, and the morphological valley may be still preserved. In continental regions, transform faults may be long fault zones with multiple strands (such as the San Andreas fault system in California or the Alpine fault zone in New Zealand). They may also be topographically distinctive "rift valleys," dominated by lateral motion rather than rifting, such as the Gulf of Aqaba–Dead Sea transform system between the Africa and Arabia plates.

At convergent boundaries, two plates are moving toward one another and plate area is being destroyed. Here, if at least one of the plates is oceanic, an oceanic plate moves down beneath the other plate, into the asthenosphere, in the process of "subduction." Subduction zones are characteristically associated with an inclined zone of seismic activity (within the downgoing plate), a deep oceanic trench at the plate boundary, and volcanism above the zone of inclined seismicity, in the overriding plate. The volcanic region is called an "island arc" (if the overriding plate is oceanic) or an "active continental margin" (if the overriding plate is continental). However, at convergent boundaries involving continental material on both sides, the convergent zone may be much broader and a true subduction zone may be lacking, because continental material is too buoyant to subduct easily (see Sec. 5.3).

Along the length of any plate boundary, there may be a combination of plate-boundary features. Midocean ridges (divergent boundaries) usually comprise a series of spreading segments separated by transform faults. A convergent boundary may have oblique motion (for instance, strike-slip plus convergence). A plate boundary can change type along its length as the direction of relative plate motion changes relative to the orientation of the boundary (Fig. 1). For example, the boundary between the Pacific and North America plates consists of a series of oceanic spreading centers and transform faults (in the Gulf of California), a continental strike-slip fault zone (the San Andreas fault zone) in southern and central California, and an ocean-continent subduction zone in Alaska and the Aleutian Islands.

1.3 Location and Characteristics of Active Plate Boundaries

1.3.1 Earthquakes If plates are rigid, active deformation should be restricted to the zones between the plates. By seeking evidence for active deformation (faulting and folding) from relevant geological and geophysical data, the plate boundaries can be located. Earthquakes, indicating active faulting, are much more common at the edges of plates and along plate boundaries than in the stable interiors of plates. In a map of global shallow seismicity (earthquakes down to 70 km depth), earthquakes are concentrated in bands corresponding to the plate boundaries. Earthquakes at spreading centers are typically in the depth range 0–10 km; earthquakes along transform faults may be in the range 0–30 km; and earthquakes in the depth range from 0 to as much as 670 km may be found in regions of convergence. Intermediate (70–300 km depth) and deep seismicity (300–700 km depth) is generally confined to the interiors of the downgoing plates at subduction zones, and indicates penetration of these "slabs" into the asthenosphere. The zone of seismicity extending downward, from the oceanic trench along the interior of the downgoing plate, is known as the "Wadati–Benioff zone" (see SEISMOLOGY).

The inclinations of Wadati–Benioff zones vary widely, ranging from steep or nearly vertical in much of the western Pacific to only 10°–30° from horizontal at the Nazca–South America boundary beneath the Andes Mountains. The depth extent of the Wadati–Benioff zone can also vary. Where old oceanic plate is being subducted at high rates, the Wadati–Benioff zones may reach 670 km depth. Where very young oceanic plate is being subducted at slow rates, the zone may extend to less than 100 km depth. Some Wadati–Benioff zones have a continuous depth range of seismicity, whereas others have either no deep seismicity, or a gap in seismicity in the depth range 300–500 km. These differences are attributed to the thermal state of the downgoing plate, which is a function of the age of downgoing plate and the rate of subduction. They also seem related to the processes that occur at about 670 km depth in the mantle, which may represent a partial barrier to continued sinking of the slab and the greatest depth at which phase transitions occur in mantle minerals (see Sec. 4.1 and also EARTH, INTERIOR STRUCTURE OF THE).

1.3.2 Magmatism Magmatism includes volcanism (surface eruptions) and plutonism (intrusion and crystallization of magmas at depth). It is characteristically associated with convergent and divergent plate boundaries: 90% of the world's volcanic rocks are produced in these settings. Magmatic processes thus dominate the creation of new oceanic plates and the addition of material to continental plates (see also VOLCANOLOGY).

1.3.2.1 Midocean Ridge Basalts. New seafloor created at midocean ridges represents about 70% of the volume production of global volcanism. This material, midocean ridge basalt (MORB), is very uniform in major-element composition (olivine tholeiitic basalt, with SiO_2 in the range 44%–53% by weight, and Al_2O_3 in the range 12%–16%). Trace elements indicate that MORB is depleted in incompatible elements (those elements that preferentially enter the melt), and isotopic ratios (low $^{87}Sr/^{86}Sr$ and high $^{143}Nd/^{144}Nd$, relative to bulk silicate earth) also indicate depletion relative to the inferred composition of bulk silicate earth.

1.3.2.2 Island-Arc and Convergent-Margin Magmatic Rocks. Magmatism at convergent margins occurs in the upper plate above subduction zones, where the Wadati–Benioff zone is at a depth of 100–125 km. This volcanism dominantly comprises andesitic (SiO_2 55%–63% by weight) stratovolcanoes (often in lines or arcs such as those of Japan, Alaska, or the Andes). A variety of other compositions are present in smaller amounts. The production of magma at this distance from the plate boundary is attributed to upward movement of volatiles released from the downgoing plate by thermally driven dehydration reactions. These volatiles react with the material in the overlying "asthenospheric wedge" and produce melts that rise through the overlying plate, causing surface volcanism and subsurface intrusion of large masses of granitic rocks at depth.

Volcanic rocks in this setting follow a calc-alkaline differentiation trend, with 12%–16% Al_2O_3. Isotopic and trace-element compositions of these rocks are generally enriched in incompatible elements, although with some variations (e.g., low Nb and Ta) that may be due to retention of these elements in the source region, or interactions of the magmas with the continental crust. The $^{87}Sr/^{86}Sr$ ratios are extremely high, because of contamination of low-$^{87}Sr/^{86}Sr$ parental magma with very high-$^{87}Sr/^{86}Sr$ continental crust.

1.3.2.3 Ocean Island Basalts. A third class of volcanic rocks, ocean island basalts (OIB), occurs in a variety of settings not correlated with plate boundaries. These are generally attributed to hotspot volcanism (see Sec. 4.2). They have higher $^{87}Sr/^{86}Sr$, lower $^{143}Nd/^{144}Nd$, and higher radiogenic lead than MORB, and are enriched in incompatible trace elements. They are isotopically variable, requiring a mixture of several end members to explain the range of compositional variation. They are derived from a different, and more highly enriched, mantle reservoir than MORB. One of their end members may be old oceanic crust that has been recycled into the mantle.

1.4 Geometry of Instantaneous Plate Motions on a Sphere

The mathematics describing the motion of rigid plates on a sphere is used to predict the rates and directions of plate-boundary motions. Euler's theorem states that the most general displacement of a sphere with a fixed center is a rotation about an axis through the center of the sphere. Hence the displacement of a rigid spherical cap on the surface of a sphere (i.e., a plate) is also a rotation. Following Euler's theorem, the instantaneous relative motion of any two plates can be described by an angular velocity vector $\boldsymbol{\omega}$ passing through the center of the Earth and projecting through a point on the Earth's surface known as the "Euler pole." The vector $\boldsymbol{\omega}$ is specified as a Cartesian vector or by its components (λ,ϕ,ω) where λ = latitude of the Euler pole, ϕ = longitude of the Euler pole, and ω = rotation rate. The linear velocity $\mathbf{V}$ of plate motion at any point on a plate boundary is related to the angular velocity $\boldsymbol{\omega}$ of the two plates by the equation

$$\mathbf{V} = \boldsymbol{\omega} \times \mathbf{R}, \therefore |V| = \omega R \sin\theta, \qquad (1)$$

where θ is the angular distance from the point of measurement to the Euler pole, and $\mathbf{R}$ is the vector from the center of the Earth to the point of measurement.

The location of the Euler pole is constrained by observations of rate and direction of recent plate motion along the plate boundary. These data are easily obtained for divergent plate boundaries, because the magnetic anomaly pattern constrains the rate of separation of the two plates, and the detailed morphology of transform faults, obtained from seafloor imaging, can constrain their direction of relative motion. Thus, the direction of motion can usually be constrained to within a few degrees of azimuth. The average rate of spreading over the last few million years before present can also usually be well determined.

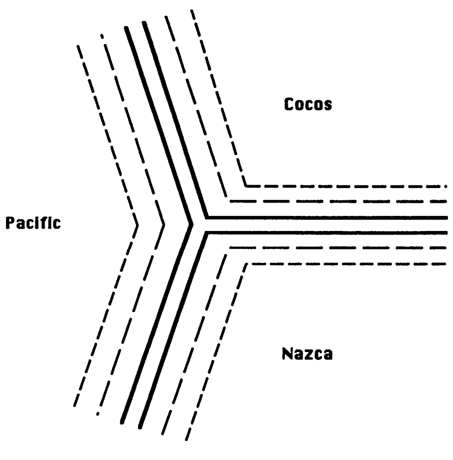
For convergent boundaries, the primary observations of "instantaneous" plate motions are earthquake focal mechanisms, often of the world's "great" earthquakes which occur at shallow depths (<100 km) in the subduction zone. The amount and direction of displacement in each earthquake can be determined. However, the average rate of plate motion may not be well represented by the observed seismicity, if some of the slip is aseismic, or if the instrumental and historical record of earthquakes is too short to give a valid long-term displacement rate. Finally, if there is deformation of the upper plate, slip in the subduction zone earthquakes will not be parallel to relative plate motion (see Sec. 5.3).

For all these reasons, at convergent boundaries, the time-averaged rate of plate convergence and the direction of plate convergence may be difficult to obtain directly. However, using data from a series of plate boundaries that are mutually interconnected, a solution can be constrained, and the assumption of plate rigidity can be tested. The simplest example of this is the situation at a "triple junction" (the location where three plates meet at a point) (Fig. 3). At this location, plate rigidity requires that the sum of the displacements across two boundaries be consistent with the amount of motion across the third boundary. This can be written in the more general form, for any system of three rigid plates,

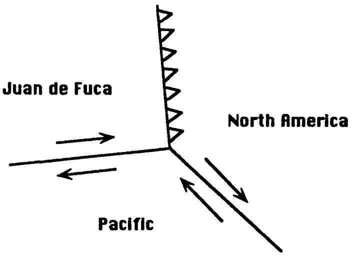
$$\boldsymbol{\omega}_{ab} + \boldsymbol{\omega}_{bc} + \boldsymbol{\omega}_{ca} = \boldsymbol{\omega}_{aa} \equiv 0, \tag{2}$$

where $\boldsymbol{\omega}_{ij}$ is the angular velocity of plate i relative to a fixed plate j.

By successively including other plates in the set under consideration, one obtains a set of linear equations that can be solved by linear inversion techniques. Several studies have used the observed rates and directions on all of the major plate boundaries, averaged over the last 3 Ma, to invert for a global set of mutually consistent relative plate velocities (e.g., Minster and Jordan, 1978; DeMets *et al.*, 1990). Such studies give relative angular velocities of the major plates of up to 2° per Ma (or about 0.035 μrad/yr). The corresponding linear velocities at plate boundaries reach up to 16 cm/yr. These results compare well with rates of plate motion estimated over much shorter time scales from satellite geodesy and Very Long Baseline Interferometry (see GEODESY).



Ridge-Ridge-Ridge Triple Junction



Trench-Fault-Fault Triple Junction

FIG. 3. Two triple junctions in map view. The Pacific, Cocos, and Nazca plates meet at a ridge-ridge-ridge triple junction, with a pattern of symmetric magnetic anomalies shown by the dashed lines. The Juan de Fuca, North America, and Pacific plates meet at a trench-fault-fault triple junction, with the sense of slip along the transform fault shown by arrows.

Some of the plate boundaries with the fastest relative motions at present include the Pacific–Nazca spreading center (with spreading rates from 13 to 16 cm/yr), the Cocos–Pacific spreading center (7–13 cm/yr), and the subduction of the Pacific plate beneath northern Japan at ~10 cm/yr. Boundaries with intermediate rates include the Tonga trench (with subduction of the Pacific plate beneath the Australia plate at 9–6 cm/yr), the Pacific–Antarctic ridge (10–6 cm/yr), the Southeast Indian Ridge between Australia and Antarctica (6–7.5 cm/yr), the subduction of the Nazca plate beneath South America (8–9 cm/yr), and the subduction of the Cocos plate beneath North America (9–6 cm/yr). Well-developed boundaries with a long history of slow motion include the Africa–Antarctica spreading ridge (~1.5 cm/yr), the North America–Africa boundary on the central part of the Mid-Atlantic ridge (2–2.5 cm/yr), and the Africa–South America boundary on the southern part of the Mid-Atlantic ridge (3–4 cm/yr).

1.5 Past Plate Motions

By Euler's theorem, the past relative position of any two plates can be described by a finite rotation of one of them, holding the other plate fixed as a reference frame. Thus, the past relative position of two plates separated by a spreading center can be given as a finite rotation, determined from the best-fit match of the equivalent magnetic anomaly lineations and fracture zones on either side of a spreading center between the two plates. The finite rotation Ω is often parameterized by latitude, longitude of the finite rotation pole, and the angle of rotation, in a fashion analogous to the parameterization of the Euler vector.

The mean age of the Earth's seafloor is, at present, about 100 Ma. The oldest known seafloor, found in the far western Pacific ocean, is about 200 Ma in age. Oceanic crust has presumably been created over many hundreds of millions of years prior to this time in Earth's history, but the older seafloor has subsequently been subducted and returned to the asthenosphere. For times older than those for which seafloor magnetic anomalies are available, the past positions of plates are determined using two alternative but less precise techniques: hotspot tracks (see Sec. 4.2) and paleomagnetic data constraining the past position of the plate relative to an axially dipolar magnetic field (see PALEOMAGNETISM).

Here we give some examples of applications of the finite rotations used in plate reconstructions. The past relative position of the North America plate relative to Africa, for a time 10 Ma in the past, can be described as a rotation, ${}_{\mathrm{NAm}}\Omega_{\mathrm{Af}}$, of 2.41° about a pole at 79°N, 78°E (counterclockwise rotations are positive). If Africa is held fixed and North America is rotated by this amount, it will be closer to Africa after this rotation, and the positions of magnetic anomaly 5 (which is 10 Ma in age) should be brought into coincidence on the two plates. Note that these finite rotations just relate the present positions of the plates to their past relative positions at a particular time; if the plate boundary has experienced changes in direction of relative motion then this finite rotation will not represent a "flow line," or path of actual relative motion, of the two plates.

Plate rigidity requires that, analogous to Eq. (2), a series of finite rotations around a triple junction or closed plate circuit sum to zero, e.g.,

$${}_{\mathrm{Ind}}\Omega_{\mathrm{Ant}}^{10\ \mathrm{Ma}} + {}_{\mathrm{Ant}}\Omega_{\mathrm{Af}}^{10\ \mathrm{Ma}} + {}_{\mathrm{Af}}\Omega_{\mathrm{Ind}}^{10\ \mathrm{Ma}} = 0. \tag{3}$$

If such finite rotations can be independently determined from the data from each plate boundary, then the assumption of plate rigidity can be tested. In addition, series of finite rotations can be combined to yield the past relative motions of pairs of plates for which no direct data are available (e.g., for two plates that are separated by a subduction zone). For example, the following sequence of three rotations, determined from marine magnetic anomalies and fracture zones bounding spreading centers, yields the past relative positions of the converging Nazca and South America plates, at 5 Ma before present:

$${}_{\mathrm{Naz}}\Omega_{\mathrm{Ant}}^{5\ \mathrm{Ma}} + {}_{\mathrm{Ant}}\Omega_{\mathrm{Af}}^{5\ \mathrm{Ma}} + {}_{\mathrm{Af}}\Omega_{\mathrm{SAm}}^{5\ \mathrm{Ma}} = {}_{\mathrm{Naz}}\Omega_{\mathrm{SAm}}^{5\ \mathrm{Ma}}. \tag{4}$$

Information derived from such a plate circuit can be used to estimate past positions of specific geographic features such as volcanic plateaus or fracture zones on the downgoing Nazca plate, or in determining the past rates of convergence through time at this subduction zone for correlation with deformational episodes or volcanic events in the overriding South America plate.

2. COMPOSITION AND STRUCTURE OF PLATES

2.1 Composition

As rigid caps on the surface of the Earth, the plates are rheologically, not compositionally, defined. However, any compositional variations affect their density and rheological structure and the response to stress. The main compositional divisions of the Earth are the crust, mantle, and core (Fig. 4), which are composed of primarily quartz (SiO_2)-rich rocks, primarily olivine ($[Mg,Fe]_2SiO_4$)- and pyroxene ($[Mg,Fe]SiO_3$)-rich rocks, and liquid metal (Fe + Ni), respectively. The base of the plate is below the crust, in the upper mantle (see Sec. 2.2). Thus, all plates contain a major compositional boundary, the crust–mantle boundary or Mohorovičić discontinuity, within them. This boundary also corresponds to a density change and a seismic velocity contrast. Its depth, determined by seismic refraction and/or reflection, ranges from ~5 to 7 km (beneath oceanic regions) to an average of 35 km (beneath stable continental interiors) to >50 km (beneath some high mountain ranges). (See also EARTH, INTERIOR STRUCTURE OF THE.)

From the world plate-boundary map (Fig. 1) it is clear that plates may have varying proportions of continental and oceanic area, ranging from primarily oceanic plates (Cocos, Nazca), through plates composed of

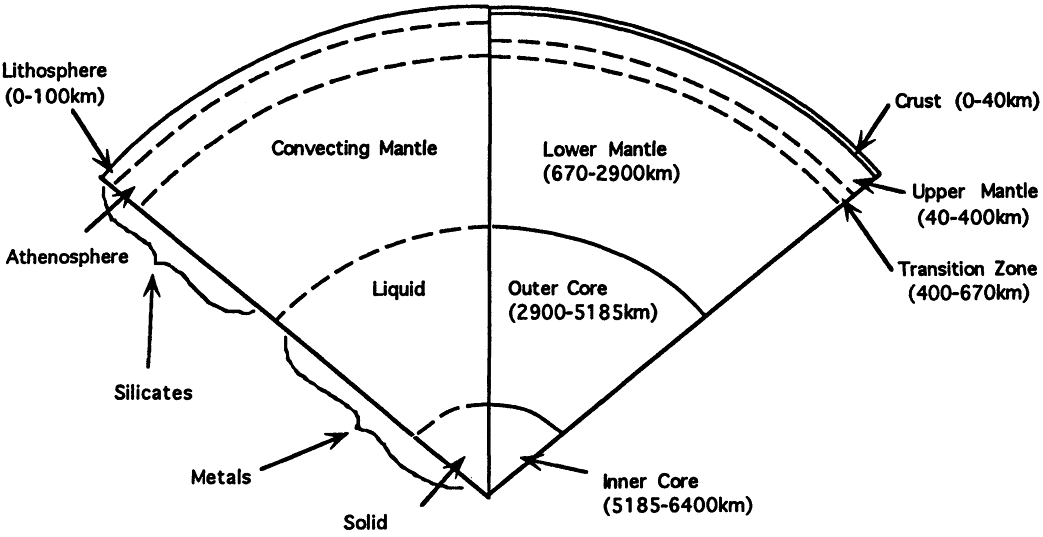


FIG. 4. Main compositional divisions of the Earth (right half of figure) compared to the major rheological divisions of the Earth (left half of figure). It is not known whether convection in the mantle is a single layer (whole mantle) or two layers (upper mantle and lower mantle separately).

both continental and oceanic regions (the majority of plates), to those with virtually no oceanic component, such as Arabia. Because plate material is continually being created and destroyed, the proportions of oceanic and continental material on a given plate can change with time.

In addition, the composition of oceanic crust is very different from continental crust. Thus, regions within plates have different compositional profiles depending on whether they are oceanic or continental (see also STRUCTURAL AND PHYSICAL GEOLOGY). These differences may extend into the mantle.

2.1.1 Oceanic Crust and Mantle An oceanic plate consists of both crust and mantle lithosphere. The crust is formed by magmatic processes at spreading centers (see Sec. 1.3.2) followed by sedimentation and rare additional volcanism at later times after formation. Beneath the oceanic crust, an oceanic plate consists of colder material of the mantle lithosphere (depleted harzburgite, containing olivine and orthopyroxene; and peridotite, which contains these two minerals plus garnet and clinopyroxene). This mantle material accretes or underplates onto the base of the plate as it cools with age and distance from the spreading center.

The magmatic structure of the oceanic crust (Fig. 5) is deduced from a combination of seismic refraction and reflection studies, dredging and drilling, direct observation, gravity and magnetics measurements, and geological observations of old ocean rocks now exposed on land ("ophiolites"). These data lead to models of a 5–7-km-thick oceanic crust with shallow (1–2 km depth) magma chambers, producing basalts that erupt on the seafloor ("pillow basalts") and intrude at shallow levels ("sheeted dikes"), as well as material that crystallizes adjacent to the magma chamber ("massive gabbro") or settles out of the magma chamber by gravity ("layered peridotite"). The magma is formed by partial melting of depleted mantle material (MORB source) at depths of 20–70 km, and then rises to reside in the shallow-level magma chamber. Up to a few kilometers of sediments may accumulate over the igneous crust and form the uppermost layer of the oceanic crustal section.

2.1.2 Continental Crust and Mantle The continental crust is more SiO_2 rich than the oceanic crust, hence less dense. It is usually thicker (30–40 km instead of 5–7 km), and it is strongly enriched in incompatible trace elements. Rather than forming in a single process of seafloor spreading, it forms over millions or billions of years of volcanism, deformation, partial remelting, and tectonic amalgamation. Thus, the continental

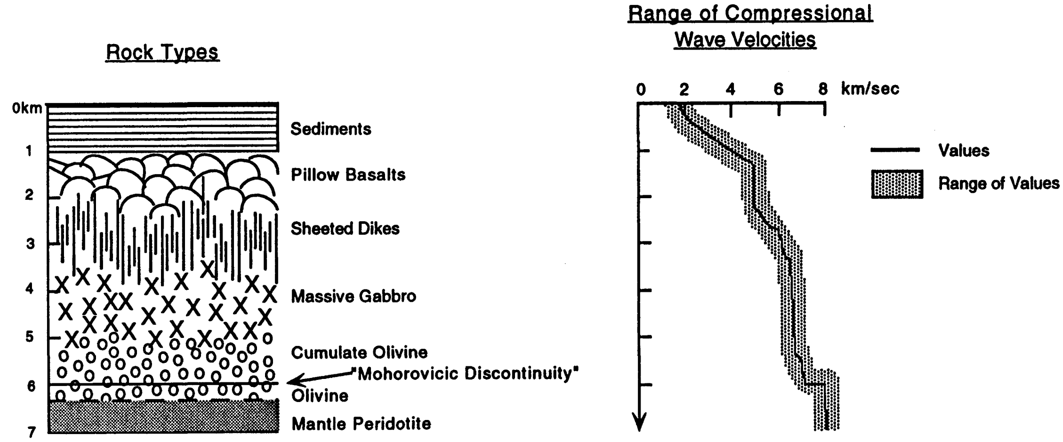

FIG. 5. Oceanic crustal structure, showing rock types inferred from drilling, dredging, and geological study of oceanic rocks preserved on land (ophiolites). Thickness of the sedimentary layer may vary. Boundaries between pillow basalts, sheeted dikes, and massive gabbros are gradational. The crust/mantle boundary (Mohorovičić discontinuity) is chosen on the basis of an increase in compressional seismic wave velocity to greater than 8 km/s.

crust varies in composition, age, and thickness from place to place. Beneath the continental crust we again find mantle lithospheric material (olivine-rich rocks).

The mantle lithosphere of the continental regions may be compositionally slightly heterogeneous compared to the mantle lithosphere of oceanic regions. Thickness of oceanic lithosphere is similar to the thickness of young (<2.5 Ga old) continental lithosphere, but the lithosphere beneath the Archean (>2.5 Ga old) crust seems to be thicker, about 150–200 km thick. These regions of thicker continental lithosphere also are sources for anomalously low-Fe and low-density xenoliths of mantle peridotite, which are brought up as inclusions in volcanic rocks.

2.1.3 Isostasy Continental areas have an average elevation of 0.8 km above sea level, whereas the oceanic regions have an average elevation of 3.7 km below sea level. Gravity measurements indicate that in general these regions are isostatically compensated—positive topography of continents is compensated by an equivalent negative mass anomaly at depth, and negative topography of oceanic regions is compensated by an equivalent positive mass anomaly at depth. The principle of isostasy states that at a certain depth (d_c, the "depth of compensation") the pressures due to the weight of the overlying materials, with surface elevation h, are equal, i.e.,

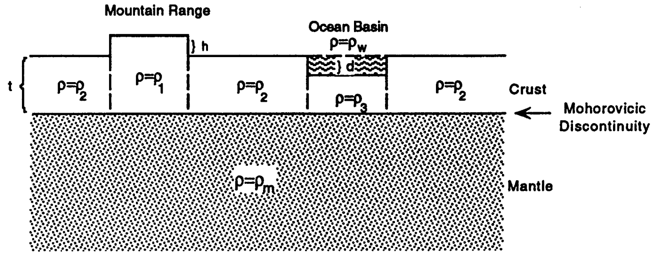
$$\int_{z=-d_c}^{z=h} \rho(z) g\,dz = \text{constant}, \tag{5}$$

where ρ is density, and g is the acceleration of gravity (Fig. 6). Below d_c the material would be in hydrostatic equilibrium. The depth of compensation appears to vary from place to place. In continental regions, it is often taken to be within the mantle lithosphere, because constraints on crustal thickness are sufficient to yield the observed gravity and topography; in this case, the mechanism of compensation is "Airy compensation"—variations in crustal thickness at constant crustal density. In oceanic regions, d_c is often assumed to lie below the plate, and the mechanism of compensation is "Pratt compensation"—material within the lithospheric column has lateral density variations due to lateral thermal contrasts.

2.2 Thermal and Seismic Velocity Structure of Plates

The "thickness" of the lithosphere is defined in various ways depending on the physics of the problem being considered (e.g., thermally, seismically, or rheologically). Each type of definition leads to different es-

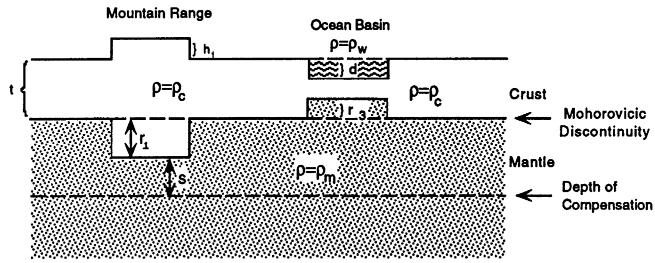
Pratt Isostasy



Equation of Isostatic Equilibrium: $g\rho_2 t = g\rho_1(t+h) = g[\rho_3(t-d) + \rho_w d]$

$$\rho_3 > \rho_2 > \rho_1$$

Airy Isostasy



Equation of Isostatic Equilibrium: $g[\rho_c(h_1 + t + r_1) + \rho_m s] = g[\rho_c t + \rho_m(s + r_1)] = g[\rho_c(t - r_3 - d) + \rho_w d + \rho_m(s + r_1 + r_3)]$

FIG. 6. Two mechanisms of isostatic compensation of regions within plates: Pratt compensation (variable crustal density, constant depth to Mohorovičić discontinuity) and Airy compensation (constant crustal density ρ_c, variable depth to Mohorovičić discontinuity). Density of mantle is ρ_m and of water is ρ_w. Depth of ocean basin is d. Equation of isostatic equilibrium is from Eq. (5).

timates for the thickness of the plates. Here we discuss thermal and seismological constraints on plate thickness, which are generally in the range of 100–150 km for old plates. Elastic thicknesses can be much less than this (see Sec. 3.1).

2.2.1 Temperature Profiles of Oceanic Plates, and the "Thermal Boundary Layer" The average depth of mid-ocean ridge spreading centers is about 2500 m below sea level; with distance from the spreading center, the depth of the seafloor increases. In global data, for ages less than about 80 Ma, the depth of the seafloor, h, is observed to be proportional to the square root of the age t of the plate:

$$h\ (\text{km}) = 2.5 + 0.35\sqrt{t\ (\text{Ma})}. \qquad (6)$$

In addition, the surface heat flux, Q_0 is observed to decrease as about $t^{-1/2}$:

$$Q_0(10^{-3}\ \text{W/m}^2) = 473/\sqrt{t\ (\text{Ma})}. \qquad (7)$$

These observations can be explained if the oceanic plate is a rigid thermal boundary layer with no internal heat generation, which thickens during conductive cooling as it moves away from a heat source at the mid-ocean ridges. This thickening process corresponds to underplating of cooled asthenospheric material to the base of the plate. This type of "cooling half-space" model gives functional relations of depth, heat flux, and age in agreement with those observed (Fig. 7). The relationship between depth and square root of age can be obtained theoretically if one assumes isostatic equilibrium at depth beneath the plates; as a plate cools and thickens, its average density increases, and so it sinks further into the asthenosphere below. The variation of the observed depth-age relationships, and ridge-crest depths, among various spreading centers suggests that the temperature variations at depth among the different spreading centers may be on the order of 100 °C.

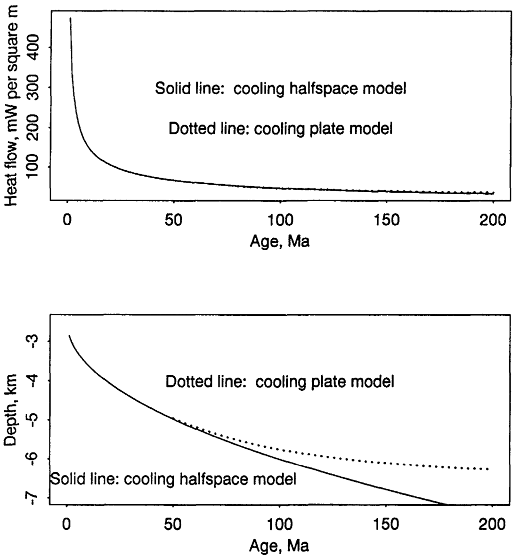


FIG. 7. Theoretical curves relating depth to the seafloor, and oceanic heat flow, to age of the oceanic plate. A "cooling half-space" model fits observations well for young times, but for older times, a "cooling plate model" is required to explain the nearly constant seafloor depth.

For seafloor ages more than about 80 Ma, seafloor depth appears to reach a constant value of about 5.5 km below sea level. This suggests that some dynamics of asthenospheric flow or heat transfer beneath the oceanic plates retard further thickening. Suggested mechanisms include requiring the base of the lithosphere to be isothermal, addition of heat via mantle "plumes," or perturbation of the depths due to pressure differences associated with the asthenospheric flow beneath the plates ("dynamic" effect). These lead to an alternative parameterization of Q_0 and h for $t < 70$ Ma, the "cooling plate model" (with t given in Ma):

$$\begin{aligned} h\,(\mathrm{km}) &= 6.4 - 3.2e^{-t/62.8} \\ Q_0(10^{-3}\,\mathrm{W\,m^{-2}}) &= 33.5 + 67e^{-t/62.8}. \end{aligned} \tag{8}$$

Note that if asthenospheric flow can cause deviations from the expected depth-vs-age curve at old ages, it can also do so at young ages, and may be one major cause of the scatter about the average relationship (residual depth anomalies) present in the ocean basins. The calculations of depth vs age traditionally have not taken this into account.

The half-space model corresponds to an error-function distribution of temperature T with depth z for seafloor of age t:

$$T(z,t) = T_a \mathrm{erf}(z/2\sqrt{\alpha t}), \tag{9}$$

where α, the thermal diffusivity, is typically 10^{-6} m²/s, and T_a, the asthenospheric temperature, is about 1300 °C. This theoretical distribution of temperature with depth in the plate cannot be confirmed by direct measurement because of our present inability to sample more than a few kilometers down into the top of the plates. However, from the surface heat flow Q_0 and measured values of thermal conductivity k one can determine the temperature gradient at the surface:

$$\frac{Q_0}{k} = -\left.\frac{dT}{dz}\right|_{z=0}. \tag{10}$$

This temperature gradient should be approximately linear and about 10 °C/km for old oceanic plates (higher for younger oceanic plates).

The temperature within the plate increases gradually with depth until asthenospheric temperature T_a is reached. Thus, the choice of plate "thickness" as defined by any given isotherm is somewhat arbitrary. It is often chosen to be 90% of T_a. This allows a comparison of the "thickness" of the plate with age.

2.2.2 Temperature Profiles of Continental Plates The structure and thermal profiles of continental plates differ from those of oceanic plates, because of the more complicated process of formation of continental material, and because the upper 15–30 km of continental crust incorporates a significant heat source: radioactive isotopes such as ^{40}K, ^{238}U, and ^{232}Th, which are very rare in oceanic crust. Thus, at a given depth, a continental plate may be warmer than an old oceanic plate. Typical surface thermal gradients for continental regions are 15–25 °C/km.

2.2.3 Seismic Velocity Structure of Plates The thickness of continental plates is not easy to calculate from any simple model, because a significant proportion of the continental material has been present at the surface for billions of years. However, seismic wave velocities (see SEISMOLOGY) indicate that the higher velocities and low seismic attenuation typical of continental and/or oceanic lithosphere extend to about 150–200 km depth beneath the main continental masses. Thus, if the plate thickness is defined seismically, the continental parts of the plates may be somewhat thicker than oceanic parts of the plates, consistent with the greater mean age of the continental lithosphere. In addition, continental regions may have older lithospheric material present beneath them at depth.

2.3 Stress and Driving Forces on the Plates

The major forces driving the plates are thought to be gravitational in nature: sinking of cold, dense plates at trenches (negative buoyancy or "slab pull," perpendicular to the trench) and gravitational sliding of thin, young plates off the thermal high above the upwelling zone at mid-ocean ridges ("ridge push," perpendicular to the ridge). Coupling between the plates and the underlying asthenosphere may cause an effective frictional drag force at the base of the plate.

The absolute levels of stress within the plates are not well known, but the directions of stress can be constrained from observations of borehole ellipticity, hydraulic fractures, overcoring, earthquake focal mechanisms, volcanic alignments, and slip directions of active faults (Zoback, 1992). These data represent stresses at different depths, but generally show good agreement within a given region over distances of hundreds to 5000 km. This broad-scale consistency in stress directions is compatible with a stress field controlled by compressive plate boundary forces (ridge push and continental collision) rather than resistive or driving basal tractions. Some second-order variations in the lithospheric stress field are caused by lithospheric flexure, lateral density contrasts, and lateral strength contrasts (Zoback, 1992).

3. RHEOLOGY OF PLATES AND UNDERLYING ASTHENOSPHERE

3.1 Rheology of Plates

The overall rheology of the Earth is, to first order, that of a fluid body; its gravity field shows that it is close to hydrostatic equilibrium. The plates are the major exception to this observation: they are the most rigid part of the Earth, and least likely to flow on geological time scales. In the theory of plate tectonics, the rigid plates are solid objects "floating" on a more fluid layer (the asthenosphere). Thus, they should be in isostatic equilibrium. Departures from local isostatic equilibrium may occur, if supported by elastic stresses within the plates or local variations of stress within the plates.

3.1.1 Elastic Behavior of Plates Plates respond elastically, by bending, when subjected to applied loads. Such loads include mountain chains, volcanic islands, ice sheets, large lakes, large sediment loads (e.g., sedimentary basins), and changes in volume of water in the ocean basins. From observations of lithospheric loading near trenches and near point or line loads (e.g., large volcanic islands such as Hawaii), the flexural rigidity, or an equivalent parameter such as the effective elastic thickness of the plate, can be determined.

For a line load such as the Hawaiian volcanic chain, the general equation governing the equilibrium deflection of an elastic plate as a function of horizontal distance x from the center of the load is

$$D\frac{d^4w}{dx^4} = V(x) - H\frac{d^2w}{dx^2}, \tag{11}$$

where $w(x)$ is the vertical deflection of the plate, V is the vertical force per unit length applied to the plate, H is a constant horizontal force per unit length applied to the plate, and D is the flexural rigidity of the plate, given by

$$D = \frac{Eh^3}{12(1 - \nu^2)}, \tag{12}$$

where E is Young's modulus, ν is Poisson's ratio, and h is the effective elastic thickness.

For a plate being bent at a subduction zone, or in a zone of continental collision (e.g., the India plate being subducted beneath Asia along the Himalayas, the Pacific plate being subducted beneath the Philippine plate at the Mariana trench), an equation for a plate with an end load and a horizontal bending moment is more appropriate in order to calculate the deflection. Such analyses yield values of effective elastic thicknesses ranging from 24 to 28 km for oceanic plates and 80 to 100 km for continental plates.

In some cases, the flexure induced by a known load is only poorly fitted by using an elastic model, and an elastic–perfectly plastic rheology may be more appropriate. A material with this rheology behaves elastically until it reaches a critical shear stress, at which it suffers permanent deformation.

3.1.2 Strength of Plates The fundamental characteristic of lithosphere is its great strength (rigidity), compared to the underlying asthenospheric material. In the simplest sense, then, the base of the plate could be defined as a particular low value of material strength. Assuming simple compositional layering (crust/mantle) and the temperature gradients within the plates suggests that brittle failure controls the strength near the surface, and temperature-dependent, grain-size–dependent, and strain-rate–dependent processes of crystal plastic flow control the strength at depth. Thus, strength increases with depth in the brittle layer and then decreases with depth in the ductile regime (Fig. 8). The position of greatest strength should lie at the brittle/ductile transition, somewhere within the mantle lithosphere; the base of the plate (as defined rheologically) will be at some greater depth. The definition of the base of the plate in this case can be chosen to correspond to material that will deform at a certain strain rate when subjected to a certain stress level (whatever values of strain rate and stress are thought to be appropriate to the problem under consideration).

The base of the plate does not correspond to a compositional change—the material both above and below it is olivine-rich mantle material in both cases. It is a Maxwell material and can exhibit both elastic and viscous behavior during deformation. Its overall level of shear stress, σ, is a combination of elastic stress and viscous stress:

$$\sigma = E\epsilon + \mu\dot{\epsilon}, \qquad (13)$$

where σ = shear stress, ϵ = strain, $\dot{\epsilon}$ = strain rate, μ = viscosity, and E = Young's modulus. If the ratio $E\epsilon/\mu\dot{\epsilon}$ is large, then elastic stresses dominate and the material can be considered to behave rigidly. If this ratio is $\leqslant 1$, then viscous stresses dominate and the material suffers permanent deformation, i.e., is not rigid. Thus, the time scale of observation (ratio $\epsilon/\dot{\epsilon}$), and the values of the material constants E and μ, influence whether the plate can be considered rigid or not. For most applications in plate tectonics, the time scales of interest are the time scales of large-scale motions of the plates, e.g., 10^7–10^8 years.

3.1.3 Viscous Behavior of Zones within the Plates From the expected temperature gradients within the plates, and the results of laboratory experiments on the mechanical behavior of the dominant minerals in the continental crust (quartz) and in the mantle lithosphere (olivine), we can calculate how the strength of a plate (that is, the maximum shear stress that can be supported by that plate) varies with depth within the plate. Simple models with a quartz-rich crust and olivine mantle lithosphere suggest that there is often a weak zone below ~20 km depth in the lower continental crust, because at the temperature and pressure conditions expected there, quartz can flow viscously. This weak zone should not exist in oceanic lithosphere, because oceanic crust is much thinner than the continental crust, and at equivalent pressure and temperature conditions the olivine of the oceanic mantle lithosphere is much stronger than quartz (Fig. 8). This lower crustal layer may flow laterally in response to loads induced by tectonic activity. In regions such as the Basin and Range province of western North America, where rocks from the middle crust have been brought to the surface by faulting, and yet the crust–mantle boundary appears to be at a constant depth, lateral flow of lower crustal material is invoked as a possible explanation for these observations.

3.2 Rebound from Loads, and Flow beneath the Plates

If plates and the underlying mantle asthenosphere were always elastic in their behavior, or if mantle asthenosphere had very low viscosity, then the removal of a load would cause immediate uplift, a complete and instantaneous elastic adjustment of the shape of the plate. However, geological observations indicate that often the uplift con-

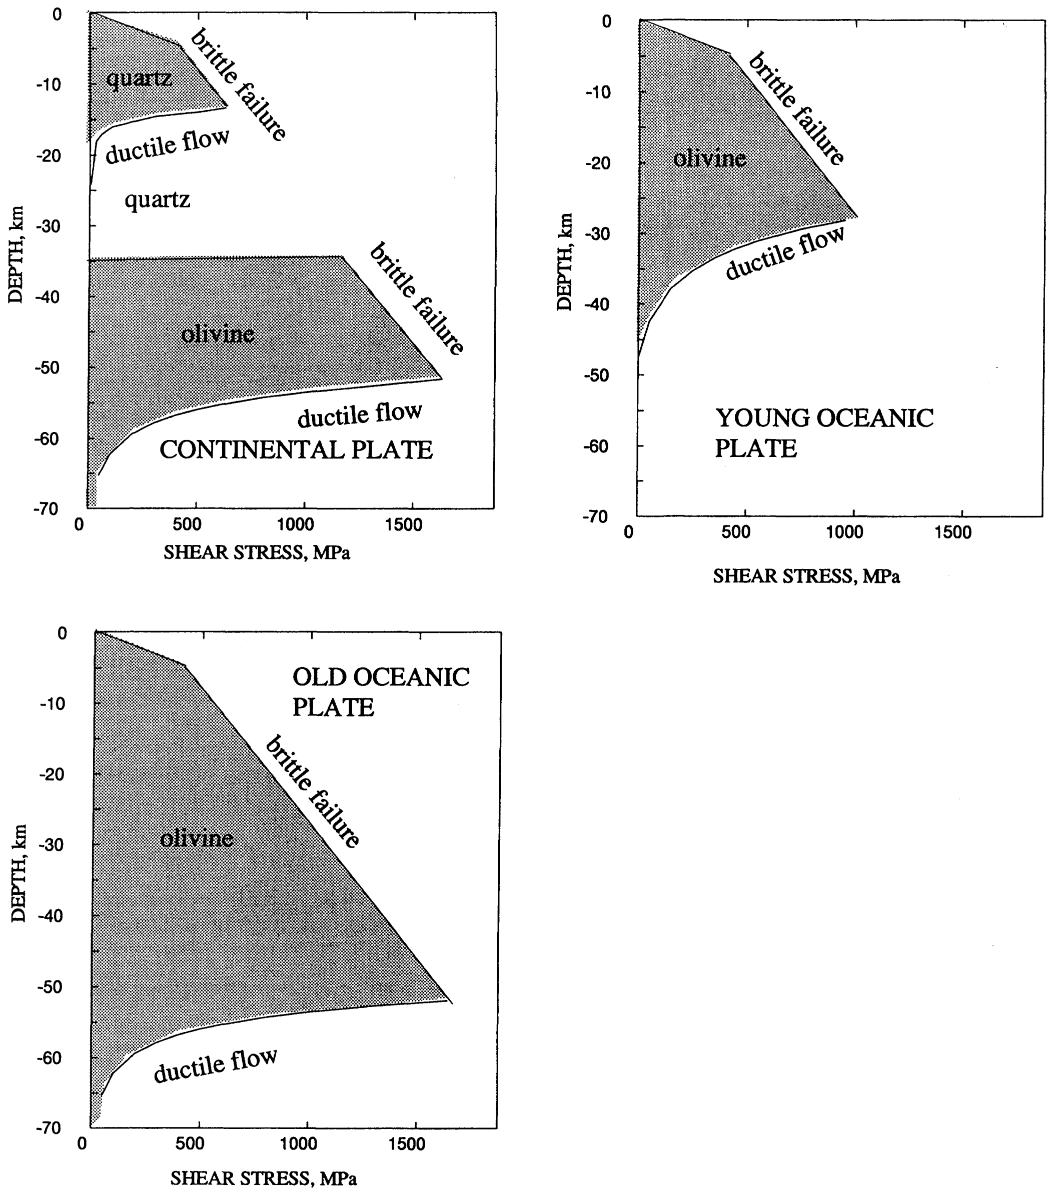

FIG. 8. Theoretical strength of plates as a function of dominant mineral (quartz or olivine) and depth. Ductile strength decreases with increasing temperature; thus, old oceanic plates can support higher shear stress than young oceanic plates because of their lower geothermal gradients. Many continental plates are in regions of low geothermal gradients but may have a weak zone in the lower crust if it is quartz rich, because quartz can flow under lower pressures and temperatures than can olivine. The brittle–ductile transition is formed by the intersection of the brittle failure and ductile flow lines. These curves move up for higher strain rates and down for lower strain rates; a strain rate of 10^{-15} was used here.

tinues after the load is removed. This time-varying behavior is attributed to viscous flow beneath the plates. Postglacial rebound is one such process; although the last Fennoscandian ice sheet melted 10 000 years ago, the crust in Fennoscandia is still slowly rising relative to sea level. Maximum uplift rates at present exceed 0.9 cm/yr. A similar rebound process has been observed, on a smaller scale, in the draining of Lake Bonneville, a large postglacial lake (ancestral to the Great Salt Lake of Utah, U.S.A.). The rebound is attributed to viscous flow in the asthenosphere, below the lithospheric plates, and indicates mantle (asthenospheric) viscosity values of about 10^{19}–10^{20} Pa s.

4. RELATIONSHIP OF PLATE MOTIONS TO PROCESSES IN THE EARTH'S MANTLE AND CORE

4.1 Interaction between Plates and Mantle Convection

4.1.1 Present Day The plates are an integral part of the Earth's convective system, because they are the rigid layer through which convectively transported heat is conducted out of the mantle, and because the cold subducted slabs help to cool the mantle. In addition, motion of surface plates seems to require a convecting mantle beneath the plates. If the subducted slabs penetrated the mantle, they would cause downward flow of asthenospheric material, requiring some compensating pattern of upwellings ("return flow") elsewhere in the mantle. The plate motions are believed to reflect, to a considerable degree, the convective motions in the mantle beneath them. They may also affect these convective motions. For instance, a thick continental layer may insulate the mantle material below it, creating a broad temperature anomaly that ultimately might give rise to convective motions which then drive plate motions.

The 3-D state of the mantle convective system is most often inferred from long-wavelength geoid anomalies and from variations in velocity of seismic waves within the mantle, observed with the technique of seismic tomography (see EARTH, INTERIOR STRUCTURE OF THE; SEISMOLOGY). Within the convecting mantle, lateral velocity and density anomalies are thought to be primarily temperature controlled, rather than indicative of compositional variations. For example, a few 100 °C increase in temperature would be expected to cause a detectable (1%) decrease in compressional seismic wave velocity. Thus, the regions of slow and fast seismic velocity anomalies are used to infer the patterns of upwelling and downwelling, respectively, in the mantle. At shallow depths in the mantle (<700 km depth), the slow and fast regions coincide with the spreading ridges and the downgoing slabs; at greater depth, these velocity anomalies and hence the inferred convection patterns vary laterally and are no longer as obviously correlated with the geometry of the surface plates. In particular, the lower seismic velocities beneath the mid-ocean ridges seem to be confined to the top 350–400 km of the mantle. The surface plate motions also exhibit a significant component of toroidal (strike-slip) power, which is not expected in a convecting fluid and does not appear to persist to depth.

The state of mantle convection is still controversial. There may be two separate convecting layers (upper mantle and lower mantle), separated by a barrier at about 670 km depth. Alternatively, there may be a single convective system ("whole-mantle convection"). Evidence for whole-mantle convection includes the observation that lower-mantle material with fast seismic velocities is found below, and apparently continuous with, the subducted slabs, suggesting that the slabs pass through 670 km depth and continue aseismically into the lower mantle. Evidence for a boundary at 670 km depth includes the cessation of Wadati–Benioff zone seismicity at this depth; cosmochemical evidence that "bulk" mantle is likely to have a different major-element composition than the olivine-rich compositions thought to characterize the upper mantle; and evidence, from the sign of geoid anomalies associated with subduction zones, that there is a substantial (factor of 100) viscosity increase at about this depth in the mantle. The isotopic differences between mid-ocean ridge and ocean island lavas (Sec. 1.3.2) suggest the presence of distinct geochemical reservoirs in the mantle.

4.1.2 Plate Tectonics during Early Earth History The time range over which plate tectonic processes have operated on Earth is important as a constraint on the history of the convection system. Unfortunately, the record of plate motions is less well defined as one goes back in time, because of the lack of remaining seafloor greater than 200 Ma in age. Paleomagnetic data on past continental positions also become more scarce for older times. The geologic time of particular concern, the Precambrian, comprises the Proterozoic (from about

2.5 Ga to 600 Ma ago) and the Archean (older than 2.5 Ga). During early Archean time, heat production in the Earth was considerably higher than at present, possibly resulting in more rapid convective motions and thinner plates than those present now. In addition, it has been proposed by some authors that the early lithosphere may have been too hot to be subducted, so that surface plate motions had a fundamentally different form involving buckling and shearing of small surface plates but no subduction.

Although direct data on the existence of lithospheric plates and on relative plate motions are lacking for these times, geologic data suggest that at least during the Proterozoic time, many of the tectonic settings were similar to the modern ones: arc systems, oceanic ridges, continental cratons, and continental rifts. In addition, paleomagnetic data from Proterozoic rocks suggest the existence of several supercontinents in relative motion. For Archean time, there are fewer similarities with modern settings. Cratonic assemblages and arc assemblages can still be identified but rock types that might represent oceanic rifts or continental rifts have not been recognized in rocks older than about 2 Ga. If subduction was occurring as far back as 2 Ga, which would be consistent with the observations, then another driving mechanism must be sought, because density contrasts of subducted slabs would probably have been insufficient to drive subduction. Many Archean orogenic belts contain a high percentage of komatiite lavas, which are more dense than basaltic lavas and were presumably derived from a less depleted upper mantle with a high percentage of partial melting. If Archean oceanic crust were composed of komatiite, the extra density may have been sufficient to drive subduction and plate tectonics starting before 4 Ga ago.

4.2 Hotspot Volcanism and the Record of Plate Motions Relative to the Hotspot Source Regions

One principal component of the convection system, mantle "hotspots" (sources of anomalous volcanism, often distant from plate boundaries), appears somewhat decoupled from surface plate motions. The best-defined "hotspot tracks" are lines of chemically distinctive, OIB composition (see Sec. 1.3.2.3), volcanoes on the seafloor (Fig. 9). These show an age progression along the chain (e.g., the Hawaiian-Emperor seamount chain in the central Pacific Ocean, formed by the Hawaiian hotspot). Other major hotspots include Iceland, associated with the Iceland–Faeroes ridge; Tristan da Cunha, associated with the Walvis Ridge and Rio Grande Rise in the south Atlantic Ocean; Reunion, associated with the Chagos–Laccadive Ridge in the Indian Ocean; and Kerguelen, associated with the Kerguelen Plateau and the 90°E ridge in the Indian Ocean. Other oceanic ridges or alignments of seamounts, such as the Louisville Ridge in the SW Pacific Ocean, are considered to be hotspot tracks although there is no evidence of modern volcanism or a presently active hotspot. The tracks of continental hotspots may be difficult to identify, because significant interaction of the hotspot magmas and the continental plate complicates both the geometry of the volcanic trace and the compositions of the volcanic products. Interpretations of continental hotspots vary, but Yellowstone (in North America) is one of the most active and well known.

The hotspots appear to originate from sources that are well beneath the plates, from the lower mantle or from the core–mantle boundary. They are generally located away from subduction zones. Their sources appear to lie in a reference frame with very slow relative motions, compared to plate motions. The age progression of the hotspot volcanoes on a single plate indicates the relative motion of the plate over the hotspot source. If the hotspot sources are assumed to be fixed to one another, then the hotspot tracks can be used to define the relative motion of the plate they lie on, relative to the "hotspot reference frame" (sometimes also considered to be an "absolute reference frame"). This provides an alternative method of determining past relative plate positions, e.g.,

$$ {}_{\mathrm{NAm}}\Omega_{\mathrm{hotspots}} + {}_{\mathrm{hotspots}}\Omega_{\mathrm{Pac}} = {}_{\mathrm{NAm}}\Omega_{\mathrm{Pac}}. \qquad (14) $$

There is not yet a consensus on the depth at which hotspots originate. There is also no known theoretical reason why the hotspot sources must be fixed to each other. Until further work is done on these topics and on detailed hotspot and plate kinematics, the validity of the hotspot reference frame cannot be unequivocally established.

4.3 Connections between Core Processes and Plate Motions

A possible link between core processes and surface tectonics has been recently suggested, on the basis of the correlation between the late Cretaceous interval of constant polarity of the magnetic field, and unusually fast seafloor spreading. The frequency of magnetic reversals may directly indicate the state of convection in the Earth's outer core, although it is not known whether periods of constant magnetic field polarity correspond to increased convective activity or decreased convective activity in the outer core. The state of convection in the outer core would certainly exert strong control on the heat input to the base of the mantle and eventually to the heat flux through the Earth's surface (as evident from seafloor spreading and intraplate volcanism). These variables may be related either instantaneously or with some time lag, depending on the time scale and processes of heat transfer between the core–mantle boundary and the lithospheric plates.

5. LIMITATIONS OF PLATE TECTONIC THEORY

As mentioned in Sec. 1.1, there are exceptions to the rigid-plate assumptions of plate tectonic theory: deformation within plates, deformation in broad zones adjacent to the boundaries, and slow vertical motions ("epeirogenic movements") of large regions within plates, without associated internal deformation. In addition, smaller pieces of crust sometimes exhibit independent motion, raising the question of the smallest scale at which plate tectonics is applicable.

5.1 Vertical Motions

The predictive value of plate tectonics theory lies in its constraints on the horizontal components of plate motion. It does not address the question of vertical motions, other than via the implied upwellings and downwellings within the asthenosphere beneath the plates (see Sec. 4.1). There are vertical motions of rocks at the Earth's surface, on both short and long time scales, that are not dealt with by plate tectonic theory. Uplift commonly results from crustal and/or mantle lithospheric thickening in zones of convergent motion. The Tibetan Plateau of Asia, and the Altiplano (high plateau) of South America, are both attributed to convergence-related uplift. Uplift can also be due to removal of a load (Sec. 3.2), to heating and thermal expansion of formerly cold lithosphere, or to removal of cold mantle lithosphere from the base of a plate (e.g., by delamination).

Subsidence can be an isostatic response to lithospheric thinning (e.g., in rift basins) or to cooling of the lithosphere, as discussed for the case of cooling oceanic lithosphere (see Sec. 2.2.1). It can also be an isostatic and flexural response to an applied load. In addition, either uplift or subsidence can be caused dynamically, as a result of density differences caused by flow within the sublithospheric mantle.

Eustatic (worldwide) changes in sea level may give the same sedimentological results on the continental margins as do more local uplift or subsidence events. However, such global events are attributed to variations in the volume of water in the ocean basins (due to melting or formation of ice sheets) or to variations in the volume of the ocean basins themselves. This latter type of variation may be strongly controlled by plate tectonic processes. If seafloor spreading has been rapid for a while, and the mean age of the seafloor is young, then the mean depth of the seafloor will also be shallower, displacing some water up onto the continental shelves and causing a global sea-level rise. For example, a time of rapid seafloor spreading in Late Cretaceous time (~120–80 Ma ago) correlates with, and is believed to be the principal cause of, a corresponding period of high sea levels worldwide.

5.2 Deformation in Plate Interiors

Worldwide, most of the release of energy as earthquakes occurs in plate boundary zones, consistent with plate tectonic theory, which suggests that most of the deformation should be concentrated there. Nevertheless, there are rare large earthquakes in the interiors of plates. Such earthquakes presumably relieve accumulated stresses in the plates, but do not account for much relative motion or internal strain of the plates. In addition, broad zones of intraplate seismicity and youthful fault scarps (e.g., the Basin and Range province of the western U.S.A., or the Tibetan Plateau region of Asia) indicate broad internal zones of extensional or contractional strain within the plates. These are usually associated with the presence of hot or weak continental material adjacent to a plate boundary. (See also STRUCTURAL AND PHYSICAL GEOLOGY.)

Some continental plates have active internal rift zones (e.g., the Rio Grande Rift in western North America, the Baikal Rift in Asia, the East African Rift). Although these narrow zones are prominent topographic features, the rate of extension across them is so low that they are considered to represent internal deformation of plates, rather than discrete plate boundaries. If extension rates increase, these may evolve into divergent plate boundaries. Their structural development is considered analogous to the very early development of divergent plate boundaries between continental plates.

Most oceanic plates seem to behave quite rigidly, and are less likely to exhibit significant internal deformation than are the continental plates. Tests of closure of oceanic triple junctions suggest that in most cases the observed rates and directions of motion fit a rigid three-plate scenario quite well. There are two major exceptions to this. Firstly, in oceanic regions where two different oceanic plates are undergoing very slow relative motions, such as along the North America–South America plate boundary in the Atlantic Ocean or along the Australia–India plate boundary in the Indian Ocean, the deformation may occur over a broad zone within the plate. Secondly, very young oceanic plates, which are thin and weak (e.g., the South Gorda region of the Juan de Fuca plate), may exhibit regions of diffuse seismicity and internal deformation manifested by active faulting and folding.

5.3 Complexities of Deformation at Plate Boundaries

Ideally, in plate tectonic theory, all deformation should be concentrated in narrow boundaries between the plates. The boundary zones between oceanic plates are generally narrow (<20 km wide), but they can be much wider in continental plates. For example, the Pacific–North America plate boundary in southern California comprises the San Andreas fault zone (with about 75% of the plate boundary displacement) and other faults in the continental material on both sides, over a zone a few hundred kilometers in width. All of this zone is characterized by high seismicity and complex patterns of active faulting driven by the motions of the more rigid plates on either side. Wide zones of continental deformation also occur in the upper plate in zones of oblique subduction: a zone of strike-slip faulting may develop in the volcanic arc, tens to hundreds of kilometers from the trench, taking up some of the oblique component of plate motion.

Because continental material is more buoyant than oceanic material, continental material does not appear to be easily subducted at subduction zones. At locations where continental material is in the downgoing plate at a subduction zone, there may be substantial geological deformation in a broad area adjacent to the plate boundary. For example, the attempted subduction of continental India plate beneath Eurasia has caused a region of broad deformation in the Himalayas and Tibetan Plateau.

5.4 Limitations on the Sizes of Plates

Although the major plates of the Earth's surface have areas in the range 10^8–10^6 km^2, some smaller oceanic plates (or "microplates") are found along mid-ocean ridges. These are usually bounded by spreading centers and transform faults, and may have dimensions as small as 100×100 km^2. These "microplates" grow in area through seafloor spreading on both sides of them, and they may be short-lived as independent plates, if one of the spreading centers ceases activity and its net motion is transferred to the other spreading center. In this case, the microplate will become accreted to one of the adjacent major oceanic plates. Microplates are also present in subduction settings, where large oceanic plates entering subduction zones have smaller fragments break off their edges, with dimensions of a few hundred kilometers. These microplates may move independently for a while prior to being subducted or they may accrete to one of the nearby major plates.

Continental material is generally not considered to form distinct microplates, perhaps because of its greater tendency to suffer pervasive deformation via geological faulting. In deforming continental regions, individual fault-bounded blocks can have different directions of relative motion; however, these blocks do not appear to extend down through the entire lithosphere, and therefore are not considered to be plates in their own right.

5.5 Application to Other Planets

Plate tectonic processes are a consequence of the formation of a relatively rigid thermal boundary layer above a convection system within the planet. One might expect plate-tectonic processes to occur on any planetary body within which convection is occurring and which has a sufficiently thin and rigid thermal boundary layer (lithosphere). Calculated temporal variations in planetary temperatures suggest that the Moon, Mercury, and Mars would have been too cold to sustain plate tectonics since about 4 Ga ago. However, on Venus, temperatures that might permit plate-tectonic processes could have persisted until much more recently.

Radar images and gravity and altimetry measurements from various spacecraft missions (most recently, the Magellan mission) show evidence for considerable tectonic activity on Venus, including features that may be analogous to transform faults, trenches, zones of continental compression or extension, and possible mantle downwellings. Although there are rift systems hundreds to thousands of kilometers long, analogues to Earth's spreading centers have not been identified. Despite these similarities, the surface of Venus is not broken up into large, relatively rigid plates, separated by narrow deformation zones, as is the Earth. Rather, Venus has broad deformation zones (hundreds of kilometers wide) surrounding smaller rigid blocks (also hundreds of kilometers wide), much more reminiscent of the broad deforming zones in some of Earth's continental regions (Sec. 5.2). Crater density suggests that the average age of plate-boundary–type features on Venus is 0.4 Ga, but no strong age variations are visible. Thus, ongoing lithospheric recycling due to plate-tectonic processes, such as that occurring in the Earth's ocean basins, seems unlikely. It is thought that the lithosphere of Venus is less rigid than that of the Earth, and differently coupled to the underlying convection system. The degree of modern activity of surface tectonic processes on Venus is not well constrained.

6. SUMMARY

The theory of plate tectonics, in which the surface of the Earth is thought to consist of different lithospheric plates in relative motion, works well for explaining many geophysical observations of the Earth. The Earth's outer rheological layer (~100–150 km thick), or lithosphere, behaves rigidly on time scales of 10^7–10^9 years, overlying a much less viscous layer (asthenosphere) that flows on these time scales. The lithosphere comprises both crust and upper-mantle material. It consists of plates whose interiors are rigid. The deformation at the Earth's surface, including earthquakes and volcanism, is concentrated at plate boundaries. The type and depth of earthquakes, and the composition of the volcanic rocks, varies with the type of plate boundary (convergent, divergent, or transcurrent).

The relative motion of these plates must follow Euler's theorem and therefore can be described in terms of rotations about axes through the center of the Earth. Where two plates diverge, the process of seafloor spreading accretes new oceanic plate material to their edges and the plate area increases. When two plates converge, one will sink below the other one, in the process of subduction. Surface area of the downgoing plate decreases and the subducted portion is resorbed into the underlying mantle. A third type of plate boundary (transform fault) is characterized by lateral slip, so that plate area is neither created nor destroyed. Present rates of relative plate motion range from 1 to 16 cm/y. Past relative plate positions are obtained by matching magnetic anomalies generated by seafloor spreading or by using paleomagnetic directions in rocks, and by assuming that hotspots (persistent sources of volcanism which generate linear volcanic traces on the Earth's surface) have sources in a relatively fixed reference frame to which plates can be reconstructed.

Oceanic and continental parts of plates have different properties because of their different processes of formation, crustal thicknesses, and viscosity structures. As oceanic plates cool with time, their strength and thickness increase. They can behave elastically, with effective elastic thicknesses of tens of kilometers, thinner than thicknesses determined by thermal considerations or by seismic wave propagation. Rebound of plates from applied loads involves elasticity of the plate and viscous flow of the underlying asthenosphere.

The lithosphere insulates the hotter convection system in the Earth's mantle. Plate motion is driven by buoyancy forces at plate edges and opposed by basal viscous drag. Upwellings of the convective system in the upper mantle (<670 km depth) coincide with divergent plate boundaries at shallow depths, and downwellings with convergent boundaries (subduction zones), but at greater depths the mantle convective system is not well correlated with plate motions. The source region of hotspots is thought to lie within the mantle or at the core–mantle boundary, well below the plates, distinct from the major convective upwellings and downwellings.

Plate-tectonic theory cannot account for many second-order features of deformations on the Earth's surface. Minor internal deformation of plates occurs in continental regions and in young and weak oceanic plates. Vertical motions may be controlled dynamically by convection in the mantle. Boundaries of continental plates may be broad zones of deformation due to the lower strength of continental crust. Nevertheless, the concept of plate tectonics successfully explains major first-order features of the Earth's surface deformation.

GLOSSARY

Asthenosphere: Part of the Earth's mantle, immediately below the plates, and of much lower viscosity than the lithosphere. This part of the mantle flows, undergoing plastic deformation on the time scale of plate motions.

Continental drift: Relative motion of continents on the Earth's surface, due to seafloor spreading.

Epeirogenic Movements: Broad, gradual uplift of one continental region relative to another (~200 m max).

Euler Pole: Latitude and longitude at which an angular velocity vector (Euler vector) projects through the Earth's surface.

Euler Vector: Angular velocity vector representing the relative motion of two plates on the surface of the Earth. The origin is at the center of the Earth.

Euler's Theorem: Any displacement of a sphere with a fixed center can be described as a rotation.

Fracture zone: Inactive trace of a transform fault; apparently offsets magnetic anomalies in the ocean basins.

Hotspot: Long-lived volcanic source, often not near a plate boundary, which produces an age-progressive line of volcanic centers and is thought to be caused by an upwelling "plume" of deeper mantle material.

Isostasy: Archimedes' principle applied to the lithosphere "floating" on weaker asthenosphere.

Lithosphere: Rigid outer layer of the Earth, comprising the different plates.

Marine Magnetic Anomaly: Difference between the observed and theoretical magnitude of the magnetic field measured over the oceans. These anomalies often occur in stripes parallel to the spreading ridges, corresponding to periods of alternately reversely magnetized and normally magnetized seafloor.

Seafloor Spreading: The process by which new igneous crust is accreted by volcanism at the mid-ocean ridges, while the plates on either side of the ridge move apart.

Spreading Center: Midocean ridge that lies along a plate boundary and has active volcanism and seafloor spreading occurring along it.

Strike-Slip Motion: Slip along a fault in which the relative motion of the blocks on either side is horizontal in the plane of the fault.

Subduction: Process by which an oceanic plate sinks beneath another plate into the mantle and the two plates can converge.

Transcurrent Motion: Strike-slip motion.

Transform Fault: An active strike-slip fault that forms the principal fault along a plate boundary.

Triple Junction: Position where three plates meet.

Volcanic Arc: Series of active volcanoes that form an arc in map view, and lie within the upper plate of a subduction zone.

Wadati–Benioff Zone: Inclined zone of earthquakes at a subduction zone, believed to lie within the subducting slab.

INTRODUCTION

In many technological applications of magnetic materials, it is advantageous to use them either as a film deposited on a substrate of some other material, or as a thin platelet that can readily be incorporated into a planar device structure. Such magnetic films and platelets are the subject of the present article.

The advantage of magnetic films over bulk magnetic material of the same chemical composition derives primarily from the need to integrate the magnetic devices with other electronic devices, which are typically based on semiconductor technology. A complete "monolithic" integration is very difficult to achieve, but various types of partial or "hybrid" integration have been used successfully.

Magnetic materials can broadly be classified into metallic and nonmetallic materials, the latter being predominantly oxides. Both of these classes can further be subdivided into magnetically "soft" materials and magnetically "hard" materials. The former are characterized by a relatively low coercivity,

i.e., they require only small magnetic fields to become magnetized or demagnetized, whereas the latter have a high coercivity and therefore resist magnetization and demagnetization. Table 1 summarizes the primary applications of the various materials as films and planar structures. It should be understood that the classification scheme described here may be ambiguous in some cases, since materials exist that may lie near the boundaries between the various classes.

Magnetically soft metallic materials are best suited for applications at low frequencies (<1 kHz), where losses due to eddy currents are relatively small. These losses can be further reduced by using multilayer laminates of the magnetic materials, with each layer being electrically insulated from the adjacent layers. Magnetically soft nonmetallic (oxide) materials are primarily used at higher frequencies, often as bulk material, since eddy-current losses are completely eliminated by the high electrical resistivity of these materials. The advantage of thin-film materials of this type lies in their suitability for devices that integrate magnetic and electronic (semiconductor) materials.

Magnetically hard materials, both metallic and nonmetallic, are used extensively in thin-film form as recording media for magnetic recording (Speliotis and Lynch, 1991). Memory devices such as "bubble" memories (Dong *et al.*, 1988), "plated-wire" memories (Luborsky *et al.*, 1974), "magnetoresistive" memories (Pohm *et al.*, 1988, 1989), and "Bloch-line" memories (Heidmann *et al.*, 1988) also use thin-film magnetic materials as essential elements. Microwave components that use high-coercivity ferrites and hence do not require a bias magnet have been demonstrated using bulk materials (Weiss *et al.*, 1989), and efforts are under way to develop similar "self-biased" microwave components using films instead of bulk material (Dorsey *et al.*, 1994).

A pervasive characteristic of nonmetallic magnetic materials is that they usually form as crystalline materials only at relatively high temperatures, typically 800 to 1200 °C. The exceptions to this rule are the oxide magnetite (Fe_3O_4) and related spinel ferrites ($Me_xFe_{3-x}O_4$, with Me a transition metal and $x < 1$), which can be formed at temperatures below 100 °C (Abe and Tamaura, 1984). Magnetite is also known to be formed as a result of biological processes (Blakemore, 1975; see also BIOMAGNETIC AND GEOMAGNETIC DETECTION BY ORGANISMS). Other spinel-type ferrites with more complex compositions are not readily crystallized at low temperatures and, as a result, do not (yet) have all the desired properties (such as low dielectric loss) that would make them attractive for high-frequency applications (Lubitz *et al.*, 1994). Thus, the deposition of ferrite films with acceptable microwave properties still requires a relatively high deposition temperature or annealing at a high temperature. This, unfortunately, presents a major obstacle for the use of certain semiconductor materials (such as GaAs) as substrates for the ferrite film deposition.

1. FABRICATION OF PLATES AND FILMS OF MAGNETIC MATERIALS

1.1 Metals and Semimetal Fabrication Techniques

According to their methods of fabrication, magnetic metals can be placed in one of three categories:

Table 1. Applications of magnetic materials as films and planar structures.

	Metallic	Nonmetallic
Magnetically "soft"	Transformer cores Inductors Electromagnets Electric motors Metal read/write heads for magnetic recording	Nonreciprocal microwave components Microwave filters Microwave phase shifters Magneto-optic devices Ferrite read/write heads for magnetic recording
Magnetically "hard"	Permanent magnets Recording media Memory devices	Permanent magnets Recording media Memory devices "Self-biased" microwave components

1. crystalline metal alloys such as Ni–Fe (Permalloy) and Si–Fe that are typically formed as sheets by standard metallurgical rolling or stamping processes (Cullity, 1972);
2. amorphous metal alloys produced by rapid cooling techniques (Grossinger and Turtelli, 1994); and
3. the permanent-magnet semimetallic compounds such as $SmCo_5$ and $Nd_2Fe_{14}B$, brittle, relatively undeformable materials that require powder processing, magnetic alignment, and sintering to make finished products (Durst and Kronmüller, 1987).

The techniques used to cast and shape sheets and plates of the Fe-based cubic metals have been well documented in the past (Bozorth, 1951; Jacobs, 1969; Parker, 1990) and are discussed only briefly here. The desired end product for high-permeability metals is a uniformly coarse-grained polycrystalline microstructure, free of defects such as pores or secondary phases that would impede the mobility of magnetic domain walls. When grain boundaries are free of secondary phases and stress, the crystallographic discontinuities from one grain to the next are not a significant impediment to domain-wall motion and permeabilities of 40 000 or more are achievable (Prutton, 1964).

The desirable characteristics of permanent-magnet materials are quite the reverse. Here the emphasis in fabrication is on a polycrystalline microstructure that will minimize rather than maximize domain-wall motion. This forces magnetic reversal to take place by a magnetization rotation process within individual grains, which requires greater energy than reversal by domain-wall motion. To achieve this goal, the crystallites must be well oriented and of a size small enough such that each grain can support only a single magnetic domain. This critical grain size is the order of a micron (Cullity, 1972) in the permanent-magnet compositions mentioned earlier.

An oriented fine-grain microstructure is accomplished by a combination of processing steps that produce magnetic alignment of micron-size particles by applying pulsed dc fields of several tesla to the powder during compaction. To keep the compacted mass of oriented particles from separating because of mutual repulsion after this alignment step, a reversal pulse is applied while the compact is within the die. The magnitude of the pulse is adjusted so as to reverse the moment in half the particles without changing the crystallographic orientation, thereby demagnetizing the part. The material is removed from the die and is then sintered to a dense form in an oxygen-free atmosphere. To minimize grain growth and simultaneously achieve a high density, the final firing is often carried out under pressure.

1.2 Formation of Metal Oxides in Planar Shapes

1.2.1 General Remarks The fabrication of magnetic metal oxides, the most important of which are compounds of iron oxide collectively known as ferrites, is very similar to the powder processing–sintering route that was described for permanent-magnet materials. One important difference in the processing of polycrystalline ferrites is the requirement for an oxidizing atmosphere, in contrast to the permanent-magnet alloys, which must be processed in an oxygen-free environment. The brittle nature of oxides again precludes the metallurgical processes of shaping from billets, requiring powder processing and the firing of bulk shapes, followed by abrasive machining and grinding.

Bulk methods are practical for the production of large pieces, but can be expensive and wasteful of material, when thin plates are needed. Alternatively, the ferrite powder can be formed and fired in shapes more closely matched to the final planar dimensions. Using circular steel dies, parts up to about 10 cm in diameter with thicknesses to about 3 mm can be formed in the green (unfired) state. For larger diameters and thinner parts, die forming becomes impractical, both from the viewpoint of handling unfired parts and because of problems with warping and cracking during firing. For ceramic shapes with larger ratios of lateral dimensions to thickness, it is more practical to employ the techniques of ceramic thick-film and thin-film processing. By convention, "thick" films are defined as being 10 μm or thicker in the plate-normal dimension, whereas thin films are limited to a few microns or less.

1.2.2 Thick-Film Techniques Of the thick-film processes, the most important is tape casting, a process developed primarily for multilayer capacitors (Tummala, 1989) and, more recently, multilayer ceramic packages (Schwartz, 1988). Ceramic plates as thin as 0.5 mm and hundreds of square centimeters in area can be produced by this technique. The tape-casting slurry is a suspension of micron-size powder in a viscous fluid mixture of solvents and organic additives such as dispersants and binders that will vaporize and disappear in the final firing. Casting is performed using a "doctor blade," which controls the thickness of the slurry film. The slurry must have sufficient viscosity to maintain its original shape during drying. The partially dried film, known as the "tape," is cut into the required planar shapes and fired, first at moderate temperature to remove volatiles and then at a higher temperature for sintering.

Tape casting is probably the most cost-effective method for producing planar ferrite materials in quantity because of the savings in grinding cost. The process is adaptable to making composite structures as well, by the alternate layering of tapes of differing composition or by punching holes in the tape and inserting plugs of differing composition before final firing.

1.2.3 Thin-Film Techniques The fabrication of magnetic materials in the form of thin films on dense substrates introduces a significant change from the method used for making free-standing metal sheets or bulk ceramics. Processes can no longer be optimized for the synthesis of a single material but must be tailored to a composite of two different compositions; a nonmagnetic substrate and a magnetic film. These two materials must coexist in intimate contact, withstanding temperature cycles and other process conditions without interfacial reactions or stresses that would cause failure or significantly degrade the magnetic properties. On the other hand, there are magnetic properties obtainable in thin films that are unachievable in bulk magnetic materials, as, for example, the uniaxial anisotropy in magnetic garnets that makes bubble memory films possible.

1.3 Deposition of Magnetic Films

The deposition of crystalline metal films from aqueous solution onto metallic or insulating substrates by electroplating is well known (Lowenheim, 1963). The Permalloy compositions have been plated from chloride and sulfate baths to thicknesses of 10–100 μm. Nickel plating forms very uniform dense deposits. The Fe-rich alloys are more difficult to plate, partly because of the tendency of the iron salts to oxidize unless strongly acidic conditions are maintained and partly because the Fe-rich compositions must be deposited at elevated temperatures. This accelerates both corrosion of the plating equipment and the oxidation of iron in solution.

Although Fe and Fe–Ni show useful characteristics for magnetic memory applications, the use of these conductors in rf devices is greatly limited by the eddy-current losses mentioned previously. As a result, there has been a concerted effort in recent years to develop techniques for depositing insulating magnetic films on appropriate substrates for high-frequency uses, particularly in the microwave range. The deposition techniques for ferrite films can, in general, be placed in one of three categories as shown in Table 2. The high-vacuum techniques such as evaporation and molecular-beam epitaxy (MBE) are generally characterized by a low deposition rate. Somewhat higher deposition rates are achieved using the lower-vacuum techniques of sputtering, pulsed laser deposition (PLD), jet vapor deposition (JVD), and metal-organic chemical vapor deposition (MOCVD). The largest rates are feasible using the atmospheric techniques of liquid-phase epitaxy (LPE), atmospheric plasma deposition (Wang *et al.*, 1992), spin-spray deposition (Abe and Tamaura, 1984; Williams *et al.*, 1994; Lubitz *et al.*, 1994), and the various plating techniques. Most of these methods are quite new, and so their relative strengths and weaknesses cannot yet be critically evaluated.

2. PROPERTIES OF MAGNETIC METAL FILMS

Many of the physical deposition techniques such as evaporation, sputtering, and pulsed laser deposition produce metal thin

Table 2. Methods of depositing magnetic thin films.

Class of methods	Individual methods	Typical deposition rate in nm/s
High-vacuum deposition	Evaporation	0.1–100 material dependent
	Molecular-beam epitaxy	0.1–0.5 material dependent
Low-vacuum deposition	Sputtering	0.1–2
	Ion-beam sputtering	0.1–1 material dependent
	Chemical vapor deposition	10–30
	Metal-organic CVD	0.1–1.5 precursor dependent
	Pulsed laser deposition	0.1–20 material/area dependent
	Jet-vapor deposition	50–150
Atmospheric-pressure deposition	Liquid-phase epitaxy	10–50
	Arc plasma spraying	100–2000
	Spin-spray deposition	0.2–30
	Ferrite plating	0.2–30
	Laser-enhanced ferrite plating	2350*
	Electroplating	5–20
	Electroless plating	1–5

*Result for an experimental technique, short deposition time.

films that are amorphous when formed at low substrate temperatures. Rather large internal stresses are typical in the as-deposited films, the magnitude and sign depending on the process used, the rate of deposition, and the relative density of the resultant film. This growth-induced stress is generally the dominant contributor to overall stress. Under extreme conditions, it may be large enough to cause visible distortions in the shape of the film–substrate composite or to produce physical separation at the interface. In other instances, the film may appear normal, but there may be substantial changes in stress-sensitive properties. These stress effects, when undesirable, can sometimes be reduced by thermal treatment, particularly when time and temperature are sufficient for recrystallization to occur.

The primary technique for following the recrystallization process and attendant relaxation of film stress is x-ray diffraction. As temperature is increased, either during deposition or during subsequent annealing, distinct diffraction peaks develop as indicators of the atomic rearrangement process taking place. If the films are dense as deposited, certain properties—for example, saturation magnetization—will remain unchanged with the transformation from the amorphous to crystalline state. Other properties, however, particularly those associated with magnetic loss, are significantly reduced as the recrystallization proceeds.

Another source of stress that occurs in single-crystal films grown on single-crystal substrates is that due to a mismatch in lattice spacing between film and substrate. The mismatch introduces an elastic strain, which can arise during growth or during the subsequent cooling to ambient temperature if there are differences in thermal expansion between film and substrate. Stresses due to thermal-expansion mismatch occur, of course, also in film–substrate pairs where there is no correlation in atomic dimensions between film and substrate. The thin-film geometry implies an intimate and continuous join between dissimilar materials. The linear thermal-expansion coefficient α of the ferrous metal films (α = 11–13 ppm K^{-1}) is larger than that of typical substrates such as Si (α = 4 ppm K^{-1}), GaAs (α = 7 ppm K^{-1}), or alumina (8.5 ppm K^{-1}). Any heat treatment that is intended to relieve stresses introduced during film deposition will necessarily introduce compressive stress in the film during heating. If the strain is relieved at the annealing temperature, the differences in thermal contraction during cooling will introduce strain of the opposite sign (tensile) in the metal film after cooling. Stresses produced in this way interact with the magnetization via the magnetostriction coefficients and can affect properties such as permeability and coercive field (H_c). Note that residual stresses could be annealed with no difficulty in free-standing magnetic materials because there is no substrate to introduce a thermal-expansion mismatch.

2.1 High-Permeability Thin Films

Crystalline thin films of the Ni–Fe and Si–Fe alloys can be made with very high permeabilities. Values approaching those obtainable for free-standing metal bodies are achievable if a uniform composition with grain boundaries free of pores and secondary phases can be produced. As with bulk alloys, the polycrystalline grain size and grain orientation do not materially affect permeability because domain-wall motion is unimpeded by grain boundaries or changes in crystallographic orientation. There is, however, a stress sensitivity in thin films that is more difficult to deal with than is true of free-standing magnetic metals. This arises from the different thermal-expansion characteristics of the film and substrate and the fact that the two, once joined, cannot be separated.

Metal films can be grown epitaxially on single-crystal substrates if there is a close match between lattice spacing of the metal and the periodicity of the substrate lattice in the chosen direction. The growth of pure Fe films epitaxially onto single-crystal GaAs substrates is an example of the type of integration that is possible between magnetic metal films and semiconductor circuits. This growth had first been demonstrated by molecular-beam epitaxy (Prinz and Krebs, 1981) and was repeated using ion-beam sputtering (Tustison *et al.*, 1987). Despite a difference of about 2% in lattice spacing between GaAs (100) and a doubled Fe unit cell, films up to a micron in thickness were grown epitaxially on GaAs. A broadened diffraction peak (Fig. 1) indicated the introduction of some strain.

Metal films lose their usefulness as high-permeability materials at high frequencies, on account of induced eddy currents. Thus, magnetic insulators, such as ferrites, are required when the frequency is sufficiently high. The highest frequency at which metals have useful magnetic properties depends on the film thickness (as well as other parameters), but is generally less than about 1 GHz.

2.2 Permanent-Magnet Film Properties

Thin films of permanent-magnet materials have significantly greater constraints on microstructure and grain orientation than the magnetically soft metals just discussed. As with bulk permanent magnets, the need is to eliminate domain-wall motion entirely because this is the mechanism by which the film can be demagnetized by fields that are significantly smaller than those predicted from intrinsic properties. If domain-wall motion is not allowed, the magnetization reversal must proceed by a magnetization rotation process at a magnetic field strength equal to the anisotropy field of the compound. In the RE–Co alloys, this is the order of several hundred thousand amperes per centimeter. The observed values of H_c are about 10% of this magnitude, suggesting that magnetization reversal by domain-wall motion is only partially controlled by microstructure.

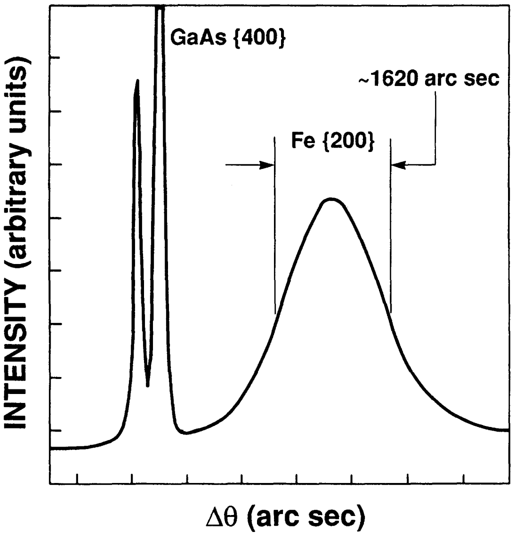

FIG. 1. X-ray diffraction rocking curve for an Fe film on GaAs in the (100) orientation. Film thickness is 570 nm.

In order to attain a high saturation induction $\mu_0 M_s$ (μ_0 = vacuum permeability, M_s = saturation magnetization), the magnetic film must be dense, single phase, and fully grain oriented. The RE–Co compositions have an intrinsic induction of 1.1 T. For the Nd–Fe–B alloy, $\mu_0 M_s = 1.3$ T. If $H_c > 0.5\ M_s$, the energy product, which is a measure of magnet performance, equals $0.25\mu_0 M_s^2$, giving values of 3.0 and 4.1 J cm^{-3}, respectively. Data obtained on sputtered films are somewhat below these maximum values, primarily because crystallite orientation is imperfect and M_s is reduced; the energy product values quoted in recent literature are 2.02 J cm^{-3} for $SmCo_5$ alloys (Cadieu *et al.*, 1990) and 1.16 J cm^{-3} for $Nd_2Fe_{14}B$ alloy (Cadieu *et al.*, 1986).

3. PROPERTIES OF INSULATING MAGNETIC FILMS

3.1 Dielectric Loss Properties

Dielectric loss, represented as the loss tangent $\tan\delta = \epsilon''/\epsilon'$, has no useful function in high-frequency devices and must be minimized to reduce the insertion loss. In polycrystalline ceramics, the spinel ferrites exhibit loss-tangent values in the range of 10^{-3} to 5×10^{-4} with higher losses generally arising from Fe^{+2} in the structure, either stabilized by impurities or introduced by processing. The magnetic garnets generally have smaller values of dielectric loss tangent, 2×10^{-4}, than the spinel ferrites because of a greater thermal stability of the phase and a more limited solubility of Fe^{+2} in garnets. Hexagonal ferrite compositions presently have dielectric losses equal to or somewhat higher than the spinel ferrites.

The dielectric loss in magnetic thin films has not been widely reported. It is inherently more difficult to measure loss properties accurately because of the low filling factor of films compared with the much larger dimensions of bulk ceramic test pieces. There is also a problem in separating the contribution from the substrate, which is considerably more massive than the film.

3.2 Magnetic Losses in Insulating Magnetic Films

An important measure of magnetic loss at microwave frequencies is the width ΔH of the ferromagnetic resonance (FMR) peak, when measured at constant frequency as a function of applied field. For single-crystal films of epitaxially grown yttrium iron garnet, ΔH is of the order of 1 A/cm. For polycrystalline films, ΔH is typically much larger, of the order of 100 A/cm or more, on account of a broadening resulting from the random orientation of crystallites in combination with crystalline anisotropy. This line-broadening effect can be significantly reduced in thin films if grain orientation can be introduced either by choice of single-crystal substrate or by control of the growth conditions, which can introduce a degree of grain orientation.

3.3 Other Properties of Insulating Magnetic Films

Certain intrinsic properties of the ferrite thin films, such as saturation magnetization (M_s) and dielectric constant (ϵ'), are essentially unchanged from their bulk-property values if the deposit is dense and compositionally uniform. The composition dependence of these properties can be obtained from standard handbooks on microwave ferrite materials (von Aulock, 1965; Wohlfarth, 1982, Vol. 2).

Other magnetic properties are dependent on thin-film microstructure and the degree of stress. Such properties are the FMR linewidth, discussed previously, and the hysteresis-loop properties of remanent magnetization (M_r) and, to a lesser extent, coercive field (H_c). In a perfectly grain-oriented, dense, and compositionally uniform thin film, the FMR linewidth would ideally be equal to the single-crystal value. In properly oriented material, M_r would be equal to M_s and would be independent of variations in average grain size. The coercive field, on the other hand, would vary inversely with the average grain size and would also be affected by the magnitude and sign of film stress through the magnetostriction coefficients. The hysteresis properties are of particular importance in microwave applications such as phase shifters and switchable circulators.

3.4 Properties of Single-Crystal Ferrite Films

One very successful film-growth technique has been the epitaxial growth of magnetic garnet films on single-crystal nonmagnetic garnet substrates, notably $Gd_3Ga_5O_{12}$ (gadolinium gallium garnet, GGG). Under growth conditions where there is a perfect lattice-parameter match between the growing film and substrate, as with YIG ($Y_3Fe_5O_{12}$) on GGG, the garnet film remains cubic with properties identical to bulk single-crystal values. However, where a controlled mismatch in lattice parameters would arise on cooling to ambient temperature, the film is placed under stress and a uniaxial anisotropy field develops from the stress working in conjunction with magnetostriction. Additionally, a lattice-parameter mismatch between film and substrate at the growth temperature can introduce cation site ordering, so called growth-induced uniaxial anisotropy, which adds to any stress-induced component. The result is a garnet thin film that has a noncubic characteristic of uniaxial magnetic anisotropy. The planar film strain forces the magnetic domains to lie in the film normal directions, thereby stabilizing magnetic bubble domains. The properties of these garnet films and the effects of induced anisotropy have been well documented by Winkler (1981).

Spinel ferrite films are more difficult to grow than the garnet ferrites. The film surfaces tend to show faceting and there is more flux inclusion. As a result, the magnetic properties of these films have not been well documented. Moreover, an ideal substrate material, such as GGG for garnet film growth, has not yet been found for the spinel ferrites. This has limited the ability of researchers to grow films of reasonable thickness and uniformity for property evaluation.

Hexagonal ferrite thin films have been grown by liquid-phase epitaxy (LPE) in sufficient size and quality on small single-crystal substrates of $ZnGa_2O_4$ to measure FMR linewidth. Values of ΔH as small as 24 A/cm (30 Oe) have been reported (Truedson *et al.*, 1993) along with x-ray diffraction data that confirm the M-type hexaferrite crystal structure. Ba-ferrite films grown by LPE onto basal-plane sapphire (0001) have too large a lattice mismatch for epitaxy but do show highly oriented (0001) polycrystalline deposits. Recent work (Dorsey *et al.*, 1994) on oriented Ba-ferrite film growth on sapphire by PLD (see Table 2) shows that deposition techniques other than LPE are also feasible.

4. DOMAINS AND DOMAIN WALLS IN MAGNETIC FILMS

4.1 Formation of Magnetic Domains

Magnetic thin films, as well as bulk magnetic materials, tend to become "demagnetized" when they are not exposed to a sufficiently strong magnetic field. In the demagnetized state, the saturation magnetization at any point within the material has the same value as in the fully magnetized state (at least to a good approximation), but the direction of the magnetization varies from place to place. The direction is substantially uniform over certain regions, known as "domains," and varies rapidly, but continuously, from any given domain to its neighbors. The borders between domains corresponding to different orientations of the saturation magnetization are known as "domain walls." The thickness of these walls is typically of the order of 0.1 μm, but varies from material to material depending upon parameters such as the anisotropy constant, the exchange constant, and the film thickness. Since the wall thickness is generally much smaller than the domain size, it is frequently appropriate to neglect the thickness altogether and consider the domain wall as a discontinuity of the local orientation of the magnetization vector.

The general principle that determines the domain pattern in demagnetized thin magnetic films and bulk magnetic materials is that all variable parameters of the pattern, such as wall positions and wall orientations, seek those values at which the total energy is a minimum. In the application of this principle to practical materials, the presence of local material imperfections must be taken into account. Since such detailed information is not usually available, it is rarely possible to predict the domain pattern with any accuracy.

An important consideration for thin films is the magnetostatic energy associated with any component of the magnetization vector that is normal to the film plane. This contribution to the total energy frequently dominates all other contributions, particularly for materials with a high saturation magnetization. Because of this magnetostatic energy, the magnetization of thin films tends to lie within the film plane, as shown in the typical domain patterns illustrated in Fig. 2. Here the top diagram corresponds to a material with a uniaxial anisotropy and an in-plane easy axis (Permalloy films are generally of this type). The local magnetization is aligned with this anisotropy axis. The orientation of the domain walls is also parallel to the anisotropy axis, because any other orientation would give rise to a discontinuity of the nor-

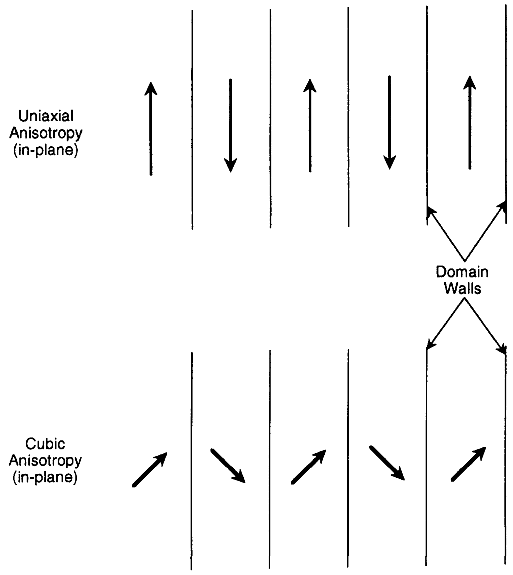

FIG. 2. Typical domain patterns in films having uniaxial (Permalloy) and cubic in-plane anisotropy (Fe on [100] GaAs). Arrows indicate the direction of magnetization.

mal component of the magnetization vector, i.e., to an effective magnetic charge density. Such a charge would raise the total energy. The bottom half of Fig. 2 corresponds to a material with cubic anisotropy, such as Fe on [100] GaAs. In this case, the anisotropy energy is a minimum for four directions of the magnetization, which differ from one another by 90°. In this case, the normal component of the magnetization is again continuous at the domain wall (as in the top illustration of Fig. 2), but the net magnetization in the horizontal direction does not vanish.

The width of the domains in the patterns illustrated in Fig. 2 is also determined by the principle of minimum energy, stated above. The domain width is dependent upon the width of the film in the vertical direction.

A very different domain pattern can be realized with magnetic films having a strong uniaxial anisotropy with an easy axis normal to the film plane. In this case, the local magnetization also tends to be perpendicular to the film plane. Typical domain patterns are illustrated in Fig. 3 for two values of the bias field, which is assumed to be applied along the vertical direction. For a relatively weak bias field, the stripe pattern at the top in Fig. 3 has minimum energy. The width of the domains with magnetization parallel to the bias field is larger than that of domains with the opposite orientation. For a stronger bias field, a pattern of "bubble domains" (as illustrated in the bottom half of Fig. 3) is stable. The bubble domains can be moved about in

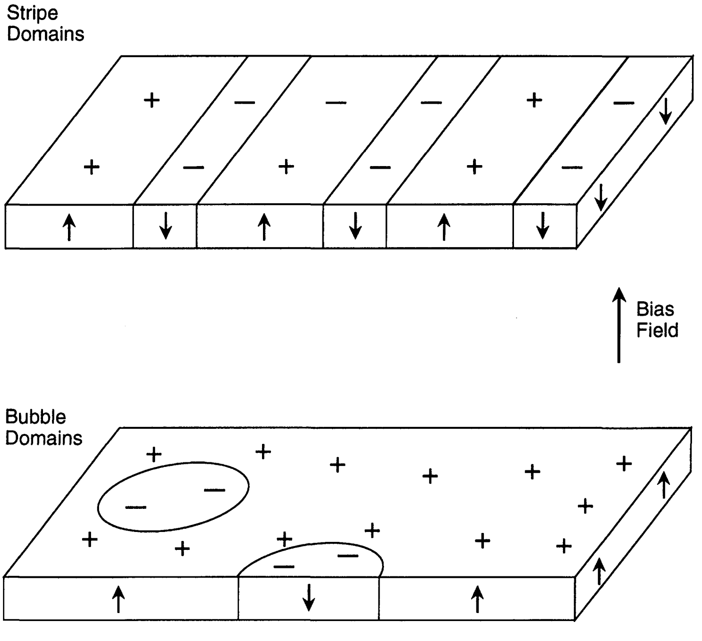

FIG. 3. Typical domain patterns in films having a strong uniaxial anisotropy with easy axis parallel to film normal. Plus and minus signs indicate the polarity of the effective magnetic surface charge.

the film and have been used as the basis of a memory technology.

4.2 Structure of Stationary Domain Walls

In the previous section, the domain wall was treated as a discontinuity in the orientation of magnetization. Consider now the internal structure of the wall itself. For films having an in-plane easy axis, the magnetizations on opposite sides of the wall point in opposite directions as shown in Fig. 4. The magnetization can be continuously taken from one orientation to the other by rotating it either out of the plane of the film (top of Fig. 4) or in the plane of the film (bottom of Fig. 4). These two types of walls are known as "Bloch" and "Néel" walls. Calculations have shown that the Bloch walls are energetically favored for relatively thick films, whereas the Néel walls are energetically favored for very thin films. For intermediate film thicknesses, a more complicated wall structure occurs, which consists of portions of Bloch and Néel walls connected by suitable transition regions known as "cross ties" and "Bloch lines."

For films with a strong uniaxial anisotropy and an easy axis normal to the film plane (the films suitable for bubble memories), the stationary wall structure is illustrated in Fig. 5. In a bulk material, the magnetization would simply be rotated in the plane of the wall as illustrated in the top diagram of Fig. 5. This "untwisted" wall may be used as an approximate model of the actual wall structure, but the model fails to take account of the magnetic surface charge present at the film surface on both sides of the domain wall. These surface charges create a magnetic field that twists the magnetization in the wall interior in the manner indicated in the lower half of Fig. 5. For further details, the reader is referred to the original literature (Slonczewski, 1973; Schloemann, 1973a,b).

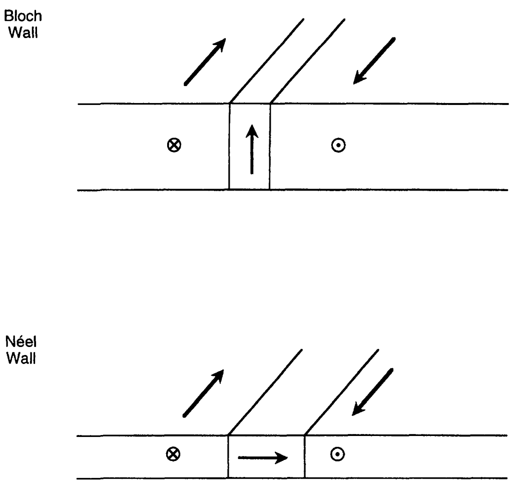

FIG. 4. Domain-wall types for films with an in-plane easy axis.

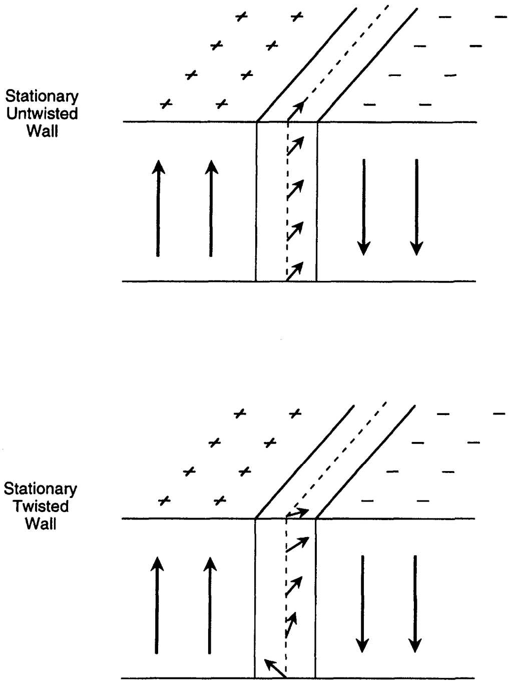

FIG. 5. Structure of untwisted and twisted stationary walls in bubble films. Arrow indicates the direction of the local magnetization vector. Also shown is the sign of the effective magnetic surface charge.

4.3 Structure of Moving Domain Walls

In all preceding discussions, it was assumed that the domain wall is stationary. Moving walls have a similar structure, except that the wall magnetization has a component orthogonal to the domain wall for Bloch walls and orthogonal to the film plane for Néel walls. This component of magnetization is generated by the driving field (applied parallel to the anisotropy axis). The orthogonal component of wall magnetization in turn gives rise to a demagnetizing field in the wall interior that rotates the wall magnetization into the direction of the driving field. For further details, the reader is referred to the original literature (Slonczewski, 1973; Schloemann, 1976).

4.4 Bloch Lines, Bloch Points

The domain-wall structures illustrated in Figs. 4 and 5 represent only one of two possible structures. The alternative structure, not shown in these figures, is the one in which the wall magnetization has the opposite polarity to that shown. It is therefore also possible to have a domain-wall structure in which both types of wall magnetization occur in different parts of the wall. The transition region is known as a "Bloch line." Its width is typically considerably smaller than the wall width. The principal types of Bloch lines are "horizontal" (parallel to the film plane) and "vertical" (orthogonal to the film plane).

Horizontal Bloch lines can be generated when plane domain walls in films suitable for bubble memories are forced to move at high velocity. Similarly, when bubble domains are forced to move at high velocity, a more complicated Bloch-line structure is generated, which consists in part of horizontal Bloch lines and in part of vertical Bloch lines. Bubble domains containing Bloch lines in their domain walls are generally referred to as "hard bubbles." Many different types of hard bubbles exist depending on the type and number of Bloch lines in their domain walls (O'Dell, 1974). Since the hard bubbles are harder to move along a well-defined track (such as used in bubble memories) than regular bubbles, their presence interferes significantly with the desired performance of bubble memories.

Vertical Bloch lines existing in a domain wall can in principle be used for information storage in much the same way as bubble domains, and would have the advantage of much greater storage density.

Bloch lines have a line magnetization analogous to the wall magnetization of the domain walls. Since the line magnetization can have either of two polarities, a composite Bloch line can be formed that consists of sections having opposite polarities. The quasidiscontinuous transition region between the two sections is known as a "Bloch point."

5. APPLICATIONS OF MAGNETIC FILMS AND PLANAR STRUCTURES

The technological applications of magnetic films and planar structures are primarily in the fields of magnetic storage and microwave technology. Since magnetic storage is described in detail in the article MAGNETIC STORAGE, it is covered only very briefly here, with most of the space devoted to microwave applications.

5.1 Magnetic Storage Applications

Data-storage techniques can generally be classified as providing either serial access or random access to the data. In the former case, one can further distinguish between techniques in which the recording medium moves relative to the read/write head and techniques in which the medium and the head are stationary and the stored data move around inside the medium on a well-defined track.

5.1.1 Magnetic Storage Techniques Providing Serial Access

5.1.1.1 Mobile Storage Medium. The storage medium moves relative to the read/write head. This category comprises magnetic recording, which is certainly the most important application of magnetic films. The substrates used for depositing the magnetic layers can be either rigid ("hard disks") or flexible ("floppy disks," tapes). The recording layer itself may consist of small particles of magnetic oxide (such as barium ferrite) in a magnetically inert matrix, or of a continuous layer of high-coercivity magnetic metal. The information is written into the medium by the application of a highly concentrated magnetic field, which may be either parallel or perpendicular to the recording layer. The information is read either inductively (a voltage is induced in a small coil by the motion of the stored bit of information through the sensitive region of the read head), magnetoresistively (the stored bit of information creates a magnetic field that causes a small change in the resistance of the read head), or magneto-optically (sensing the direction of the local magnetization by the Faraday or Kerr effect at optical frequencies).

5.1.1.2 Stationary Storage Medium. Storage medium and read/write head are stationary, stored data move inside medium. Magnetic storage technologies of this type are the "bubble memory" and the "vertical Bloch-line memory." In most (but not all) types of bubble memories, the bubbles propagate around a closed track defined by a thin, patterned layer of Permalloy on the surface of the bubble film. A rotating magnetic field is applied in the plane of the film. This field together with the patterned Permalloy layer creates a series of traveling energy minima for the bubbles on the track. The bubbles therefore propagate around the track in a controlled fashion and can be read magnetoresistively. Bubble memories received much attention in the 1960s and early 1970s, but have found few real applications because of competition from conventional magnetic recording and from semiconductor memories.

In vertical Bloch-line memories, a domain wall serves as a track for propagating vertical Bloch lines (see Sec. 5). At the present time, this type of memory is the subject of considerable academic study, but little practical development. Its advantage over bubble memories is the potential for considerably larger storage density (Konishi, 1983; Wu and Humphey, 1985; Asada *et al.*, 1993).

5.1.2 Magnetic Storage Techniques Providing Random Access The earliest magnetic storage technology providing random access was based on small ferrite toroids ("cores") that were threaded by multiple windings and arranged in a rectangular array. Interrogation occurs by simultaneously sending a current pulse through one vertical and one horizontal wire of this array. The magnetic field generated by a single wire is not large enough to reverse the magnetization in any of the ferrite cores. However, at the intersection of the horizontal and vertical current-carrying wires, the field is sufficient to reverse the magnetization. Thus, the state of the ferrite core at the intersection of the two wires can be set and also sensed by this technique.

A storage technology based on magnetic films and similar to the ferrite-core technology described above is the so-called "plated-wire memory." This technology uses thin CuBe wire (typically 100 or 50 μm in diameter), on which a thin layer of Permalloy ($Ni_{0.8}Fe_{0.2}$) is deposited by electroplating (Luborsky *et al.*, 1974). These wires are placed in a set of parallel grooves and combined with a set of conductive strips that are oriented at right angles to the plated wires. Operation of the plated-wire memory is similar to that of the ferrite-core memory described above. The storage density is, of course, considerably higher. Plated-wire memories were used, for instance, in the Lunar Lander vehicle of Project Apollo, but are now considered obsolete, because they cannot readily be integrated with the semiconductor devices needed for operation of the memory.

In order to provide the high degree of integration with semiconductor devices required for practical high-capacity random-access memories, several techniques are being explored that use magnetic films deposited on a semiconductor substrate. Part of the same substrate can then be used to house the required amplifiers and other devices. Magnetoresistive memories on a silicon substrate with Permalloy storage cells that have a storage density of up to 10^8 bit/cm^2 have been demonstrated (Pohm, 1988, 1989; Ranmuthu *et al.*, 1993). An alternative approach that utilizes films of single-crystal iron on a GaAs substrate has also been described (Schloemann *et al.*, 1988).

5.2 Microwave Applications

The microwave applications of magnetic films may generally be classified as applications involving linear devices, such as filters, delay lines, circulators, and isolators, or nonlinear devices, such as limiters and signal-to-noise enhancers.

5.2.1 Linear Devices

5.2.1.1 Filters and Delay Lines. The use of magnetic films in filters and delay lines generally involves the phenomenon of "ferromagnetic resonance": When a static magnetic field of strength H and an oscillatory field are applied to the material, it exhibits a resonant behavior at a frequency that is approximately given by

$$f_r = \gamma H.$$

Here $\gamma \simeq 2.8$ MHz/Oe $= 3.52$ MHz cm/A is approximately the same for all materials, and is known as the "gyromagnetic ratio." The equation is directly applicable only to spherical samples of the magnetic material and must be modified for film as further detailed below.

Microwave filters based on magnetic materials are generally tunable with the application of a magnetic field. Such filters, based on spherical resonators of YIG, have been used in many practical applications since the late 1950s. More recently, the trend has been toward filters based on magnetic films, because of the ease of fabrication and the greater compatibility with semiconductor components. These filters generally use films of YIG deposited by liquid-phase epitaxy on a substrate of GGG. The technique for growing such films was developed largely as a by-product of the very intensive effort to develop materials for bubble memories, which require similar materials.

For a detailed explanation of filters and delay lines based on magnetic films, the concept of magnetostatic waves (MSW) is important. MSWs are electromagnetic waves in ferromagnetic (or ferrimagnetic) materials, for which the phase velocity is very much smaller than the velocity of light in vacuum. The energy of such waves is almost entirely magnetic in origin. A small electric field is associated with these waves, but it can usually be neglected by way of approximation. The waves can be excited by a current-carrying strip stretched along the surface, and can be received by a similar transducer at a different location on the film surface, as shown schematically in Fig. 6. According to the orientation of the bias magnetic field relative to the film surface and relative to the transmission path, one can distinguish three different MSW propagation modes:

1. Magnetostatic forward volume waves (MSFVW): In this case, the bias field is orthogonal to the film plane.
2. Magnetostatic backward volume waves (MSBVW): In this case, the bias field is in the film plane and parallel to the propagation direction.
3. Magnetostatic surface waves (MSSW): In this case, the bias field is in the film plane and orthogonal to the propagation direction.

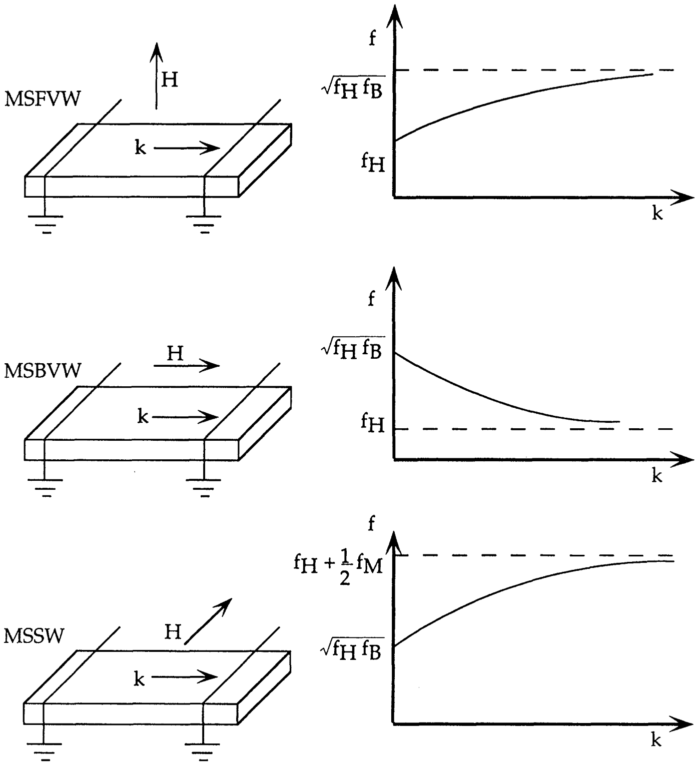

FIG. 6. Principal MSW propagation modes and dispersion diagrams.

A schematic device structure and the corresponding dispersion diagrams showing frequency (*f*) vs wave number (*k*) for these principal propagation modes are illustrated in Fig. 6. As the names suggest, the two types of volume waves exist with equal amplitude throughout the film thickness, whereas the surface-wave type has different amplitudes on the two sides and decays exponentially with distance from the side having the large amplitude. In addition to these principal modes, a large number of mixed modes may exist in which the bias field is oriented at some intermediate angle.

In Fig. 6, $f_H = \gamma H$, $f_B = \gamma(H + M_s)$, $f_M = \gamma M_s$, where γ is the gyromagnetic ratio, H is the internal magnetic field, and M_s is the saturation magnetization (corresponding to $4\pi M_s$ in the cgs system of units). For very thin films, the internal magnetic field equals the externally applied field H_{ext} when the field is in the film plane (cases **2** and **3**, above), and is equal to $H_{ext} - M_s$ when the field is orthogonal to the film plane (Case **1**).

MSWs are generally strongly dispersive, i.e., the phase velocity is a function of wave number or frequency. This feature can be exploited for the design of filters with desirable dispersion characteristics, such as used for pulse compression. The relatively high insertion loss of MSW devices is a significant disadvantage for such applications.

An alternative device structure for magnetic filters based on YIG films is illustrated in Fig. 7 (Ishikawa *et al.*, 1992). This filter uses two YIG films on GGG as separate chips. The two chips are in separate metal enclosures that are connected through a small hole by a copper wire. This device structure is quite similar to YIG filters based on sphere resonators, except that each YIG sphere is replaced by a YIG film. Without further refinement, such filters have a high level of spurious responses. Suppression of these spurious responses has been achieved by creating multiple metal rings on both surfaces of the YIG/GGG chips used in the filter. A design theory based on MSW propagation is used for optimizing the ring configuration with regard to the suppression of spurious responses.

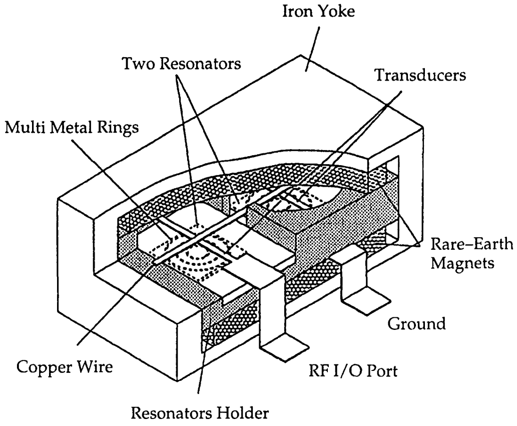

FIG. 7. Construction of the MSW filter (courtesy of Murata Manufacturing Company).

Another application of YIG films on GGG substrates is for filter banks that split an incoming broad-band signal into many narrow-band components at high dynamic range. This work has resulted in a 13-channel magnetostatic-wave filter bank that uses an array of narrow-band MSW delay lines that have a common microstrip input transducer and 13 separate output transducers (Adam *et al.*, 1988). The magnetic field bias is supplied by a permanent magnet with a linear field gradient.

YIG films have also been used to achieve useful tunable band-stop filter characteristics. Such "notch" filters are expected to be used in phased-array antennas as a means of suppressing unwanted signals that might otherwise interfere with the performance of the antenna. A notch filter has been demonstrated that is tunable from 8 to 10 GHz and shows a rejection notch of 40 dB in a bandwidth of over 20 MHz (Daniel and Adam, 1992). This performance is achieved in the $1 \times 1 \times 1\text{-cm}^3$ package illustrated in Fig. 8.

5.2.1.2 Nonreciprocal Devices. The major use of bulk ferrites at microwave frequencies is for nonreciprocal devices, such as circulators and isolators. A monolithic integration of such devices with semiconductor devices such as amplifiers, switches, and phase shifters would be highly advantageous from the point of view of avoiding expensive hand labor and increasing the reproducibility of subsystems, such as phased-array modules (Schloemann, 1988). The use of high-quality ferrite films on semiconductor substrates or on mutually compatible substrates may eventually lead to this kind of monolithic integration. For the nearer term, it appears likely that ferrite nonreciprocal devices will usually

be made as separate components, with a high degree of compatibility with semiconductor technology achieved by the selective use of magnetic films.

5.2.2 Nonlinear Devices For the linear devices discussed in the preceding section, a monochromatic input signal generates a monochromatic response. For nonlinear devices, on the other hand, the response to a monochromatic input signal involves components at frequencies other than the input frequency. These frequencies are usually either multiples of the input frequency ("harmonic generation") or such that the sum of two of the generated frequencies equals the input frequency. Especially important is the case in which the generated frequency equals half the input frequency ("subharmonic generation").

For the devices discussed in the preceding section, the response is, of course, "linear" only at sufficiently low power levels and will inevitably become nonlinear when the power level is raised. Thus, the devices themselves are not linear; they are merely designed to function in the linear regime. By contrast, the devices discussed in the present section are designed to function in the nonlinear regime.

The most important nonlinear microwave device involving magnetic materials is the "limiter." An ideal limiter would transmit a low-level monochromatic signal without attenuation and a high-level monochromatic signal with just enough attenuation to make the output power independent of input power beyond a certain threshold. Actual limiters based on magnetic materials only approximate this ideal behavior. They have a finite insertion loss at low power levels; and the attenuation at high power levels, although much higher than the low-power attenuation, is not enough to keep the output power constant. Another significant shortcoming of magnetic limiters is their transient response. At the start of a high-power pulse, the incident power is transmitted without substantial attenuation for a short time (of the order of 1 μs). Only after this initial "leakage spike" is the power transmitted through the limiter significantly reduced.

The operation of ferrite limiters relies on "parametric excitation" of certain modes of oscillation that can exist in the ferrite material. These modes, generally known as "spin waves," are analogous to elastic waves (lattice vibrations) in solids, except that the magnetic moment associated with each atom, its "spin," rather than the atom's position is varying with time. All magnetic materials can support a huge number of such magnetic oscillating modes, much the same as all solids can support a huge number of lattice vibrations. In the absence of any externally imposed oscillating magnetic field, all spin waves are excited to a small extent to a level corresponding to thermal equilibrium. When an oscillating magnetic field is applied to the ferrite, certain spin waves can be excited above their thermal level by either the "direct" or the "parametric" process. The direct process excites spin waves whose resonant frequency equals the frequency of the oscillating magnetic field, increasing the amplitude of these waves in proportion to the strength of the externally imposed oscillating magnetic field. The parametric process, on the other hand, excites primarily spin waves whose resonant frequency equals one-half the frequency of the oscillating magnetic field (although other frequency combinations can also occur). In this case, the excitation is characterized by a sharp threshold: Virtually nothing happens until the strength of the oscillating field reaches a critical value, at which the excitation level suddenly increases substantially.

Parametric excitation of spin waves can occur under many different experimental conditions. The high-power effects observed in ferromagnetic resonance (FMR) (Bloembergen and Damon, 1952; Bloembergen and

Wang, 1954; Damon, 1953) were explained (Suhl, 1956, 1957) as arising from parametric excitation of spin waves. In these experiments, and in Suhl's theory, a high-frequency magnetic field was applied perpendicular to a constant bias field, as required in FMR. This leads to a rather complicated theoretical analysis, which is not conducive to a simple physical explanation.

A much simpler analysis applies when the oscillating magnetic field is applied parallel to the dc bias field (Schloemann *et al.*, 1960; Schloemann, 1962). Parametric excitation of spin waves occurs under these conditions, known as "parallel pumping," at a threshold comparable to that realized for "perpendicular pumping" (except when the ferrite is biased close to resonance). The parallel-pumping configuration also lends itself to the operation of ferrite limiters, although one type of limiter can only be realized in the perpendicular-pumping configuration as discussed below.

For a simple physical explanation of spin-wave instability under parallel pumping, consider the precessional motion of the magnetization vector of a thin disk of ferrite that is magnetized in its plane by a dc bias field. The spin precession follows an elliptical rather than a circular path in this case, because a strong demagnetizing field is generated when the magnetization vector has a component perpendicular to the disk plane. The elliptical spin precession that occurs in a thin disk of ferrite magnetized by a dc field in its plane is shown as the solid line in Fig. 9.

Consider now the influence of an rf magnetic field $h(t)$ applied parallel to the dc field. We assume that the frequency ω of this "pump field" equals twice the precession frequency ω_0, and that the precession motion is established before the pump field is switched on. We shall then investigate how the pump field affects this motion. In this discussion, the phase relation between the pump field and the precession motion will be important.

Consider the case in which the phase relation is such that the pump field adds to the dc field when the magnetization vector is at points 1 and 3 of the precession cycle and subtracts from the dc field at points 2 and 4 as indicated in Fig. 9. The resultant contributions $\delta(dM/dt)$ to the rate of change of the magnetization vector arising from the pump field are proportional to the vector product of the pump field and the magnetization vector. In Fig. 9, $\delta(dM/dt)$ is indicated by arrows for each of the four points under consideration. It should be noticed that in every case the arrow points toward the exterior of the precession ellipse. This implies that the pump field tends to increase the precession angle if the assumed phase relation is in fact realized.

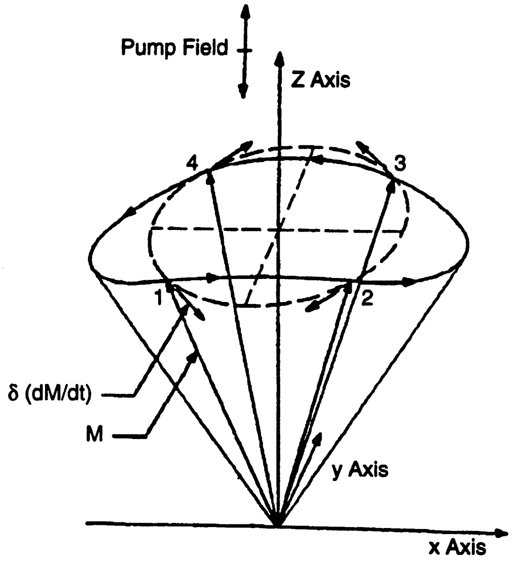

FIG. 9. Physical explanation of spin-wave instability in an rf magnetic field applied parallel to the dc field.

If the phase of the pump field is reversed, a picture very similar to Fig. 9 applies. In this case, all arrows point toward the interior of the precession ellipse, indicating that the pump field tends to decrease the precession angle if this phase relation is realized.

Consider now the case in which the pump field tends to increase the precession angle. In actuality, this tendency is at least partially compensated by relaxation processes, which always tend to decrease the precession angle. Instability occurs when the pump field is sufficiently large to overcome the relaxation processes.

In the above discussion, it was assumed that the ferrite sample has the shape of a thin disk. Actually, the results apply to samples of any shape, because spin waves that propagate through bulk ferrite at right angles to the dc bias field have the same behavior as the uniform precessional mode of a thin disk.

The spin-wave instability threshold h_{crit} calculated from the theoretical analysis of parallel pumping is given by

$$h_{\text{crit}} = \Delta H_k f_p / f_M.$$

Here f_p is the pump frequency, f_M is the magnetization frequency ($\approx$5 GHz for YIG), and ΔH_k is the so-called spin-wave linewidth, a parameter proportional to the relaxation rate of the spin waves. Further details on this subject may be found in the original literature (Schloemann, 1962; Rezende and de Aguiar, 1990).

The parametric excitation process just described has two significant features that are important in its application to microwave limiters:

1. It is effective only for high-amplitude signals. Low-amplitude signals are transmitted without significant loss.
2. It is "frequency selective" in the sense that a high-power signal at any frequency f_1 makes the ferrite lossy only in the vicinity of this frequency. A weak signal at some other frequency f_2 can still be transmitted without significant loss as long as the difference between f_1 and f_2 is substantially larger than the linewidth Δf of the resonant modes.

Ferrite limiters that have been described in the literature can broadly be classified as waveguide limiters, sphere resonator limiters, or microstrip limiters.

Waveguide limiters typically consist of a rectangular waveguide in which part of the cross section is occupied by a suitable ferrite. A dc magnetic field is applied that biases the ferrite into the so-called "subsidiary absorption" region. These devices have frequency-selective limiter characteristics over a broad frequency band. While a strong signal at some frequency f_1 is strongly attenuated, a weak signal at some other frequency f_2 (not too close to f_1) can be transmitted substantially without loss. The limiting threshold of waveguide limiters is relatively high.

Sphere resonator limiters have the same basic structure as sphere resonator filters (YIG filters). These devices have much lower limiting thresholds than the waveguide limiters, but the performance is restricted to a relatively narrow frequency band (which can be tuned if desired).

Microstrip limiters consist of a microstrip line on a thin ferrite substrate, which is exposed to a dc bias field. Stripline versions of the same type of device have also been described in the literature. These devices have the same kind of broad-band performance characteristics as waveguide limiters. The limiting threshold depends sensitively upon the substrate thickness, as well as on other parameters such as the spin-wave linewidth (Adam and Stitzer, 1993).

Although magnetic limiters can be based on polycrystalline bulk ferrites, the use of single crystals has significant advantages, because the threshold power level is generally much lower for single crystals. Since large single crystals of YIG grown by conventional bulk growth techniques are quite expensive, the use of YIG films grown by liquid-phase epitaxy on GGG is very attractive. Recent progress is exemplified by a microwave limiter using a 100-μm-thick film of YIG originally grown on GGG (Adam and Stitzer, 1993). For optimal performance, the GGG substrate was ground away, and the YIG film was used as a free-standing plate, with a conductive ground plane on one side and a microstrip transmission line on the other. The limiting threshold was about 1 mW in this case for frequencies between 2.5 and 5.3 GHz.

GLOSSARY

Atmospheric Plasma Spraying: A method in which particular material is drawn into a plasma discharge that provides the thermal energy to melt and/or vaporize the entrained particles.

Bloch Line: Boundary line between two parts of a Bloch wall in which the wall magnetizations have opposite directions.

Bloch Wall: Domain-wall type. The wall magnetization is parallel to the plane of the wall.

Delay Line: Device that delays a signal by a certain amount of time.

Doctor Blade: Device used for making slurry layers of constant thickness for use in tape casting.

Domain, Magnetic: Region inside a magnetic material in which the magnetization vector has a uniform orientation.

Domain Wall: Boundary between adjacent domains.

FMR: Ferromagnetic resonance.

Jet Vapor Deposition (JVD): A low-vacuum deposition technique in which evaporated metals from a heated wire are entrained in a high-velocity, low-pressure gas stream and rapidly deposited on a substrate. Oxygen gas can be introduced in the carrier gas to yield metal oxides (ferrites) as required.

Liquid-Phase Epitaxy (LPE): A high-temperature atmospheric-pressure film-growth process in which the desired phase is dissolved in a high-temperature solvent and is grown epitaxially onto a (usually) nonmagnetic substrate of closely matched crystallography.

Magnetostatic Approximation: Simplified approach to electromagnetic theory in which the effects of sources of the magnetic field are treated as if they were static.

Magnetostatic Wave (MSW): A type of electromagnetic wave that is predominantly magnetic in character. Its wavelength is much smaller than that of "light" of the same frequency.

Metal-Organic Chemical Vapor Deposition (MOCVD): A thin-film deposition process in which metal-organic compounds are separately vaporized and drawn into a carrier gas that impinges on a heated substrate, where decomposition and final compound formation occur.

Microstructure: The arrangement of crystalline and amorphous phases in a solid. Includes considerations such as crystallite size, size range, random or nonrandom orientation, and the presence of secondary phases and/or pores.

Nonreciprocal Microwave Device: Microwave device that has different propagation characteristics for opposite directions of wave propagation.

Parametric Excitation: Nonlinear excitation process in which the sum of the resonant frequencies of two or more fundamental modes of excitation equals the frequency of the exciting field.

Phase: A homogeneous solid that is distinguishable by optical microscopy, x-ray diffraction, or other techniques as an identifiable part of the microstructure.

Pulsed Laser Deposition (PLD): A film-deposition process in which a laser beam ablates material of the desired film composition from a target. A gaseous/particulate plume of this material is transported to the substrate, where deposition and growth take place.

Spin-Spray Deposition: A low-temperature, atmospheric-pressure technique in which aqueous solutions of soluble salts and precipitation-inducing agents are sprayed onto a substrate and rapidly evaporated by heat sources. The precipitation/growth process can be accelerated and localized by secondary sources, such as laser beams.

Spin Wave: Magnetic wave propagating in a ferromagnetic, ferrimagnetic, or antiferromagnetic medium; an elementary excitation analogous to a lattice vibration in a crystal lattice.

Tape Casting: Method used for making relatively thin plates of ceramic materials.

Wall Magnetization: Magnetization associated with a domain wall.

INTRODUCTION

The perfect crystal is a conceptual framework that can be closely approximated under careful preparation conditions. Simply stated, a perfect crystal is a periodically repeated array of identical building blocks such as atoms or arrays of atoms. For example, a perfect sodium chloride (NaCl) crystal can be thought of as an infinite array of cubes in which alternating corners are Na^+ and Cl^- ions.

Perfect crystals are both less interesting and much less important technologically than crystals that contain imperfections, or defects. Defects in crystals are responsible for many of their most important properties,

such as the tunable electrical behavior of semiconductors and plastic deformation and fracture of materials. Defects are thus the basis for much of modern technology. This article discusses various types of defects, dividing the material along a few main lines. Point defects have rather simple structures and by themselves have relatively little impact on mechanical properties. Their electronic and optical properties, on the other hand, are very important both scientifically and technologically and have been widely studied; hence these properties are emphasized in this article.

The additional complexity of extended defects makes their structural properties considerably more varied than is the case for point defects. Furthermore, extended defects play a key role in determining the mechanical properties of solids, and hence these aspects are emphasized in this article. Finally, a synthetic view is taken that points out the crucial role played by interactions between these various types of defects.

1. POINT DEFECTS

1.1 Definition

The point defect is the simplest class of crystal defects by virtue of its reduced dimensionality. Point defects are of the order of atomic size, in contrast, for example, to an interface between two chemically distinct materials, which is of macroscopic size and two dimensional. Implied in the definition of point defect is the notion that these defects occur at sufficiently low concentration that they do not interact with each other. In other words, their effects on crystal properties are simply additive. The defect concentration must be small for this condition to be satisfied. For example, if the point-defect concentration is 1 in 10^6, the average separation is 100 atomic spacings. With a random arrangement, many will be closer, but the fraction that interact is expected to be small. However, if the concentration is much larger, interaction effects may become important.

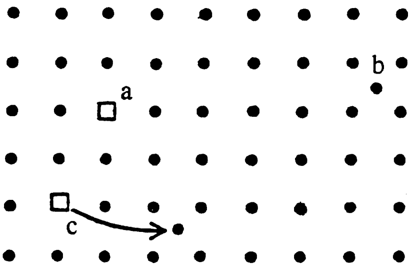
Even with this very dilute concentration it turns out that major optical and electrical properties can be profoundly affected by the presence of point defects. These properties may be desirable or undesirable. Hence, one may deliberately foster the presence of particular point defects, or, conversely, pains may be taken to eliminate others.

1.2 Types of Point Defects

The most common point defects in chemically pure crystals are vacancies and interstitials. A vacancy is the absence of an atom or ion from its perfect-crystal site, while an interstitial is an atom or ion at a position other than a perfect-crystal site. Vacancies and interstitials may occur in pairs, if an atom is removed from its normal site and placed elsewhere within the crystal, or individually, as for example if an atom is removed from its normal site and leaves the crystal. A vacancy-interstitial pair is called a Frenkel defect, while an isolated vacancy is called a Schottky defect. Figure 1 illustrates these defects schematically.

Another class of point defect is the chemical impurity—an atom, ion, or (small) molecule that is chemically different from the perfect-crystal constituents. A chemical impurity may replace a perfect-crystal atom, in which case it is called substitutional, or it may occur at an interstitial site.

The antisite defect can occur in a crystal that contains more than one type of chemical constituent. Consider, for example, the case in which the perfect crystal consists of a regular array of atoms of types A and B. If instead an A atom is on a B site, or vice versa, an antisite defect is said to exist. A



Key:
a = vacancy (Schottky defect)
b = simple interstitial
c = vacancy-interstitial pair (Frenkel defect)

FIG. 1. Schematic illustration of simple defects.

specific example is an arsenic atom on a gallium site in gallium arsenide (GaAs).

These descriptions of point defects barely hint at what in fact is a wide range of structures and properties. Some of these will be treated as examples, but it should be pointed out here that in general the atoms and ions that make up crystals are not inert "billiard balls" but rather are chemically reactive species. Consequently, when an atom is removed, those atoms in the vicinity of the vacancy experience chemical and physical forces that can lead to large, possibly symmetry-lowering relaxations. And when an interstitial is formed, that atom or ion may interact chemically with its neighbors in a way that leads to relaxations and rather different local chemistry. Finally, small molecules may form substitutional or interstitial defects, and their properties can reflect the extra degrees of freedom that they possess. Thus, a CN^- or an OH^- may replace a Cl^- in KCl, for example.

A type of defect that is intermediate between point and extended defects is the cluster or nanocrystal. A number of examples exist. In alkali halide crystals such as KCl, a small cluster of alkali atoms may form into a metallic colloid. The silver halide photographic process involves small metallic silver clusters formed upon exposure to light. Other articles in the Encyclopedia address such topics; for example, see NANOPHASE MATERIALS.

1.3 Origins of Point Defects

1.3.1 Thermodynamics One feature that distinguishes point defects from typical extended defects is that they can exist purely as a consequence of thermal equilibrium. We imagine a particular perfect-crystal structure to represent the lowest-energy arrangement of a large number of atoms or ions at a temperature of 0 K. Any other arrangement, such as a Schottky or a Frenkel defect, will require the addition of energy to the system. If the system is in thermal equilibrium at a finite temperature, a fraction of such defects will exist as determined by Boltzmann statistics:

$$N_D = BN\exp(-AE/kT). \qquad (1)$$

Here N_D is the number of defects, N is the number of atomic sites, A and B are factors of order 1, E is the energy required to create the defect, k is Boltzmann's constant, and T is the Kelvin temperature. Since chemical energies are often of order 1 eV, and since at room temperature kT is about 0.025 eV, the atomic fraction of defects at room temperature may be of order 10^{-18}, a number much lower than can be detected. But if the creation energy is only 0.4 eV, the fraction can be of order 10^{-7}, clearly large enough to have noticeable effects. Figure 2 shows data on the number of vacancies in sodium as a function of temperature, which follows Eq. (1) very closely.

Thermodynamics can play other roles. A given defect may have more than one possible structure. In thermal equilibrium, thermodynamics will determine the fraction of defects in each structure. Also, crystal processing may involve high-temperature operations. If cooling occurs faster than thermal equilibrium can be established, defects can be "frozen in" at concentrations appropriate to the higher temperature, and this higher

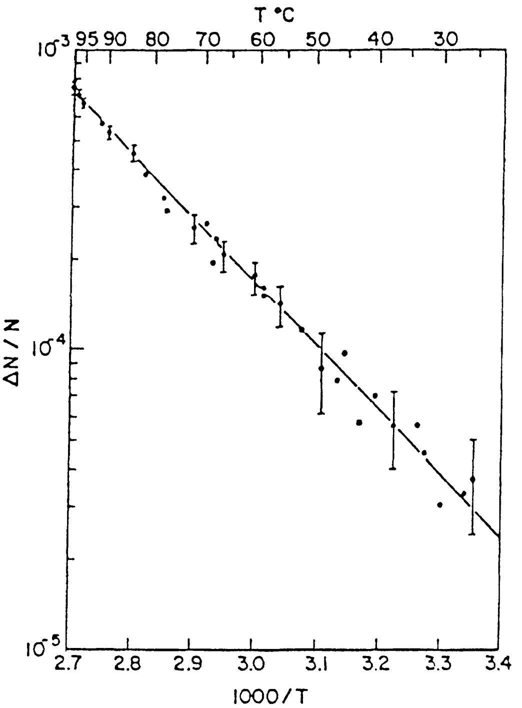


FIG. 2. Fractional number of sodium vacancies in sodium vs temperature. The solid line is a fit by Eq. (1). After Feder and Charbnau (1966).

nonequilibrium concentration can then persist at lower temperatures.

1.3.2 Irradiation Point defects may be introduced by irradiation. The mechanisms and details of various processes will depend on the nature of the crystal. It is easy to see how heavy particles (such as neutrons) of sufficient energy can displace atoms in the crystal by momentum- and energy-conserving "billiard-ball" collisions. For lighter particles such as electrons or gamma rays, the requirements of both energy and momentum conservation require very high energies for the lighter particle; there is a threshold for collision processes such that, for example, electron energies must typically be hundreds of electron volts to induce collisional damage.

In some crystals, irradiation can introduce point defects by simply ionizing atoms or ions, in which case the energy required is just the band gap, of order several electron volts. In such cases, the defect creation occurs via a chemical reaction between the ionized atom, or the atom in an excited state, and other atoms in its vicinity.

1.3.3 Growth Chemical impurities may be introduced into a crystal during the growth process. This is called doping. In the simplest case, one begins with a chemically pure constituent, melts it, and adds a definite amount of the desired impurity to the melt. Then, by one of a variety of growth processes, one cools the melt and ends up with a crystal that contains the impurity, suitably dispersed throughout and in the proper location and chemical state.

1.3.4 Implantation Growth is not always a suitable way to introduce desired impurities. For example, some systems are chemically immiscible, and the impurity segregates from the crystal as the melt is cooled. In other cases, the impurities do not form the desired type of defect during the cooling process. One way to avoid such problems is by ion implantation. Ion implantation (*q.v.*) involves firing a beam of impurities into a crystalline sample under controlled conditions. When this process works as desired, the result is a dispersed set of impurity defects of the proper type. Implantation works best with thin samples, such as those used in planar microelectronics technology. An undesirable side effect is often the creation of defects due to collisions of the implanting ions with atoms in the host crystal. Often most of these undesired defects can be removed by annealing.

1.3.5 Molecular-Beam Epitaxy (MBE) Molecular-beam epitaxy (*q.v.*) (MBE) is a technique that is widely used to grow planar crystals with desired chemical and physical characteristics. In its simplest form, it involves depositing atoms from molecular beams, layer by layer, onto a substrate, thereby forming thin films. This is a very powerful technique that is used to form precisely engineered layered compounds. We mention it here only to point out that chemical impurities can be introduced as part of the process, and so doping can be achieved.

1.4 Effects of Point Defects in Metals

1.4.1 Electrical Effects In most cases, point defects contribute to the electrical resistivity of metals. A perfect metallic crystal such as copper at low temperatures has a high conductivity because the conduction electrons move as Bloch waves, plane waves modulated by functions that have the periodicity of the lattice, without scattering through large regions of the crystal. Point defects break the symmetry and serve as scattering centers for the Bloch waves. This scattering tends to be rather weak, however, because of the screening of the impurity potential by the rest of the conduction electrons. Considering a zinc impurity substituting for a copper atom in copper, for example, there is an extra positive charge on the zinc and therefore the possibility of Coulomb scattering. The conduction electrons, which are free to respond to the Coulomb field, act to screen it and consequently the scattering potential is relatively weak.

1.4.2 Magnetic Effects The magnetic effects of defects depend on the magnetic characteristics of both the host material and the defect. This leads to a wide variety of effects in metals, some of which are very complicated. We mention only one situation here, a magnetic impurity in a nonmagnetic host. A magnetic impurity could be an atom or ion with a partially filled *d* shell, such as vanadium, while a nonmagnetic host could be copper. The interaction between the impurity electrons and the conduction electrons of the host leads to broadening of the defect levels and may render the system nonmagnetic, as in the case of vanadium in aluminum. Further discussion of magnetic defects is beyond the scope of this article.

1.4.3 Diffusion Atomic diffusion is a general property of defects in solids (see SOLIDS, DIFFUSION IN), but it is particularly important in metals where the diffusion of point defects to extended defects can have important effects on the mechanical properties of the system. Many detailed mechanisms of defect diffusion exist, depending on the defect, the host, and other conditions such as temperature and external fields. All share the feature that motion of a defect occurs over a macroscopic distance as the result of a series of individual microscopic motions, which are statistical in nature.

A simple model will suffice to present ideas of diffusion. Consider an impurity A at an interstitial site. The number of equivalent sites will be approximately equal to the number of host atoms, i.e., it will be a very large number. There will be a small number of equivalent nearest-neighbor sites. For A to move to one of these nearest-neighbor sites will require a thermal event, motion over a potential barrier. We assume that the temperature T is high enough that such motions can occur reasonably rapidly. If there is just one A defect and no additional fields the net motion of A will be a "random walk", its net displacement will be hindered by its tendency to jump back, or sideways, in addition to away from the initial site, and it will not tend to move in any particular direction. Its net displacement will vary as the square root of time. If, however, there is an external field that exerts a net force in one direction, then the probability of jumps in that direction will be greater than the probability of jumps in the reverse direction, and so there will be a net motion of A in the direction of the net force.

An additional feature of diffusion is that it can take place in the absence of external fields if there is a concentration gradient of impurity atoms A. Atoms will tend to hop from regions of high concentration to regions of lower concentration, since in a direction of higher concentration the neighboring interstitial sites are likely to already be occupied. This effect is described by Fick's first law:

$$J = -D\frac{\partial C(x)}{\partial x}. \qquad (2)$$

Here J is the particle flux, the number of particles passing through a unit area per unit time, C is the concentration, and D is the diffusion coefficient. The diffusion coefficient D contains all the material properties, and it is also a function of temperature. In fact, since the diffusion process involves thermal motion over a barrier, the diffusion coefficient often has a variation with temperature whose form is similar to that of Eq. (1):

$$D = D_0\exp(-\Delta E/kT). \qquad (3)$$

Here, ΔE is a measure of the height of the potential barrier and k is Boltzmann's constant. Figure 3 shows experimental data for the diffusion coefficient of carbon in iron as a function of temperature, which fits Eq. (3) very closely.

1.5 Effects of Point Defects in Semiconductors

1.5.1 Shallow Donors and Acceptors Semiconductors are important in technology because of the existence of impurity atoms

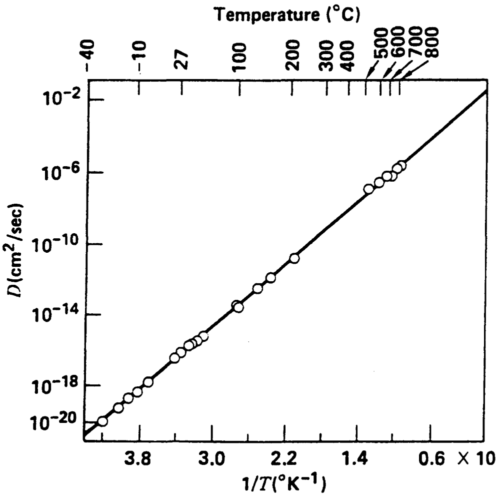

FIG. 3. Temperature dependence of the diffusion coefficient D of carbon in iron. The solid line is a fit by Eq. (3). After Borg and Dienes (1988).

that serve as so-called shallow donors or acceptors and provide electrical carriers. An example of a shallow donor is substitutional phosphorus in silicon. Phosphorus is a group V element, one column to the right of silicon, which is group IV. Silicon has four valence electrons, and in the diamond lattice these form tetrahedral hybrid orbitals and make strong covalent bonds with four silicon neighbors that lie in tetrahedral positions. Phosphorus has five valence electrons. Four of these form tetrahedral hybrid covalent bonds with neighboring silicons. The fifth electron, redundant for bonding and attracted by the positive charge of the phosphorus core, goes into a modified hydrogen-like state that is weakly bound to the core. This state is characterized by an effective mass, associated with the silicon conduction band, and a large dielectric constant, also a silicon characteristic. The electron is bound by 0.044 eV with respect to ionization into the conduction band, a small enough number that by Eq. (1) a substantial fraction of the phosphorus atoms will be ionized, donating their weakly bound electron to the conduction band at room temperature. The number of conduction electrons will be proportional to the number of donor impurities; hence the electrical properties of the system may be customized. Figure 4 shows schematically the energies of several types of semiconductor defects.

A similar argument leads to an understanding of shallow acceptors. A group III impurity such as aluminum has one fewer valence electron than does silicon. It then accepts one of the electrons from the filled valence band, becoming negatively charged. The empty valence state, or "hole," is positively charged and is attracted to the aluminum core. Again, a shallow effective-mass state is formed and the hole is bound, this time to the valence band, by 0.057 eV. At room temperature a large fraction of ionized holes will be present; these conduct electricity much as excess electrons in the conduction band do, so that again the electrical properties may be customized.

A semiconductor with an excess of donors is called "n-type"; one with an excess of acceptors is called "p-type."

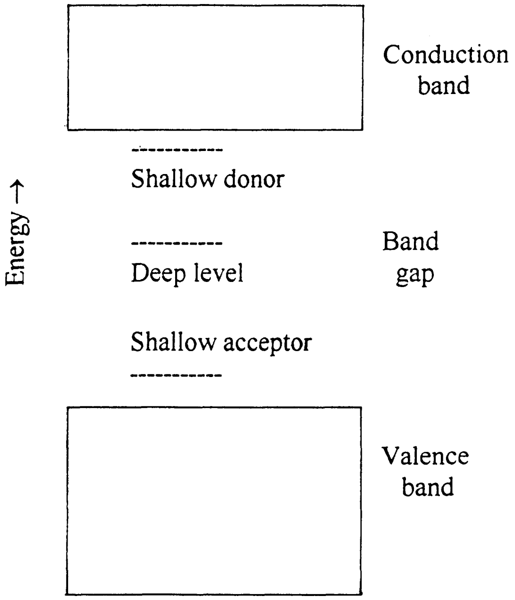

FIG. 4. Schematic illustration of the energies of several types of semiconductor defects.

The formation of shallow effective-mass states, while logical, is by no means guaranteed. It depends on the small effective masses and large dielectric constants that are characteristic of semiconductors. In the insulating crystal silicon dioxide in the alpha quartz structure, silicon also has four neighbors (which happen to be oxygens) in a nearly tetrahedral arrangement. But in this case, when phosphorus or aluminum substitutes for silicon, the resulting defect level is "deep," far away in energy from the conduction or valence band edges, and the defect electron or hole is localized near the impurity. Thus, in silicon dioxide the impurities do not readily provide charge carriers, as they do in silicon.

1.5.2 Deep Defects Deep-level defects also exist in semiconductors. Such defects are generally characterized by wave functions that are localized near the defect, and by energy levels that are not close enough to the conduction or valence band to be thermally ionized in large numbers at room temperature. Deep defects typically have another interesting characteristic, namely, the ability to occur in several charge states. Deep defects exist in great variety, and we mention for illustration here only two: the vacancy in silicon and the anion antisite in gallium arsenide.

The silicon vacancy features "dangling

bonds," hybrid orbitals from four neighbors pointing toward the vacancy. In the case of the neutral vacancy, these neighboring silicons relax toward each other, pairwise, to form extended Si-Si bonds. As electrons or holes are trapped at the vacancy, further symmetry-lowering atomic displacements occur, explainable in large part by a molecular-orbital picture of the defect. Five charge states of the vacancy, ranging from -2 to $+2$, are found to exist within the band gap of silicon. One of the most interesting characteristics of the silicon vacancy is a "negative-U" ordering that means, in effect, that two vacancies in the $+1$ charge state are unstable with respect to one vacancy in the neutral and the other one in the $+2$ charge state. Here U is an "effective" Coulomb interaction between electrons or holes; it can, in principle, be negative (attractive) if the actual repulsive Coulomb interaction is weak and if sufficient energy can be gained by atomic relaxations in particular charge states to offset the weak Coulomb interaction.

Arsenic on a gallium site, labeled $\mathrm{As_{Ga}}$, is of particular interest because of its likely connection to a defect called EL2 in gallium arsenide. EL2 is a deep defect that is desirable in certain cases; as a charge trap it makes gallium arsenide semi-insulating, an important feature for device substrates. EL2 is, however, metastable; its stable configuration is a deep donor, and optical excitation converts EL2 into an alternative metastable atomic configuration, from which there is a 0.3-eV activation energy to return to the stable configuration. EL2 has been extensively studied, and the most likely model is an isolated $\mathrm{As_{Ga}}$, whose metastable state consists of an adjacent As interstitial–Ga vacancy pair.

1.5.3 Hydrogen Passivation

Hydrogen is a common impurity in solids. Its chemical activity makes hydrogen of particular importance in semiconductors, where its presence can drastically change the nature of both shallow and deep defects. For example, an isolated dangling-bond defect, which otherwise might trap electrons or holes, can be passivated by attachment of a hydrogen atom. This is a particularly important effect in amorphous silicon, where otherwise the large number of dangling silicon bonds leads to so many deep traps that the material is electrically useless. But the Si-H combination is not a deep trap, and so hydrogenated amorphous silicon is electrically important. There are many other examples where hydrogen can eliminate deep traps.

Hydrogen can, however, also passivate shallow traps and reduce electrical activity. For example, in boron-doped silicon a hydrogen atom is trapped in a bond-centered site between B and Si. This leads, in a first approximation, to a 3-coordinated boron and a Si-H bond and removes the effective-mass acceptor state associated with boron. This situation is shown in Fig. 5. The model for donors is different, and the situation changes in detail as one considers other semiconductors, but the effect is the same: shallow traps can be passivated and charge carriers can be removed by hydrogen.

1.5.4 Further Electrical Properties

The preceding sections have outlined the essential electrical properties of semiconductor defects. Shallow donors or acceptors provide electrical carriers in numbers proportional to the defect concentrations. Deep defects can trap electrical carriers, also in numbers proportional to their concentrations. Hydrogen can passivate both types of defects and so remove their effect.

As in the case of metals, defects can also scatter conducting electrons and holes and thereby contribute to the electrical resistivity of the solid. Thus, for example, while every

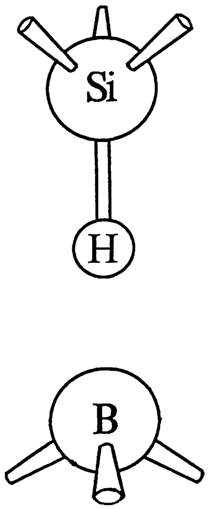

FIG. 5. Illustration of the structure of hydrogen-passivated boron in silicon.

phosphorus impurity can contribute to the conductivity by donating an electron to the conduction band, every phosphorus is also a potential scattering defect for those very electrons. The scattering effects are, in general, larger in semiconductors than in metals, because the much smaller concentrations of conducting electrons (or holes) are less effective in screening the scattering potential. In some device applications, the scattering problem is overcome by arranging that the conducting particles move in a region of the crystal that is defect free. This is possible in planar geometries, where the current flows in a shallow region of the semiconductor near an interface while the donor or acceptor atoms that provide the carriers are engineered to lie in the bulk of the semiconductor.

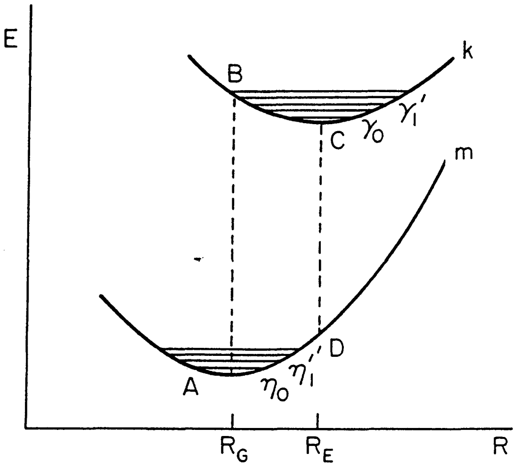

FIG. 6. Configuration-coordinate diagram for an idealized system.

1.5.5 Optical Properties Point defects in nonmetallic crystals will, if they have energy levels within the gap between the valence and conduction bands, lead to characteristic optical absorptions that involve the excitation of electrons or holes from a ground to an excited state. In some cases, there is also luminescence as the excited defect returns to the ground state.

The general theory of optical absorption, as well as some aspects of luminescence, is similar for semiconductor and insulator defects, although details tend to differ somewhat. The simplest conceptual model is adapted from molecular physics and involves the electron–phonon interaction. The defect in its ground state has neighboring atoms that vibrate about certain equilibrium sites. When the defect is excited the neighboring atoms, responding to a new defect wave function, relax to new equilibrium positions. This may be represented by a configuration-coordinate diagram (Fig. 6), which in an idealized case consists of two displaced parabolas [representing the harmonic energy of the vibrating atoms in ground (*m*) and excited (*k*) states]. The vibrational levels are quantized, and hence quantum levels η and γ are shown in association with the parabolas. An optical transition, in general, involves a change of both electronic and vibrational quantum numbers, and the results in two limits are instructive.

In the small-relaxation limit, where the excited-state parabola is nearly directly above that of the ground state, the strongest transitions involve no change in vibrational quantum number. Thus, at low temperature, if only the zero-point vibrational level of the ground state is occupied, the strongest transition will be a sharp "zero-phonon" transition from A to C to the zero-point level of the excited state. In the large-relaxation limit, with both horizontal and vertical displacements of the parabolas, the zero- and few-phonon transitions are weak because the wave functions of the low-lying displaced oscillators do not overlap strongly, and the optical absorption is characterized by a broad multiphonon transition A to B, which is approximately vertical in the configuration coordinate *R*.

In the absence of nonradiative channels, the excited defect will luminesce, emitting a photon as it returns to the ground state. In general, the radiative lifetime is at least several orders of magnitude longer than the vibrational relaxation rates, and so the excited defect will relax to its lowest vibrational state; e.g., at low temperature it will relax to the zero-point state C before the defect radiates. In the weak-coupling limit the zero-phonon line C to A will lie congruent with that for absorption, while few-phonon lines will lie at lower photon energy (in contrast to absorption, where they lie at higher energies). In the strong-coupling limit, the broad multiphonon emission C to D will be Stokes-shifted from that for absorption by a relaxation energy, as shown in Fig. 6. (The difference in energy between the absorption and the emission bands is referred to as the Stokes shift.)

The above discussion is a highly truncated and simplified version of actual situations. It in fact works well to describe, at least qualitatively, many defects in insulators, as discussed in the next section. It also works well in describing some deep-level semiconductor defects such as the carbon–phosphorus pair in silicon. However, for many semiconductor defects, especially shallow ones, the situation is somewhat different. For example, for shallow defects the excited electronic states lie very close to the respective bands and optical transitions into them are rather weak. Thus, rather than observe an isolated transition between two states one sees the superposition of many ground-to-excited-state transitions blending into ground-to-unbound (or continuum) transitions. The corresponding luminescence may or may not be observed; the excited state is likely to be thermally ionized and so one might observe continuum-to-ground-state transitions. However, the conduction electron or hole may well journey to a surface or other defective portion of the crystal at which some nonradiative decay process may take place, or the electron or hole may simply be trapped away from the original defect.

1.6 Effects of Point Defects in Insulators

1.6.1 Color Centers Because many point defects in insulators generate optical activity in the visible, they have been given the general name of color centers. Given the variety of possible hosts and defects, the number of examples of color centers is enormous. The study of simple color centers has been of great importance in elucidating basic physics, while more complicated color centers have proven to be of technological importance in, for example, solid-state laser systems.

As discussed in Sec. 1.5.5, defects in insulators and deep-level defects in semiconductors share many basic concepts. However, defects in insulators generally tend to lie more in the strong-coupling limit than those in semiconductors, although examples in both strong- and weak-coupling limits are found.

In this section, we present several topics as examples. First, we discuss the F center in alkali halides as the prototype color center. Next, we discuss F-center creation by UV irradiation as an example of defect chemistry. Finally, we discuss vibrational luminescence of the F-center–CN^- complex as an example of energy transfer.

1.6.2 F Center in Alkali Halides The simplest color center is the F center in alkali halides, an electron trapped at a halogen$^-$ vacancy. As a quasi one-electron defect, it is the "hydrogen atom" of defect centers in insulators. The site at which the electron is trapped has cubic symmetry, with the nearest-neighbor alkali ions equally spaced along $\pm x$, $\pm y$, $\pm z$ directions. This makes the analogy with hydrogen even stronger since the lowest-lying electronic wave functions are approximately *s*- and *p*-like. The potential-energy function more closely resembles a square well than a hydrogenic potential, however, and this leads among other things to a removal of degeneracy in the angular momentum quantum number; e.g., 2*s* and 2*p* states will not be degenerate.

The absorption transition may then be thought of as follows. The trapped electron is in a "1*s*" state whose energy and wave function are consistent with the positions of neighboring ions. Optical absorption involves a transition to a "2*p*" state, whose energy and wave function are consistent with the positions of the ions before the transition took place: this is the Franck–Condon principle. The peak position is the 2*p*-1*s* energy difference associated with these equilibrium positions, while the width of the band reflects the vibrations of the ions and the consequent instantaneous variation in the transition energy. In KCl, the peak position for absorption at liquid helium temperature (4 K) is 2.31 eV, and the full width at half-maximum is 0.16 eV.

After absorption there is a high probability in many alkali halides at low temperature that luminescence will follow. Now the lattice relaxes and the system comes to equilibrium in an excited state and undergoes a Franck–Condon transition to the ground state. In KCl, the peak position for luminescence is 1.22 eV and the full width at half-maximum is 0.26 eV. Thus, nearly half the absorption energy is lost to heat in the form of lattice relaxation as the F center goes through a complete optical cycle.

1.6.3 F-Center Creation by UV Irradiation It is found that F centers may be created by light that excites an electron from the valence to the conduction band (in fact, light of slightly lower energy that creates an exciton also leads to F-center generation). Thus, defects are created by orders of magnitude less energy than required by familiar collision processes. This is an example of defect chemistry and is analogous to known chemical processes in other systems in that a reaction may be made to go if the system is raised to the appropriate excited state.

A highly simplified explanation of F-center creation is the following. An excited electron–hole pair (a self-trapped exciton, or STE) in an alkali halide relaxes into a configuration in which the hole is shared by two adjacent halogen ions, which in turn move together to form a molecule–ion configuration. The electron is somewhat weakly bound to the self-trapped hole. An alternative configuration for the STE is one in which the halogen molecule-ion moves away from one of the halogen sites along the molecular axis. This creates an adjacent halogen-vacancy-like region, into which the weakly bound electron can be trapped into an F-center-like ground state. It turns out that this process is energetically favorable, at least in some cases, and furthermore the hole can continue to move along the first axis, one step at a time. Each step it moves, the hole is retrapped by a new pair of halogen ions, which then relax. Eventually, the self-trapped hole finds itself some distance from the electron, and one has relatively isolated pair defects consisting of an F center and a so-called F_H center. Following through this process, one sees that an F_H center consists of a halogen molecule-ion at a site normally occupied by a halogen ion.

1.6.4 Energy Transfer: Vibrational Luminescence of the F-Center–CN$^-$ Pair Transfer of excitation energy from one defect to another is of both scientific and technological interest. The scientific interest involves understanding the mechanisms of energy transfer, and from that being able to predict its occurrence. The technological interest arises from a number of possible and achieved applications, one of the oldest of which is sensitized luminescence. Sensitized luminescence involves two different defects, one of which (the sensitizer) absorbs light in a desired wavelength range, the other of which (the activator) emits light in a different wavelength range. Typically, the activator's optical transitions are forbidden, which means that it does not absorb light readily. The sensitizer has allowed transitions and so absorbs light. Subsequent lattice relaxation brings the sensitizer's emission energy difference into resonance with the activator's absorption energy difference (more specifically, the broad bands overlap), which means that an energy-conserving transfer from sensitizer to activator may occur. Its actual occurrence requires that the transfer rate be greater than the rate for the sensitizer to return to the ground state by other means.

There are two transfer mechanisms that have been explored in detail. One is a dipole–dipole process and is analogous to a classical nonradiative transfer of energy between two antennas. The other is a quantum-mechanical exchange process. It should be noted that similar energy transfer also occurs in photosynthesis, and some of the early theoretical work involved biological systems.

The F-center–CN$^-$ pair is a particularly interesting example of energy transfer in which the detailed mechanism is not yet known. In this case, electronic energy from the excited F center is converted to internal vibrational energy, the stretch mode of the CN$^-$ molecule ion. The prototype system utilizes a CsCl host and has an F center and a CN$^-$ ion on nearest-neighbor halogen sites. Absorption into the F band leads to very efficient vibrational luminescence within the CN$^-$ ion, starting from a high vibrational state such as the fourth excited state. The luminescence occurs with a long lifetime, deexciting one vibrational state at a time, so that a series of lines is observed as the excited CN$^-$ works its way to the ground state. Calculations of transfer probabilities show that a dipole–dipole energy transfer is orders of magnitude slower than the observed radiative decay rate of the F center, and an exchange mechanism would not be appropriate in relating an electronic to a vibrational process. Thus, another mechanism must exist, whose nature at present eludes investigators.

2. EXTENDED DEFECTS

2.1 Definition

Extended defects are those that extend through a substantial part of the crystal in at least one direction. These defects, like point defects, can have a profound effect on the properties of a material. In fact, some material properties arise almost exclusively from the presence of extended defects. For example, plastic deformation would be almost entirely absent in metals at low temperatures if it were not for the presence of dislocations. Similarly, a large density of grain boundaries can cause the hardness of a material to increase by 100% or more, can alter the conductivity of semiconductors, and can result in significant enhancements in diffusion rates. Interfaces between different semiconductors can give rise to undesirable electronic effects that can greatly reduce the performance of devices. The growth of small cracks into macroscopic ones can cause an otherwise well-behaved material to fail catastrophically by fracture.

Each of these examples illustrates the role of extended defects in governing real material properties. Although here our primary emphasis is on extended defects in crystalline solids, we note that there are many analogies between the effects discussed here and those in related fields involving defects in other types of hosts. Examples range from the creep of vortex lattices in superconductors to the role of extended defects in dictating the crumpling of membranes. In this part of the article, we give a brief exposition of the definition and structure of extended defects, their response to external forces, and their effects on materials properties.

2.2 Types of Extended Defects

The goals of the study of extended defects within applied physics are to establish their basic structure and character, to explain their origins, to understand their effects on material properties, and eventually to control these effects. We begin with an overview of the basic types of extended defects that commonly occur in materials. The broadest classification is via dimensionality, with line and planar defects as the primary cases, and cracks treated separately.

2.2.1 One-Dimensional or Line Defects

The major types of line defects are dislocations and steps at surfaces or interfaces. Within crystals, the dominant line defects are dislocations. The nature of a dislocation is best illustrated via a picture. Figure 7 shows the two basic kinds of dislocations that are present in a three-dimensional crystal. The edge dislocation [Fig. 7(a)] results from slip of the upper half crystal relative to the lower half by a lattice translation vector, although the slip is confined to only a part of the plane. The translation vector, known as the Burgers vector, is a vector of the lattice, so that in the bulk of the half-plane the bonding is still perfect. For an edge dislocation, the Burgers vector is perpendicular to

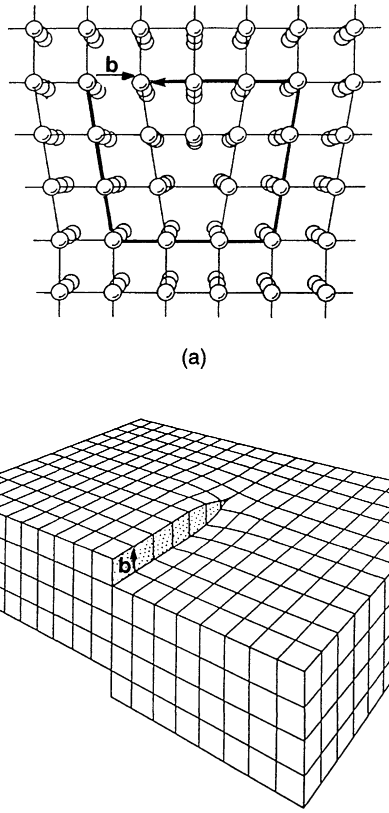

FIG. 7. Schematic drawings of edge and screw dislocations. (a) An edge dislocation viewed along the line direction. An extra plane of atoms is evident in the upper half of the crystal. (b) Illustration of a screw dislocation. The slip associated with the dislocation is indicated by the arrow, which denotes the Burgers vector.

the dislocation line and lies in a plane commonly referred to as the slip plane. Motion in the slip plane is called "glide"; motion out of the slip plane is known as "climb," and is typically more difficult than glide. A different type of structure, the screw dislocation [Fig. 7(b)], is obtained when the Burgers vector is parallel to the dislocation line. A dislocation will in general have mixed character with the Burgers vector neither parallel nor perpendicular to the dislocation line. Ultimately, a strict definition of a dislocation is that it is a boundary between slipped and unslipped regions of the crystal. From the standpoint of continuum mechanics, this is indicated by the fact that in traversing a contour around the dislocation line, the displacement field is found to be multivalued.

In general, crystal surfaces are not strictly planar, but rather include inhomogeneities such as steps between adjacent terraces. In Fig. 8, we show a stepped Si(100) surface as revealed by scanning tunneling microscopy. These steps on such a surface may be treated as one-dimensional defects. In some cases, the density of these steps is related to the slight deviation of a surface from its optimal orientation, with the steps accommodating this geometric mismatch. On the other hand, such steps may also arise as a result of thermal fluctuations at elevated temperatures.

2.2.2 Two-Dimensional or Planar Defects These occur as surfaces of materials, interfaces between regions of a crystal having different orientations (grain boundaries), and interfaces between distinct materials (heterojunctions).

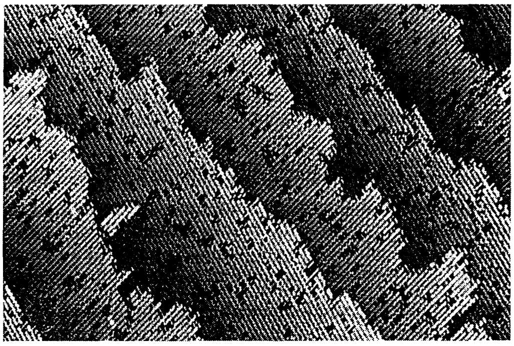

FIG. 8. Scanning tunneling microscopy image of a stepped Si(100) surface tilted by 0.4°. Steps separate flat terraces. Note the imperfections in the steps themselves, which are clearly jagged. After Alerhand *et al.* (1990).

A surface is essentially defined by its orientation and in some cases the type of atom (in compound materials) that terminates the surface. A grain boundary is defined in terms of the orientations of two adjacent parts of the crystal (grains) relative to the boundary, as well as possible translations of the grains relative to each other (see GRAIN BOUNDARIES). In Fig. 9, the change in directions of the lines of atoms, corresponding to grain misorientation, is clearly seen. One often distinguishes between low-angle boundaries, in which much of the interface material is perfectly bonded, and high-angle boundaries, in which the bonding is severely disrupted, though even for certain high angles there are special orientations resulting in a high degree of registry. There are special misorientations and translations for which the bonding at the boundary is not disrupted at all, which are known as stacking faults. Figure 10 shows a typical stacking sequence in which the stacking fault corresponds to a rearrangement of the stacking order. Planar defects are characterized by a hierarchy of energies with stacking faults having the lowest energies, high-angle grain-boundary en-

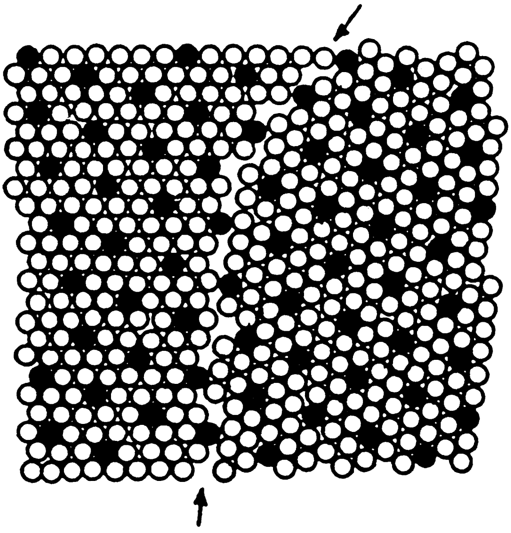

FIG. 9. A two-dimensional model of a pure tilt grain boundary. The arrows indicate the grain-boundary surface, which is perpendicular to the page. The coincident-site lattice is indicated by dark atoms—these form a lattice of sites common to both grains. After Murr (1975).

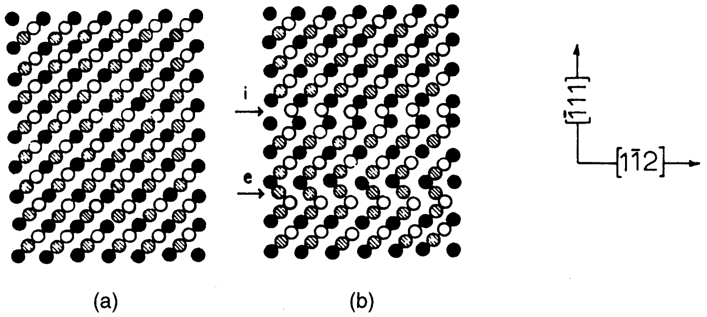

FIG. 10. (a) Regular stacking sequence (ABCABC . . .) of a perfect fcc lattice along a (111)-type direction. (b) Stacking sequence illustrating extrinsic (*e*) and intrinsic (*i*) stacking faults. The intrinsic stacking fault has a stacking sequence (ABCABABC . . .) and corresponds to a missing C-like layer. The extrinsic stacking fault has a stacking sequence (ABCBABC . . .) and corresponds to the addition of a B layer. After Murr (1975).

ergies falling in an intermediate range, and surfaces having the highest values. Typical stacking-fault energies are of the order of 100 mJ/m^2, while grain-boundary energies are 5 to 10 times higher. Surface energies typically fall in the range from 1500 to 3000 mJ/m^2. In compounds, one has defects known as antiphase boundaries or complex stacking faults, which are like stacking faults in that the interfacial bonding is not disrupted. However, the ordering between different atom types is disrupted across the interface. For example, in a material with only unlike-neighbor bonds, an antiphase boundary can lead to energetically unfavorable like-atom bonds.

2.2.3 Cracks Cracks may be thought of as having partly one-dimensional and partly two-dimensional character, as they involve the creation of surfaces. In the ideal case, the crack tip itself is defined by a line. An idealized crack is defined by the crack plane, the crack line, which bounds this plane, and the mode of loading that holds the crack open. In Fig. 11, we show an example of a crack illustrating the three major categories of loading geometry. Cracks are often found along interfaces or grain boundaries, probably because the energy of breaking the solid along these preexisting defects is less than that of breaking the perfect solid.

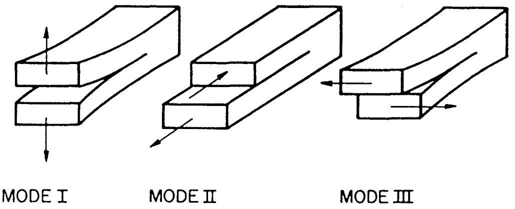

FIG. 11. Various pure loading geometries for an ideal planar crack. Mode-I loading corresponds to a pure tensile stress, while modes II and III correspond to loading by an applied shear stress. Loading is illustrated schematically by arrows. After Thomson (1986).

2.3 Origins of Extended Defects

Unlike many point defects, extended defects such as dislocations do not arise spontaneously in thermal equilibrium. The entropy gain associated with a thermal population of point defects suffices to compensate for typical point-defect formation energies, which are of the order of 1 eV. On the other hand, the formation energies of extended defects are essentially infinite, rendering the entropy contribution to their free energy insufficient to stabilize them. Thus, kinetic factors, possibly combined with work from external sources, must be responsible for their formation. In the case of dislocations, typical densities range from 10^4 cm^{-2} or less in high-quality semiconductors to 10^{12} cm^{-2} in highly deformed metals. The density of grain boundaries in polycrystalline materials is determined by the grain size, which is typically in the range of 5 to 10 μm.

Extended defects often occur directly as a result of the synthesis of a material. For example, after annealing, soft metals invariably have a density of 10^6 to 10^8 cm^{-2} of dislocations. An example of the origins of grain boundaries and interfaces is as a result of the impingement of particles that spontaneously nucleate out of a melt. Dislocations can occur when layered materials are synthesized by, for example, molecular-beam epitaxy, with the mismatch between the two materials leading to the formation of dislocation networks.

Various types of postsynthesis processing can also lead to the formation (and in some cases destruction) of extended defects. Processing methods involving deformation, such as rolling or cold working, lead to internal stresses that can activate dislocation sources such as "Frank–Read" sources. Figure 12 shows such a Frank–Read source in Si, where the contrast of the dislocation loops emerging from the source has been heightened by the use of "chemical decoration." From the central region, dislocation loops can be seen to emerge quite regularly. The operation of these sources results from a dislocation being locked to two points, which in turn causes the dislocation to bow out into a loop under the action of an applied stress. This loop eventually "ties off" and grows into a new dislocation. These sources can operate at very low stresses if the pinning-point separation is large. Deformation eventually leads to increased stress levels, which can activate progressively more and more sources.

Annealing of alloys can result in the formation of heterojunctions at interfaces between the nuclei of new phases and the host. Alternatively, extended defects can be destroyed by annealing processes. For example, dislocations can migrate to the surface of the material and leave it there. Grain boundaries can migrate, resulting in the coalescence of grains and thus reduced grain-boundary area.

2.4 Structure

The structure of extended defects is usually described at large distances in terms of a long-ranged elastic strain field and at short distances in terms of the atomic arrangements in some core region. The elastic field can often be obtained analytically, but the atomic-level bonding requires the use of computer simulations.

The elastic distortions associated with dislocations are characterized by strain fields that decay as $1/r$, where r is the distance from the defect. In the case of straight screw dislocations, the strain field is cylindrically symmetric, but for edge dislocations it is more complicated. Using isotropic elasticity theory, these strain fields lead to an elastic strain energy per unit length of the form

$$E/L = C(\mu \mathbf{b}^2/4\pi)\ln(R/r_0), \qquad (4)$$

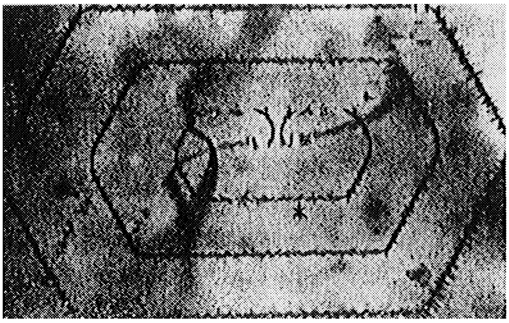

FIG. 12. Series of expanding dislocation loops emerging from a Frank–Read source in Si. The two pinning points about which the dislocation segments bow out are in the center of the figure. After Hull (1965).

where C is a prefactor determined by Poisson's ratio, μ is the shear modulus, $\mathbf{b}$ is the Burgers vector of the dislocation, R is a large-distance cutoff corresponding to the radius of a cylindrical sample containing the defect region, and r_0 is a core cutoff parameter; both R and r_0 are necessary in order to obtain a finite value of E/L. Further details may be found in Hirth and Lothe (1982). One critical atomic-level feature of dislocations is the nature of their dissociation, if any, into partial dislocations (see Fig. 13). Dissociation is driven by the energetic gain

Burgers vectors of partial dislocations

FIG. 13. Illustration of the geometry of partial dislocations in a fcc crystal. The Burgers vectors of the partial dislocations are related to that of the full dislocation by $\mathbf{b}_c = \mathbf{b}_{pb} + \mathbf{b}_{pa}$. Note that $\mathbf{b}_{pb}$ and $\mathbf{b}_{pa}$ both involve out-of-plane displacements. After Hull (1965).

associated with having two dislocations with small Burgers vectors as opposed to a single one with a large Burgers vector, according to the $\mathbf{b}^2$ term in Eq. (4) (although the estimates of elasticity become more complex when the elastic anisotropy of the medium is taken into consideration). The two dislocations then have Burgers vectors that are not lattice vectors, which results in the terminology "partial dislocations." Partial dislocations are of necessity terminations of planar faults, which are stacking faults in elemental materials and antiphase boundaries or complex stacking faults in compounds. The energy penalty for these planar faults tends to reduce the separation between the partial dislocations. The elastic interaction between the partials is repulsive, on the other hand, resulting in a balance of forces at the equilibrium separation. More complex types of core dissociation can also occur. For example, it is believed that screw dislocations in bcc metals are spread onto three distinct planes, which results in their being hard to move.

Dislocations in real materials are not straight, but rather contain "kinks" and "jogs" (see Fig. 14). A kink is a perturbation of the dislocation line in the slip plane; a jog is a perturbation out of the slip plane. As will be discussed below, kinks are believed to be very important in the low-temperature mobility of dislocations in their slip planes, while jogs become relevant to dislocation motion out of their slip planes at high temperatures.

More complex features of dislocation core structure involve possible "reconstructions" (cf. Fig. 15). Reconstruction means that there are distortions of the atomic geometry in the core region that are parallel to the line direction of the dislocation. These distortions result in the formation of a repeat distance along the line direction that exceeds the repeat distance associated with the unreconstructed structure. The simplest example is demonstrated in Fig. 15, where in Fig. 15(a) the unreconstructed structure is shown and in Fig. 15(b) the "dimerization" is shown. This reconstruction involves alternating pairs of atoms, which pull closer to and farther away from each other. Such reconstructions are thought to occur in Si.

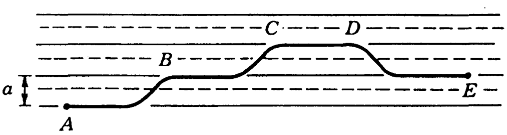

FIG. 14. Schematic illustration of the formation of kinks in a dislocation line. B, C, and D are points at which kinks have formed, allowing segments of the dislocation to move from one potential well to another. After Hirth and Lothe (1982).

FIG. 15. Projections of the {111} slip plane for the diamond cubic structure illustrating (a) unreconstructed and (b) reconstructed core structures for the 30° partial dislocation. Note that the reconstruction restores the conventional tetrahedral bonding configuration. Adapted from Duesbery and Richardson (1990).

In general, the elastic fields of interfaces are short ranged. When viewed as an array of dislocations, a simple low-angle grain boundary may be characterized by stress fields that decay exponentially away from the boundary. The atomic-scale structure of interfaces is best attacked by starting with grain boundaries. Ideal planar grain boundaries are commonly categorized into "tilt" and "twist" boundaries according to whether the axis of the rotation that takes one grain's orientation into the other is parallel or perpendicular to the boundary. Just as edge and screw dislocations are the simple limits of dislocation character, tilt and twist character to grain boundaries are special cases of more general boundary character that have both twist and tilt components. A small-angle tilt grain boundary, as indicated in Fig. 9, can be thought of as an array of edge dislocations. Above each edge dislocation is an extra plane between the two grains; the increasing number of planes between the grains as one goes up in the picture corresponds to a tilt between the two grains, with the number of such dislocations per unit length dictating the misorientation between the grains. Similarly, a small-angle twist boundary may be thought of as an array of screw dislocations.

The coincident-site lattice (CSL) is a useful conceptual structure for analyzing commensurate boundaries in which a unit cell (possibly large) can be repeated to form the boundary structure. The number of atoms in the unit cell is known as the "Σ" number, so that, for example, a $\Sigma5$ grain boundary has five atoms per interface unit cell. A high Σ number corresponds to a complex boundary structure. The coincident-site lattice (CSL) is the collection of the lattice points that both of the grains have in common, with $1/\Sigma$ giving the fraction of sites common to both lattices. If the boundary unit cell is large, then the coincident-site lattice has a large lattice constant and correspondingly a low density. In Fig. 9, the coincident-site lattice is indicated by the filled circles.

For analyzing more general high-angle boundaries, a "structural-unit" model has been found to be useful. In this model, the structure of a number of high-Σ boundaries (and incommensurate ones as well) is created from two or more distinct small building blocks that are derived from the structures of low-Σ boundaries. The complexity in the high-Σ structures then comes from the arrangements of these building blocks into larger unit cells. Atomistic simulations have shown that many complex grain-boundary structures can be modeled quite well in this fashion. Grain-boundary structure is more completely discussed in GRAIN BOUNDARIES.

At heterojunctions, mismatch between the lattice constants of the constituents leads to disruption of the interfacial bonding. If the mismatch is small, this disruption may take the form of a network of misfit dislocations having at least some edge character, where the extra planes are inserted on the side with the smaller lattice constant. Figure 16 shows such misfit dislocations at a CdTe–GaAs interface; the dislocations appear as light spots.

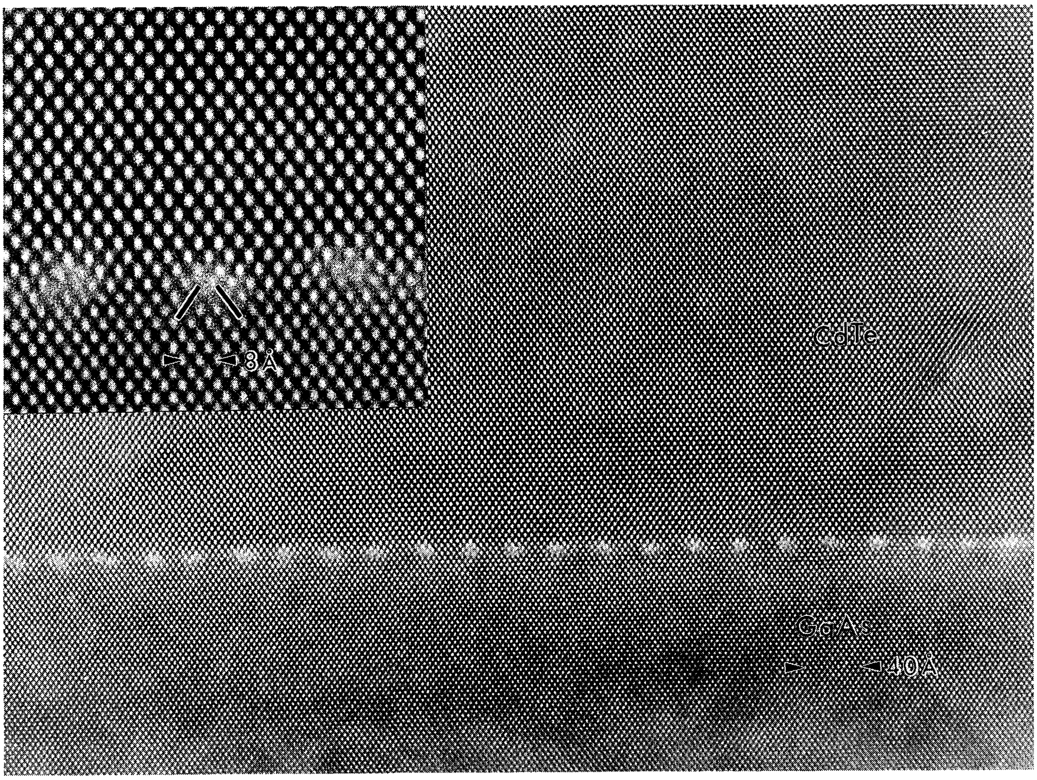

FIG. 16. High-resolution electron micrograph showing a periodic array of Lomer misfit dislocations for an annealed CdTe/GaAs interface. Inset magnifies the two half-planes associated with the perfect pure edge Lomer dislocation (courtesy of A. F. Schwartzman).

At surfaces, the perturbation of the bonding is much greater than at grain boundaries or interfaces. This leads, in addition to the expected relaxation of surface layers into or away from the bulk, to symmetry-breaking reconstructions that can be quite complex. For example, the Si (111) surface displays a "7×7" reconstruction (see Fig. 17) in which both dimensions of the surface unit cell are seven times larger than they would be in the absence of reconstruction. Some types of reconstruction can be explained via simple bond-healing effects, but others involve more complex electronic effects such as the splitting of bands of electronic surface states or environmental dependence of the interatomic forces.

At large distances, the structure of cracks, like dislocations, is best described in terms of associated continuum fields. In elasticity theory, the stress field (which is proportional to the strain) $\sigma(r)$ of a straight, sharp, planar crack has a $1/\sqrt{r}$ behavior, where r is the distance (measured in two dimensions) from the crack line. This is conveniently described in terms of a stress-intensity factor K, where

$$\sigma(r) \propto K/\sqrt{2\pi r}.$$

For details, see Thomson's review article on fracture (Thomson, 1986). For real cracks, this analysis is valid far from the crack tip. Closer to the crack tip, the stress field can often be described by a local stress-intensity factor that accounts for the effects of surrounding dislocations. The continuum description certainly must break down at distances of the order of interatomic spacings. In addition, the crack may well not be sharp on an atomic scale. Some brittle materials can sustain atomically sharp cracks but many others invariably have blunt cracks. Figure 18(a), for Si, shows no dislocation activity indicative of crack-tip deformation. Figure 18(b), for Fe, shows a crack that is blunted by the emission of dislocations. In addition, for real cracks the crack front is not straight, and the crack itself is nonplanar. Indeed, the deviation of the crack surface from strict planarity can be used to quantify the intrinsic ductility of a given material. Some of these effects can be described in terms of kinks in the crack line, which may serve as dislocation sources. These "de-

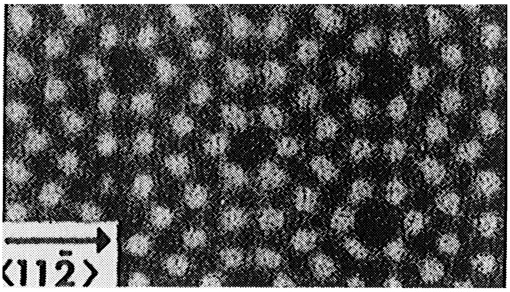

FIG. 17. Scanning tunneling microscopy image of the Si(111) (7×7) reconstructed surface. After Tromp *et al.* (1986).

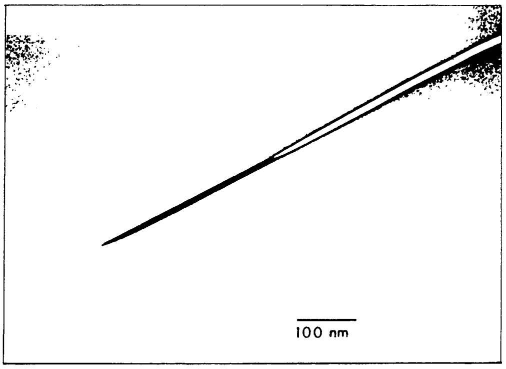
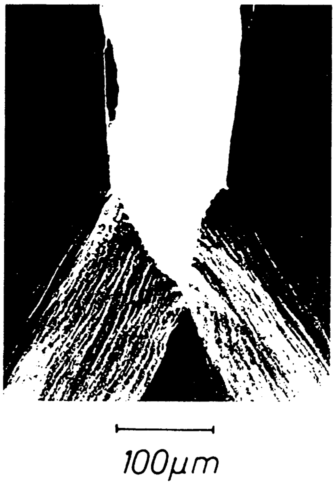


(a)



(b)

FIG. 18. (a) Sharp crack tip in Si. After Lawn (1975). (b) Blunted crack in Fe. After Vehoff and Neumann (1980).

fects with a defect" must certainly be included in a complete analysis of crack stability and propagation.

2.5 Motion and Response to External Forces

Although defects are not physical objects in the same sense as atoms themselves, it is still possible to define forces on defects precisely. The defect force is defined as

$$F = -\nabla U, \tag{5}$$

where U is the free energy of the entire system including the defect. The position of the defect does not vary continuously, but can only move by lattice translations. However, provided that U varies slowly on a length scale corresponding to the lattice vectors, the gradient in Eq. (5) can still be defined in a discrete sense, by calculating the energy change corresponding to a virtual displacement equal to a lattice vector.

The force on a dislocation per unit length due to a stress field (the Peach–Koehler force) is the following:

$$\mathbf{F}/L = (\mathbf{b}\cdot\boldsymbol{\sigma}) \times \boldsymbol{\xi}, \tag{6}$$

where $\mathbf{b}$ is the Burgers vector, $\boldsymbol{\sigma}$ is the stress tensor, and $\boldsymbol{\xi}$ is the unit vector parallel to the dislocation line. This equation is discussed in more detail in Hirth and Lothe (1982). Since the stress field of a dislocation decays as $1/r$, this implies that the force between dislocations also decays as $1/r$. The sign of the force is repulsive between parallel straight dislocations having the same Burgers vector, and attractive if the Burgers vectors are opposite. Counteracting the Peach–Koehler force is the frictional or "Peierls" force, which arises because the dislocation must go over an energy barrier in going from a local free-energy minimum to a neighboring one. This means that a minimum "Peierls stress" is required to move the dislocation. In close-packed metals, the Peierls stress is generally very small, typically on the order of $10^{-4}\mu$ or $10^{-5}\mu$, where μ is the shear modulus. In covalently bonded materials, it can be a few orders of magnitude larger; bcc metals typically have values intermediate between the close-packed metals and covalently bonded materials. In general, at finite temperatures the motion of a dislocation is not uniform, but rather consists of the activated motion of kinks parallel to the dislocation line (cf. Fig. 14). These are nucleated as kink–antikink pairs. The motion of a single kink along the whole dislocation line leads to the forward motion of the dislocation line by one Burgers vector. In covalently bonded materials, and bcc metals, the kink nucleation and migration energies are high enough to give rise to a strong exponential dependence of the dislocation velocity on temperature.

The motion of dislocations according to Eq. (6) gives rise to plastic deformation in the direction of the applied stress. For example, for a nonvanishing σ_{xz} component of the stress tensor, a dislocation parallel to the y axis, with a Burgers vector in the x direction, will experience a force in the x direction. Its motion will move an extra half-plane in that direction, resulting in plastic deformation that relieves the applied stress.

Another mechanism for plastic deformation that is related to the migration of dislocations is that of interfacial migration. The motion of interfaces may be broadly classed into two categories: grain-boundary migration, which involves a motion of the boundary perpendicular to the plane of the interface, and grain-boundary sliding, which results upon relative translation of adjacent grains along a direction parallel to their common interface. The relation between grain-boundary and dislocation migration is argued on the basis of models that hold that grain boundaries may be thought of as being built up of dislocations. A host of experiments on both migration and sliding reveal the dependence of these processes on a variety of parameters ranging from geometrical quantities such as the angle of misorientation to chemical effects such as the concentration of impurities.

The force on a crack is most easily understood in the mode I geometry of Fig. 11. There are two contributions to the force. The first is the elastic strain energy. Under a virtual displacement of the crack tip to the right, the elastic strain energy is reduced because the surface moves in the direction of the applied stresses, and thus the energy associated with the external forces is lowered. Thus, the elastic strain energy tends to expand the crack. The corresponding force per length of crack line is proportional to $\sigma^2 a/\mu$, where a is the crack length. The second contribution to the force comes from the surface energy. As the crack tip moves to the right a distance δx, there is an energy increase by an amount $2\gamma_s\delta x$, corresponding to the creation of new free surface, where γ_s is the surface energy per unit area (the prefactor of two arises because two surfaces are created). Thus, the force from this contribution is simply $2\gamma_s$, to the left. The equilibrium crack length is determined by the competition between these two forces. In terms of the stress-intensity factor K discussed above, the equilibrium condition becomes (for mode I loading) the "Griffith criterion"

$$K_c = \sqrt{4\gamma_s\mu}, \qquad (7)$$

where μ is the shear modulus. The criteria for modes II and III are similar, but with prefactors that differ slightly from unity.

Under a given applied stress σ the stress-intensity factor for a crack of length a has the form

$$K \propto \sigma\sqrt{a}. \qquad (8)$$

This means that a long crack will have an increased stress-intensity factor, and thus will be more likely to grow.

2.6 Effects on Materials Properties

The effect of extended defects on the properties of materials is an extremely rich and complex topic, and we can only give some representative examples here.

2.6.1 Mechanical Properties The crucial importance of extended defects in explaining these properties is demonstrated by the failure of models based on perfect crystalline solids. In these models, the ideal shear strength of a solid is computed by evaluating the energy to shift the upper half of a crystal rigidly relative to the lower half along a shearing plane. The energy of such a process is periodic as a function of displacement. It was first modeled by assuming a sinusoidal form for the periodic energy profile. The stress predicted by this model to shear a perfect crystal is $\tau_{\mathrm{ideal}} = \mu b/2\pi d$, where μ is the shear modulus, d is the distance between the planes being sheared, and b is the period length in the slip direction. A comparison of the ideal shear strength with the observed shear strength for a variety of materials indicates, however, that this idealized model of plastic deformation drastically overestimates the stress required to deform a crystal permanently. The "Peierls" stress required to move a dislocation, as noted above, is much smaller.

Since dislocations are the "carriers" of plastic deformation, one might be tempted to think of them as softening agents. However, the hardness of materials usually increases with the dislocation density. This is because the dislocations give rise to spatially varying stress fields, which create energy barriers that inhibit the motion of dislocations. This is the origin of the phenomenon of work hardening. As a material initially containing a small density of dislocations is deformed, progressively more and more dislocation sources become active and the dislocation density increases. This increases the energy barriers that must be traversed for dislocation motion, and the material becomes harder. As a result, the shear strength of the material becomes roughly inversely proportional to the average dislocation spacing.

A material can also be strengthened by having a small grain size, which inhibits the motion of dislocations. In addition, grain boundaries can make a material either more or less brittle, depending on the grain-boundary chemistry and the grain size. Several impurity elements, such as H and S, can segregate to grain boundaries in metals and thereby weaken them, resulting in brittleness. Much of the discussion of this effect has been based on the assumption that the grain-boundary bond strength is reduced by the impurities, but this scenario is by no means proven. A small grain size can reduce stress concentrations in a material, thereby making it less brittle. Finally, fine-grained materials can deform at high temperatures via a mechanism known as superplastic deformation. In this mechanism, grains slide over each other, and mass transport along the grain boundaries results in changes in grain shape, which corresponds to deformation of the material.

The presence of small cracks in a material can have the effect of making the material more brittle. As with dislocations, the necessity for preexisting cracks in explaining brittle fracture is shown by the failure of models based on defect-free solids. In these models, the ideal tensile strength is computed analogously to the ideal shear strength. Estimates of the tensile strength derived in this way again severely overestimate the fracture stress as determined experimentally. Cracks act as "concentrators" of applied or internal stresses, so that in the region near a crack tip these stresses may reach values comparable to the ideal tensile strength. The key issue here is whether the cracks grow under stress or not. As discussed above, at a given stress level, large cracks tend to grow more than small ones. Thus, one hopes that the cracks in a material are below the critical length for growth under the intended conditions of use. It is often observed that the critical stresses for crack growth significantly exceed the Griffith value given above [cf. Eq. (7)]. This is because the work done on the crack can be dissipated via toughening mechanisms such as plastic deformation, whose energy can greatly exceed the surface energy. Inherently brittle materials can be improved via toughening mechanisms such as stress-relieving structural transformations ahead of the crack, toughening fibers, or even subcritical microcracks that shield the applied stresses.

2.6.2 Mass Transport Surfaces, dislocations, and grain boundaries all provide low-energy paths for atomic migration. This effect is known as "pipe diffusion" in the case of dislocations. In part, this effect may be attributed to reduced point-defect formation and migration energies in the core region of the extended defect. In most cases, high-temperature diffusion is dominated by bulk effects, because of the great number of possible paths. Diffusion along extended defects becomes more important at low temperatures, because the higher-energy bulk diffusion paths are "frozen out." The spectra of observed diffusivities for bulk lattices and along extended defects are contrasted in Fig. 19. This figure not only illustrates the wide range of observed diffusivities, but also reveals the variety of activation energies associated with diffusion at extended defects.

2.6.3 Acoustic Attenuation Extended defects (in addition to point defects) provide a variety of "internal friction" mechanisms that result in the dissipation of acoustic energy. Point defects as well as linear and extended defects give rise to acoustic attenuation in characteristic temperature and frequency regimes. For example, in the case of dislocations, acoustic energy is converted to the energy of forming kink–antikink pairs along the dislocation. This dissipation mechanism gives rise to the so-called Bordoni peak in the spectrum of acoustic attenuation.

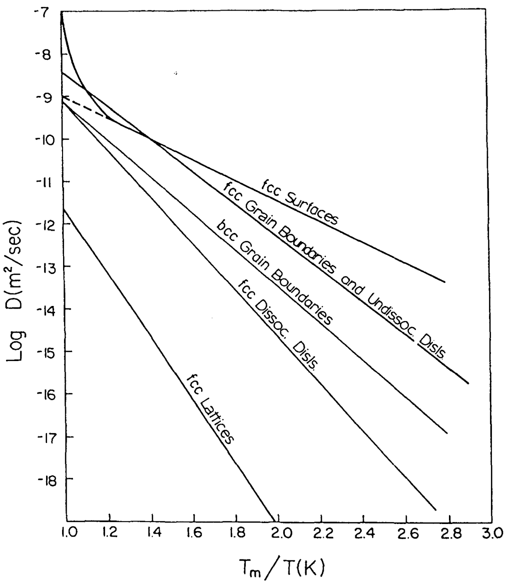


FIG. 19. Diffusivity spectrum for metals as deduced by Gjostein. This schematic illustrates the enhancement in diffusion rates seen at surfaces, grain boundaries, and dislocations in comparison with perfect lattice diffusivity. Taken from modified figure of Balluffi (1984).

2.6.4 Electrical Properties The conductivity effects are particularly pronounced in semiconductors. Extended defects can scatter carriers by reason of their deviation from bulk crystalline geometry. They can also cause defect-localized states, due either to the intrinsic defect geometry, or to the segregation of impurities and other imperfections to the defect. Such states can provide electron–hole recombination paths, which greatly reduce the carrier lifetime. In addition, the occupation of the defect states by charged carriers can result in electrostatic fields that locally shift the valence and conduction bands relative to the Fermi level, and can create barriers for charge transport. For example, grain boundaries in Si can have barriers of several tenths of an electron volt, which strongly inhibit transport. These effects are particularly important in samples with small grain sizes. Similar effects occur at interfaces between different semiconductors. Dislocations in several types of semiconductors have been shown to cause characteristic defects of acceptor character, which can locally change the character of the material from *n*-type to *p*-type. Defect states associated with dangling bonds in semiconductors can be passivated by hydrogen, thereby removing states from the gap and reducing charge trapping.

2.6.5 Magnetic Effects Grain boundaries can have a significant impact on magnetic properties, via their interaction with domain walls. The magnetic permeability of polycrystalline materials is mainly due to the motion of domain walls. This motion is generally inhibited by grain boundaries, resulting in reduced permeabilities. In very fine-grained materials, the grain size is smaller than the domain size, so that there are no domain walls (or the domain walls coincide with the grain boundaries). In this case, the permeability is reduced to the contribution from the spins themselves.

2.6.6 Interaction Effects Many properties are also strongly affected by the interaction of point defects with extended defects. As mentioned above, the interaction of point defects with extended defects can lead to dramatic enhancements in the rates of diffusion in materials. In addition, a wide range of other phenomena are affected as well. In semiconductors, doping by either *n*- or *p*-type point defects results in a change in the Fermi level, which in turn can alter the dislocation mobility (as measured by their velocities). A second relation between point and extended defects relates to the mechanism of dislocation motion. Besides the conventional dislocation glide described earlier, dislocations can climb out of their slip plane through the absorption or emission of point defects. This mechanism is generally observed to begin closer to the melting temperature, and has been invoked as a dominant mechanism in explaining creep phenomena. The elastic interactions between point defects and dislocations can lead to the pinning of dislocations. Such pinning has the consequence that the stress needed to activate dislocation motion is larger than that in the point-defect–free case. This effect is referred to as solution hardening. Finally, point defects are known to segregate to extended defects. In particular, segregation to grain boundaries can either strengthen or weaken an interface, leading to an overall change in the mechanical response of a material.

3. CONCLUDING REMARKS

The understanding of the full complexity of real materials is ultimately predicated upon the ability to predict and control the properties of both point and extended defects. Though our treatment has emphasized point defects, line defects, and planar defects each separately, it is only when taken in conjunction that the full implications of such defects can be realized. For example, we have noted the rich interplay between the diffusion of point defects and the presence of extended defects such as dislocations and grain boundaries that provide low-energy pathways for point-defect migration. Dramatic enhancements in the rate of point-defect migration were seen to be related to the presence of extended defects such as dislocations and grain boundaries. Conversely, the motion of dislocations is strongly inhibited by the presence of point defects. Similarly, realistic treatments of processes near a crack tip must involve a description of the dislocations that accompany plastic deformation in the near-tip region. Finally, the electronic properties of planar semiconductor devices are strongly affected by the interplay of defects and interfaces; for example, the defect known as a P_b center is a threefold-coordinated silicon atom at the silicon–silicon dioxide interface. In each of these cases, it is clear that the behaviors of point and extended defects are inextricably linked. The synthesis of our understanding of these defects and their interaction will undoubtedly remain an important part of applied physics.

GLOSSARY

Antisite Defect: An atom on the "wrong" site in a crystal that contains more than one type of chemical constituent.

Atomic Diffusion: The motion of an atom over a macroscopic distance as the result of a series of individual microscopic motions that are statistical in nature.

Bloch Waves: Plane waves in a crystal modulated by functions that have the periodicity of the lattice.

Bordoni Peak: A feature in acoustic attenuation associated with the formation of kink–antikink pairs.

Burgers Vector: The translation vector associated with a dislocation.

Chemical Impurity: An atom, ion, or (small) molecule that is chemically different from the perfect-crystal constituents.

Climb: Dislocation motion out of the plane of the Burgers vector (the slip plane).

Cluster or Nanocrystal: A type of defect that is intermediate between point and extended defects.

Coincident-Site Lattice (CSL): The collection of the lattice points that both of the grains in a grain boundary have in common.

Color Centers: Point defects in insulators that generate optical activity in the visible.

Configuration-Coordinate Diagram: Plot of energy vs atomic position for a molecule or defect.

Cracks: May be thought of as having partly one-dimensional and partly two-dimensional character, as they involve the creation of surfaces. An idealized crack is defined by the crack plane. In the ideal case, the crack tip itself is defined by a line, the crack line, which bounds this plane.

Deep Defects: Defects in semiconductors or insulators in which the electron or hole is strongly bound and is not likely to be unbound at room temperature.

Dislocation: A line defect in a crystal that represents the boundary between the slipped and the unslipped parts of the crystal.

Doping: The introduction of chemical impurities into a crystal during the growth process.

Energy Transfer: Transfer of excitation energy from one defect to another.

Extended Defects: Defects that extend through a substantial part of the crystal in at least one direction.

F Center in Alkali Halides: An electron trapped at a halogen$^-$ vacancy.

Franck–Condon Principle: Optical absorption or emission in which the energies and wave functions are consistent with the positions of the ions before the transition took place.

Frank–Read Source: Source of dislocation loops under the action of an applied stress.

Frenkel Defect: A vacancy-interstitial pair.

Glide: Dislocation motion in the plane of the Burgers vector (the slip plane).

Grain Boundary: A planar defect that is defined in terms of the orientations of two adjacent parts of the crystal.

Heterojunction: An interface between two materials, or two phases of the same material.

Hydrogen Passivation: The change of the nature of the electrical properties of defects by the incorporation of hydrogen into the defect.

Interstitial: An atom or ion at a position other than a perfect-crystal site.

Ion Implantation: The introduction of chemical impurities by firing a beam of impurities into a crystalline sample under controlled conditions.

Jog: A perturbation of a dislocation line out of the slip plane.

Kink: A perturbation of a dislocation line in the slip plane.

Metastable Defect: A defect that has more than one arrangement of atoms.

Molecular-Beam Epitaxy (MBE): Deposition of atoms from molecular beams, layer by layer, onto a substrate, thereby forming thin films.

***n*-Type:** A semiconductor with an excess of donors.

Negative-*U*: A situation in which the "effective" Coulomb interaction between electrons or holes is negative.

***p*-Type:** A semiconductor with an excess of acceptors.

P_b Center: A threefold-coordinated silicon atom at a silicon–silicon dioxide interface.

Peach–Koehler Force: The force on a dislocation per unit length due to a stress field.

Peierls Force: The frictional force that arises because a dislocation must go over an energy barrier in going from a local free-energy minimum to a neighboring one.

Perfect Crystal: A periodically repeated array of identical building blocks such as atoms or arrays of atoms.

Pipe Diffusion: Atomic migration along a dislocation.

Plastic Deformation: Deformation of a crystal under applied stress. This deformation remains after the stress is removed.

Point Defect: An imperfection in a perfect crystal that is of the order of atomic size.

Reconstruction: Distortions parallel to the dislocation line that result in the formation of a unit cell in this direction that is larger than the original one.

Schottky Defect: An isolated vacancy in an otherwise perfect crystal.

Self-Trapped Exciton, or STE: An electron–hole pair in a nonmetallic crystal that is fixed in space by lattice relaxation.

Sensitized Luminescence: A situation involving two different defects, one of which (the sensitizer) absorbs light in a desired wavelength range, the other of which (the activator) emits light in a different wavelength range.

Shallow Donors and Acceptors: Defects in semiconductors in which the electron (donors) or hole (acceptors) is weakly bound and is likely to be unbound at room temperature.

Stacking Fault: A planar defect in which the regular stacking sequence (ABCABC . . .) is interrupted.

Stokes Shift: The energy difference between absorption and emission bands.

Substitutional Defect: A defect that occurs on a perfect-crystal atom site.

Tilt Grain Boundary: The axis of the rotation that takes one grain's orientation into the other is parallel to the boundary.

Twist Grain Boundary: The axis of the rotation that takes one grain's orientation into the other is perpendicular to the boundary.

Vacancy: The absence of an atom or ion from its perfect-crystal site.

Zero-Phonon Transition: An optical transition from the zero-point level of one state to the zero-point level of another state.

INTRODUCTION

The electrochemical method called "polarography" was introduced in 1922 by a Czech scientist, Jaroslav Heyrovský, professor of physical chemistry at Charles University in Prague. In the early 1920s, Heyrovský studied the surface tension of mercury in aqueous solutions of electrolytes as a function of applied electrical voltage (so called "electrocapillarity"). In one of the experimental arrangements, the surface tension was evaluated from intervals between falling drops of mercury that slowly flowed out of a vertical glass capillary connected with a mercury reservoir above it. At this point, an ideally reproducible electrochemical sensor was discovered that featured a periodically renewable, clean, and smooth electrode surface made of metallic material permitting measurements at extreme negative potentials. Having this tool in hand, Professor Heyrovský attempted to explain certain anomalies observed on curves of the surface tension vs potential. Later he began to measure the electric current flowing through the mercury electrode as a function of externally applied potential. Measurement of current-potential curves with the dropping mercury electrode immersed in a solution containing dissolved reducible or oxidizable species is the principle of the polarographic method (Heyrovský, 1922). The discovery of polarography as a powerful analytical and research method for investigation of the most abundant reactions in Nature, redox reactions, was appreciated by the scientific community by the award to its inventor of the Nobel prize for chemistry in 1959.

1. GENERAL PRINCIPLES

The description of the virtues of polarography assumes some essential knowledge of principles of electrochemical reactions and cells, which we review first. This article deals with the transfer of charge across the interface of a metallic electrode and a liquid solution containing dissolved ions or neutral molecules. Such a transfer of charge is observed as the flow of electrical current, and the goal is to relate the observed current to the elementary processes at the interface and in the solution (Vetter, 1961; Thirsk, 1972; Albery, 1975). For principal reasons we cannot handle an isolated boundary of a single electrode because the electric current can flow only in a closed circuit. We have to place in the solution at least another electrode (often called the counter electrode, or the auxiliary electrode), forming thus an electrochemical cell. The two electrodes are connected to appropriate external circuitry that controls the potential difference be-

tween the electrodes and monitors the current resulting from electron-exchange processes at the two interfaces. The overall process taking place in the cell then consists of two half-reactions representing actual chemical changes invoked by the charge transfer and occurring at each of the two interfaces. To make the situation simpler, we choose as a counter electrode an interface that will maintain a constant composition during the current flow. According to international conventions (Ivez and Janz, 1961) the counter or reference electrode should be the standard hydrogen electrode. For practical reasons, the most widely used electrodes are silver or mercury covered with a layer of insoluble chlorides, immersed in a solution of chlorides of a specified concentration. The latter is called the calomel electrode—according to the concentration of chloride solution one encounters most often, either the *saturated calomel electrode (SCE)* or the *normal calomel electrode (NCE).* The reference electrode is made in such a manner that, as a result of a surplus of insoluble chloride, its composition remains unaffected by the passage of current and hence its potential is well defined and constant. The voltage applied to an electrochemical cell will change exclusively the potential of the other electrode, called the *working electrode.* For the sake of comparison of data in every electrochemical experiment, the type of reference electrode with respect to which the potentials are measured has to be specified.

The voltage applied to an electrochemical cell controls the energy of electrons in the working electrode. When the energy of free electrons in the metallic phase is made sufficiently high, the electrons can occupy vacant orbitals in substances present in the solution near the electrode surface giving rise to a reduction current. In contrast, when the electrode potential is driven toward positive values, the lower energy of electrons in the metal can initiate an electron transfer from the substance to the metal, yielding an oxidation current of the opposite sign. Electric currents caused by the heterogeneous exchange of electrons obey Faraday's law and are termed *faradaic currents.* The exchange of electrons between the electrode and the species in the solution is confined to a very short distance. The concentration of an electroactive substance near the electrode quickly becomes depleted and mass transport resupplies the reaction zone (Heyrovský and Kůta, 1966; Bard and Faulkner, 1980).

An electrode in contact with a solution of electrolyte is surrounded by a very thin layer of solution where there is an enhanced concentration of ions of one kind attracted by the charge of the electrode surface. The layer is known as the electrode double layer (Delahay, 1965, Delahay and Tobias, 1961), and the potential difference between the electrode and the solution is confined within this space. The mass transport of electroactive ions, if present as the only ionic species, would necessarily involve migration, change of the double layer in time and space, and other complications. For these reasons, a strong electrolyte that is not electroactive in the given potential range (called the *indifferent* or *supporting electrolyte*) is added to the electrolyzed solutions in order to assure their good electrical conductivity, the elimination of migration phenomena, and relative simplicity of the double-layer composition. The electric current due to the charging of the double layer is called the *charging current* or *nonfaradaic current.* The theory of polarography and other electrochemical techniques solves the interplay of the electron-transfer rate (governed by the potential, by properties of the reacting substance, etc.) and the mass-transport rate. The instrumentation of electrochemistry solves the main problem of separation of faradaic and charging currents.

2. POLAROGRAPHY IN ITS CLASSICAL FORM

The polarographic experiment is rather a simple one: the objective is to measure the dependence of the electric current i flowing through the mercury drop/solution interface as a function of the potential E applied to it (the "polarographic curve") (Bard and Faulkner, 1980). Since the days of Heyrovský, this is done in an automatic manner, and the "polarograph" ranks among the first automatic scientific instruments [Fig. 1(a)]. A slowly and linearly changing dc voltage (originally derived from a car battery and a ten-turn motor-driven potentiometer) is applied to the cell containing the solution of a sample. Solutions must be deoxygenated by passing a stream of an inert gas (nitrogen or

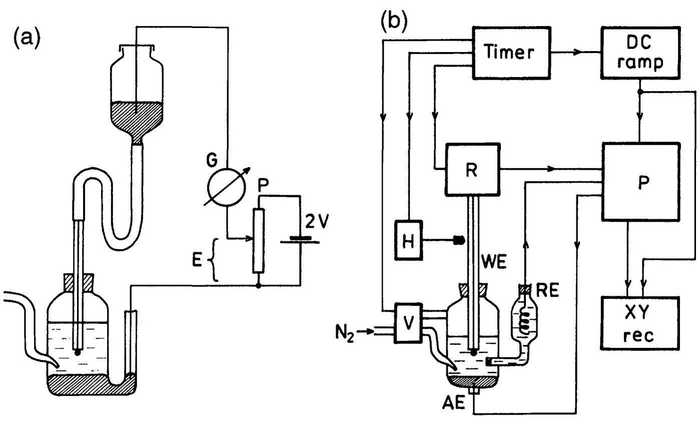

FIG. 1. Experimental setup for polarography: (a) Historical arrangement, where *P* is a ten-turn potentiometer and *G* is a galvanometer. (b) A contemporary polarograph consisting of a potentiostat *P* (see Fig. 6), a timer/synchronizer *T*, a dc ramp voltage generator, a mercury reservoir *R* with a solenoid valve, a mechanical hammer *H* for displacement of a drop, a gas valve *V*, and an *xy* recorder. The electrodes are denoted as WE, the working electrode; AE, the auxiliary electrode; and RE, the reference electrode.

argon) prior to the measurement because dissolved atmospheric oxygen itself gives a large reduction current. The range of 2 V or less is scanned in about 5 minutes. Every 2 to 6 seconds a mercury drop falls off (when its mass cannot be held by surface tension) and a clean new drop electrode pops out of the glass capillary. The current, of the order of microamperes, is amplified and an *xy* recorder is used for the desired chart of the current vs potential. Heyrovský's polarograph produced the record by focusing a beam of light reflected from a mirror galvanometer on the slit of a cassette with a rotating photographic paper coupled to the same motor as the potentiometer. The invention of solid-state devices profoundly changed the design of modern polarographic instrumentation [Fig. 1(b)] and enabled the development of many related methods. Advanced techniques differ from classical polarography by using a more complex shape of the potential wave form (superimposed small pulses, sine waves, and other perturbations) and by detecting only certain components of the resulting current response. A contemporary polarograph is a computer-controlled, multipurpose, electrochemical instrument that offers a variety of methods. Also, the dropping-mercury electrode is often replaced by a stationary mercury drop hanging on a more compact short column of mercury where the outflow is controlled by a magnetic valve at the upper orifice of the glass capillary. A sound understanding of the principles of classical polarography is still a prerequisite for a successful application of more advanced techniques.

Current-voltage curves, or polarographic curves, have shapes given by basic thermodynamic and kinetic principles. Let us consider an aqueous solution of a simple reducible cation like Cd^{2+} in a surplus of 0.1 M potassium chloride. In the potential range from 0 V to about -0.5 V, only a very small residual current flows corresponding to the charging of the electrode double layer. When the applied potential approaches the value of the standard potential $E^0 = -0.64$ V of the redox couple Cd^{2+}/Cd-amalgam, the electrolysis of cadmium salt begins and a reduction (or cathodic) current is observed. The magnitude of the current is given by Faraday's law,

$$i = nFA\frac{dN}{dt}, \qquad (1)$$

where n is the number of exchanged electrons ($n = 2$ for Cd^{2+}), F is the Faraday constant relating the electrolyzed amount to the passed electrical charge, and A is the surface area. The term dN/dt is the flux of particles reaching the surface, which in a general case can be expressed by the Nernst–Planck equation, including diffusion, migration, and convection terms. In the case of pure diffusion control, the electrolytic, or *faradaic*, current is proportional to the concentration gradient at the electrode surface, which can be derived on the basis of Fick's law expressed for an expanding spherical electrode. The solution of the corresponding partial differential equations yields proportionality of i to $t^{1/6}$ and to the bulk concentration. The seemingly unusual time exponent is the result of the mass transport decay ($t^{-1/2}$ according to the Cottrell equation) and the time dependence of the growing mercury-drop electrode (expanding with $t^{2/3}$). For a very fast reversible electron-transfer reaction, the concentrations at the electrode surface must obey the Nernst equation, which relates the potential E of an electrode with the concentration of oxidized and reduced forms (Ox and Red, respectively):

$$E = E^0 + \frac{RT}{nF} \ln \frac{[\mathrm{Ox}]}{[\mathrm{Red}]}. \tag{2}$$

The reduction current thus increases toward more negative potentials according to an exponential law. As a result of the depletion near the surface at potentials sufficiently more negative than E^0, the surface concentration of reducible substance (like Cd^{2+}) finally reaches zero. The further current increase levels off [Fig. 2(a)]. For the remaining part of the current-voltage curve, one observes a constant current, independent of the applied potential, which is called the *limiting current* or the *diffusion-limited current.* An uncomplicated fast–electron-transfer reaction is characterized by a polarographic curve in the form of an S-shaped dependence centered around E^0 with the limiting diffusion current proportional to the bulk concentration of electroactive substance (Cd^{2+} in our example). The magnitude of the limiting diffusion current is given by the Ilkovic equation (Heyrovský and Kůta, 1966), which gave the polarographic method a rigorous background:

$$i_d = 708nD^{1/2}\, C\, m^{2/3}\, t^{1/6}, \tag{3}$$

where C is the bulk concentration (in mol/cm^3), m is the flow rate of mercury (in mg/s), D is the diffusion coefficient (in cm^2/s), and the numerical term includes F and other constants. Already, from this simple introduction, we can deduce that the polarographic curves can be used for determination of the following parameters:

1. the bulk concentration of an electroactive substance,
2. the number of electrons involved in the redox reaction,
3. the standard redox potential,
4. the diffusion coefficient, and
5. the identity of an unknown substance on the basis of its E^0.

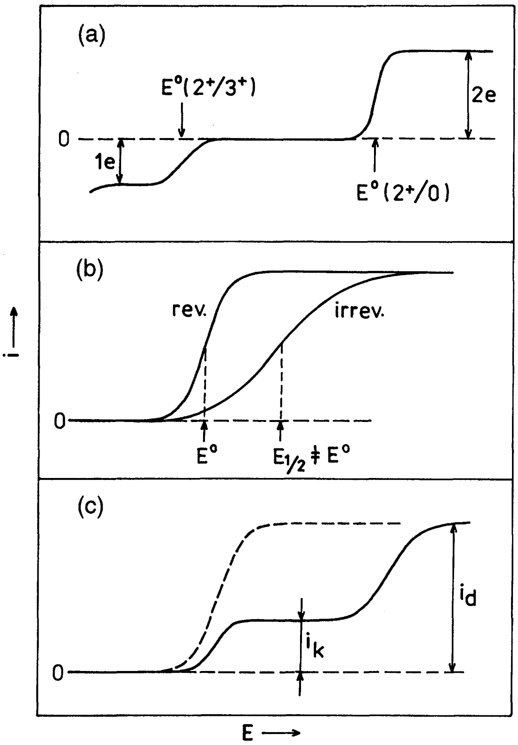

FIG. 2. Selected typical shapes of polarographic curves of current vs potential. (a) Example of a divalent metallic cation which is reduced to metal at $E^0(2^+/0)$ in a two-electron wave and oxidized to a trivalent state at $E^0(2^+/3^+)$. (b) Position of the half-wave potential of a reversible (rev.) and an irreversible (irrev.) wave with respect to E^0. (c) Limiting kinetic current (i_k) of a reversibly reduced form controlled by a preceding chemical reaction of an irreversibly reduced form (i_d). The dashed curve would be observed for a chemical reaction much faster than the diffusion.

The last two cases require a precise knowledge of other parameters and have only a limited scope.

2.1 Electrochemical Kinetics in Polarography

The previous section considered an ideal case of a simple electrode process with an infinitely fast electron-transfer rate. However, numerous redox reactions proceed with an energetic barrier resulting in a finite rate of the electron-transfer step

$$\mathrm{Ox} + ne \underset{k_b}{\overset{k_f}{\rightleftharpoons}} \mathrm{Red}, \tag{4}$$

where k_f and k_b are potential-dependent heterogeneous rate constants for reduction and oxidation, respectively. Kinetic hindrance in the reaction scheme (4) has a profound consequence on faradaic currents. The polarographic waves differ in shape and position in comparison with the previously described reversible case [Fig. 2(b)]. The wave is less steep, and the displacement from E^0 toward higher potentials (more negative for reduction and more positive for oxidation) reflects the kinetic hindrance. Furthermore, the observed currents depend on the time constant of the electrochemical method being used, or, in other words, on a time interval that a particular method affords to the mass transport (Macdonald, 1977). The time constant of polarography is given by the interval between two consecutive mercury-drop falls. Technical obstacles do not allow change of the drop time by more than one order of magnitude, and this limitation was one of the reasons for the introduction of other related polarographic techniques. The quantitative measure of a finite rate of electron transfer (Hush, 1971) is the value of the *standard heterogeneous rate constant* k^0 which has the dimensions $\mathrm{cm \cdot s^{-1}}$. The magnitude of k^0 determines the deviation of the *i-E* curve from the Nernstian shape, or the deviation from a fast equilibrium between oxidized and reduced forms of the substance under investigation. The rate of the electrochemical reduction at a given potential depends exponentially on E according to the Butler–Volmer formalism (Vetter, 1961),

$$k_f = k^0 \left[\frac{\alpha n F}{RT} (E - E^0) \right], \tag{5}$$

where α is the *transfer coefficient* (having values between 0 and 1, but in most cases approximately 0.5). A full explanation of the concept of the slow electrode reaction is a complex subject, and we will only mention that α is connected with the symmetry of the energy barrier for conversion between oxidized and reduced forms. The quantum mechanical theory of k^0 led to numerous correlations between homogeneous and heterogeneous electron-transfer rates, and studies of structural effects and of the influences of external fields, the solvation shell, etc. (Hush, 1971). The upper limit for the estimation of k^0 by the polarographic method is about 0.01 $\mathrm{cm \cdot s^{-1}}$, which implies that the faster reactions appear to be controlled solely by diffusion. In order to measure faster redox rates, numerous faster relaxation techniques have been developed. Unfortunately, the influence of diffusion diminishes in proportionality to $t^{-1/2}$, and hence the lowering of the time constant of a method by two orders of magnitude allows one to measure k^0 higher by only one order.

Another type of kinetic effects in electrode reactions involves the coupling of a chemical reaction and an electron-transfer reaction (Heyrovský and Kůta, 1966). From a long list of various reaction schemes (Rossiter and Hamilton, 1986), we will give here only a few representative mechanisms:

1. A preceding chemical reaction (called also CE mechanism, which is an abbreviation for the order of reactions "Chemical-Electrochemical"):

$$A \pm X \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{Ox} + ne \rightleftharpoons \mathrm{Red}. \tag{6}$$

The kinetic hindrance in this case is due to the finite rate of a chemical reaction between substances A and X, quantitatively expressed by the rate constants k_1 and k_{-1} (which are independent of E because the process is a homogeneous one). Typical examples are protonations $A + H^+$ and ligand dissociations $AL_n \rightarrow A + nL$. Chemical reactions can be coupled with both reversible and irreversible electron-transfer reactions. The reaction scheme (6) describes a situation when the solution contains substances A and X that are electroinactive (or active at much higher potentials), but their reaction yields a reducible product Ox participating in the electrode reaction. By analogy one can write the scheme for generation of an oxidizable substance Red. The consumption of Ox at the electrode surface shifts the equilibrium between $A + X$ and Ox. When the rate of that particular chemical reaction becomes the rate-determining step, the reduction current of Ox will be limited by a homogeneous reaction instead of mass transport [Fig. 2(c)]. Kinetic currents have been used for estimation of homogeneous rate constants of systems that would be difficult to tackle by other techniques.

2. Follow-up chemical reactions (abbreviated sometimes as "EC mechanism" for the sequence "Electrochemical-Chemical" reaction) have an order of reactions the reverse of that for the scheme (6):

$$\mathrm{Ox} + ne \rightleftharpoons \mathrm{Red} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{Product}. \qquad (7)$$

   The product of a follow-up chemical reaction can originate from a simple monomolecular decomposition of Red or from a bimolecular coupling of electrogenerated radicals, or the reaction mechanism can involve other substances present in the solution.

3. Catalytic regeneration of the electroactive substance is a special case of follow-up reaction in which the product is the starting material; in the case of Eq. (7) it is the Ox form. The observed currents then exceed the diffusion-limited values (given by the concentration in the solution) because Red is "recycled." This class of mechanism is the focus of interest for many reasons. For example, the analytical applications take advantage of catalytic enhancement of the faradaic current to achieve a substantial extension of the detection limits.

3. DERIVED POLAROGRAPHIC TECHNIQUES

The previous section pointed to certain restrictions of classical polarography in kinetic studies, but this is not the only limitation. So far we did not consider the circumstance that the electrode–solution interface consists of the electrode double layer having a fairly large electrical capacity, of the order of 10–100 $\mu\mathrm{F}\cdot\mathrm{cm}^{-2}$. This capacitor must be recharged with any change of the electrode area and during the formation of a fresh electrode surface. The ever-present double-layer charging current imposes a lower limit for detection of faradaic processes, which at trace concentrations become hidden in a much larger charging current. Fortunately, the charging current and the faradaic current differ in their time decay, a fact that is the basis for a better resolution of more sophisticated techniques. The electrode double layer behaves as a condenser connected to the voltage source via a solution resistance R_s. Upon application of a constant potential the charging current decays exponentially, with the time constant R_sC (where C is the double-layer capacitance), and after the time lapse of $5R_sC$ its contribution is negligible. The faradaic current also decays with time, but more slowly ($t^{-1/2}$ decay according to the Cottrell equation). Sampling and subtraction of the experimental current at different time instances is the essence of pulse polarography. Different time lags of the two current contributions leads to different phase relations when transformed to the frequency domain, and this property is the main virtue of ac polarography. The methods described below tackle the same problem: the discrimination between charging and faradaic phenomena.

3.1 Pulse Polarography

The applied potential in classical polarography is practically constant during the life of each drop of the dropping-mercury electrode (more precisely, its linear change with time is so slow that it becomes negligible). The pulse polarographic techniques are based on the application of a short rectangular pulse (10–100 ms) superimposed on the dc potential shortly before the end of the drop life. Three related techniques (Greef *et al.*, 1985; Bard and Faulkner, 1980) are called "normal pulse polarography" (NPP), "differential pulse polarography" (DPP), and "square-wave polarography" (SWP), and all differ solely in the form of the pulse shapes and the current sampling modes. The recent revival of electrochemistry in environmental control is due to the high sensitivity and the low cost of equipment for DPP and SWP. DPP uses a polarization regime in which a linearly increasing potential ramp is applied to the electrode (as in the classical polarography); however, close to the end of the drop life the current is sampled, a rectangular pulse of an amplitude of 10–50 mV is triggered, and prior to the end of the pulse another current sampling is made [Fig. 3(a)]. The recorded signal is the difference of the two current samples, which gave this method its name "differential pulse." The difference signal suppresses substantially the

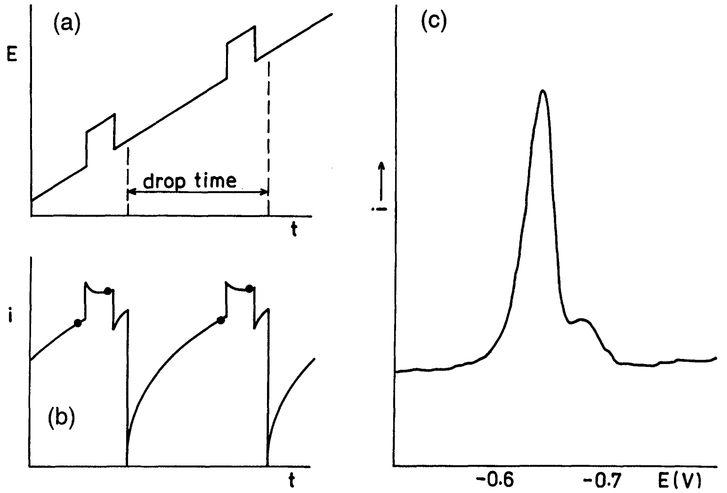

FIG. 3. Differential pulse polarography: (a) The shape of the applied potential; (b) current during the drop life; (c) example of a DPP curve of arsenic at concentration 50 μg/l.

contribution of the unwanted charging current, and the recorded curve has the shape of the first derivative of the corresponding classical polarographic wave. Closely spaced faradaic peaks are hence better resolved than the merging waves. A small drawback of the DPP is a nonlinear background line, which comes into question only at the highest sensitivity levels. DPP is often used in combination with pre-electrolysis or other means of accumulation of products followed by the reverse reaction. This type of sensitivity enhancement is called *stripping* and finds application in the trace analysis either of heavy metals, which form amalgams with the mercury electrode (anodic stripping), or of substances that form insoluble compounds with mercury ions (cathodic stripping). Analogously, *adsorptive stripping* makes use of adsorption accumulation, which saturates the electrode surface with the substance to be determined by its adsorption at a certain constant potential. A voltage scan that follows the accumulation (often accelerated by stirring the solution) changes the electrode potential to values where desorption from the surface takes place. The desorption process yields a sharp current maximum proportional to the bulk concentration provided that the accumulation time, stirring, and other parameters are identical to those in the calibration experiments.

3.2 ac Polarography

ac polarography is a technique based on the measurement of the electrode admittance (the reciprocal of the impedance) as a function of the dc potential. The method is implemented by perturbing the slowly scanned dc potential by a small-amplitude sine-wave form. The signal processing involves filtration of the ac current component corresponding to the ac perturbation followed by amplification and phase-sensitive detection (Smith, 1966; Sluyters-Rehbach and Sluyters, 1970). The ac current is a vector having a phase relation to the ac potential determined by the impedance of the electrochemical cell and by the frequency of the ac signal. The most common mode of ac polarography records two vector components of the ac current (the in-phase and the out-of-phase components, sometimes called the "real" and "imaginary" components, respectively) as a function of the dc potential. The ac polarogram of a sample containing only the supporting electrolyte yields a real component equal to zero and an imaginary current component proportional to the double-layer capacity and the applied frequency [Fig. 4(a)]. Phase-sensitive ac polarography is often used for investigation of adsorption processes, evaluation of adsorption isotherms, and studies of the growth of adsorbed films and of the influence of adsorption of inhibitors on the rate of electrode reactions.

The presence of an electroactive substance in the solution gives peak-shaped maxima on both vector components [Fig. 4(b)], which can be used for analytical purposes. The positions and ratio of the two faradaic maxima may be used for diagnostics of the mechanism of electrode processes and

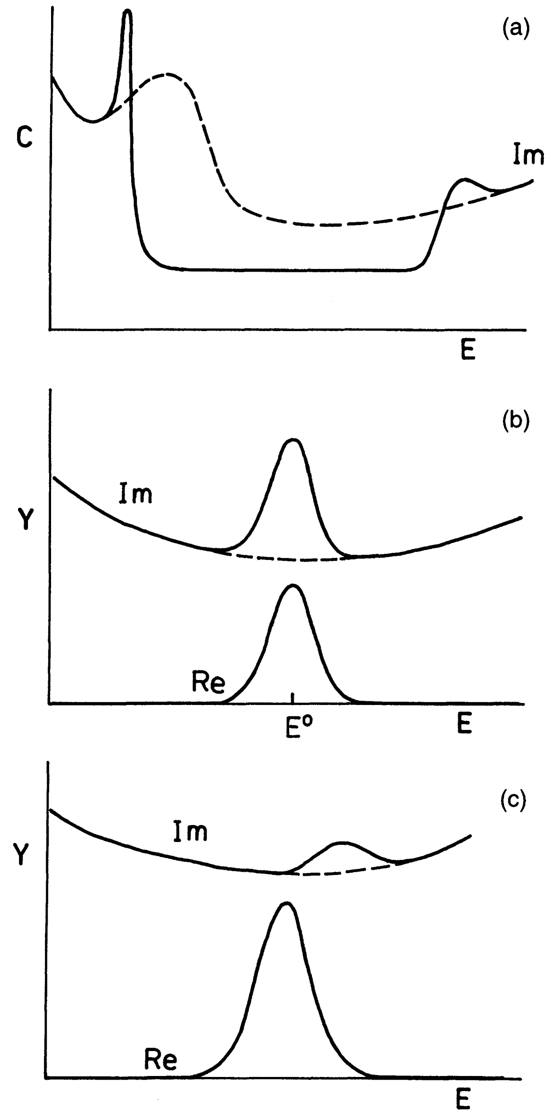

FIG. 4. Selected typical shapes of phase-sensitive ac polarograms (Re and Im denote the real and imaginary components, respectively): (a) The double-layer capacitance of an indifferent electrolyte (dashed curve) and in the presence of an adsorbable surfactant. The two maxima frame the potential region of adsorption. (b) Faradaic maxima of a reversible redox system. (c) Faradaic maxima of a system with kinetic control. Such a picture can be obtained from case (b) by choosing a sufficiently high frequency.

for the estimation of kinetic parameters (Macdonald, 1977). The time constant of ac polarography is given by the frequency of the ac perturbation, and hence it could be varied over a much wider range than for previously described techniques. The impedance data extracted from a set of ac polarograms are often analyzed in the complex plane and interpreted in terms of an equivalent circuit or a transmission-line model. A faster collection of impedance spectra is achieved by a broadband perturbation combined with the fast Fourier transform or similar procedures. Other derived ac techniques, like second-harmonic ac polarography and the faradaic rectification method, have been developed, but at present are rarely used.

4. VOLTAMMETRY

The mercury electrode can be used in a wide potential range limited at negative potentials by the electrolytic decomposition of the solvent (−2 V in water and about −3.2 V in dry nonaqueous solvents) and at positive potentials by the anodic oxidation of mercury (+0.6 V or less). Platinum, gold, and carbon are the most common materials used for the investigation of oxidation reactions proceeding at positive potentials not attainable at mercury electrodes. In experiments performed with solid electrodes, the surface concentration cannot be renewed (as for liquid mercury drops) and the current–voltage curves have shapes characterized by depletion of the electroactive substance near the surface. Instead of the potential-independent plateau of limiting currents in polarography, the voltammetric limiting current steadily decays, reflecting the exhaustion of concentration. Otherwise both polarography and voltammetry are techniques that measure the same quantity, the faradaic current as a function of the applied potential. Since the electrode surface and the initial concentrations at the interface are not periodically renewed (as in polarography), the observed *i*-*E* curve combines the effects of an *i*-*t* decay and a linear *E*-*t* change. For voltammetry a more accurate name, *linear potential sweep chronoamperometry,* is sometimes used, but most of the applications refer to this method as *linear sweep voltammetry.* The change of the potential with time is $E(t) = E_i - vt$, where the initial potential is E_i and v is the sweep or scan rate. The sweep rate is an important variable, which determines the time constant of the voltammetric method. In contrast with polarography, the sweep rate can be chosen in the range of v from 0.05 to

1000 V/s (or even to MV/s), and this feature makes the method very suitable for the detection of short-lived intermediates of complicated redox reactions. The original design of a voltage source for variable scan rates used solid-state operation amplifiers generating the desired linear voltage ramp on the basis of an analog integrator. Currently, many instruments implement the voltage ramp by means of computer-controlled digital-to-analog converters, which results in a staircase voltage. The two methods are theoretically equivalent only for very small step increments. When differences are noticeable, the latter method is called *staircase voltammetry* and a corresponding theoretical treatment is available. We recall that commercial oscillators or function generators are not suitable for a voltammetric experiment. Voltammetry requires the ability to vary the asymmetrical amplitude (the initial and final potentials) and at the same time maintain an unchanged slope (the scan rate), while the change of frequency is irrelevant.

In the course of a potential-sweep experiment, there develops a concentration gradient of generated products of electrode reactions. By reversing the direction of the potential sweep at a certain potential we can record the corresponding reverse redox processes (reoxidation or rereduction). This reversal technique is called *cyclic voltammetry* and has proven to be one of the basic tools for analysis of an unknown complicated electrode mechanism (Noel and Vasu, 1990; Smyth and Vos, 1992). Unfortunately, there is always a price to be paid for an advantage, and in the case of voltammetry it is the complicated mathematics originating from the time dependence of $E(t)$. Many important reaction schemes cannot be easily solved in a closed form, which led to the development of sophisticated simulation methods (Feldberg, 1969; Britz, 1981).

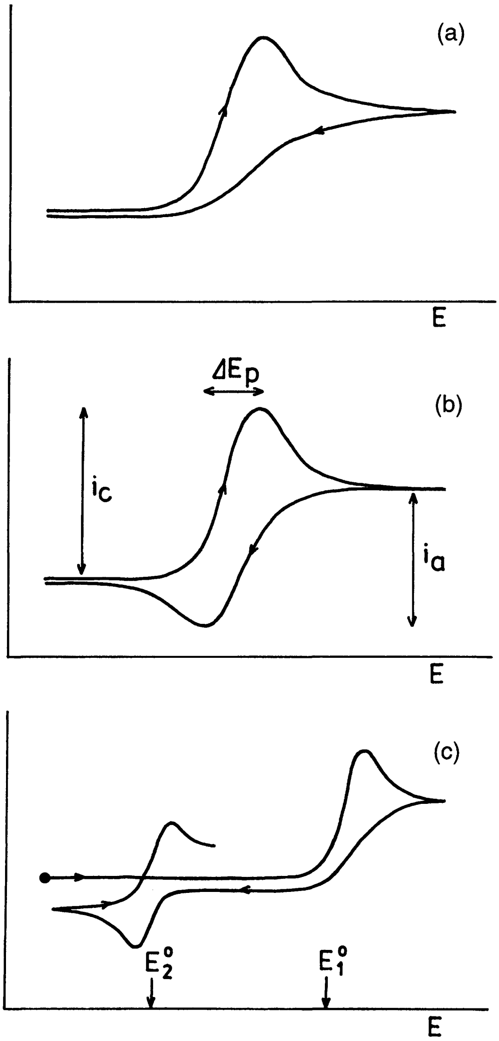

FIG. 5. Selected typical shapes of cyclic voltammograms (arrows mark the scan direction): (a) Reduction coupled with a follow-up chemical decomposition of the product measured at a slow scan rate; (b) the same system as in (a) measured at a high scan rate yielding reversible behavior. Important diagnostic parameters are the ratio of cathodic and anodic currents i_c/i_a, and the separation of peak potentials ΔE_p. (c) Example of a system with E_1^0 yielding in a follow-up reaction a new reversible redox system with E_2^0.

An uncomplicated reversible system yields a cyclic voltammogram that features the forward and reversed wave shapes as mutual mirror images of one another with respect to E^0. Any kind of irreversibility of the electron-transfer reaction is sensitively reflected in the differences of the currents recorded during the forward and backward scanning. A typical area of application is the detection of a coupled chemical decomposition of the primary product (Fig. 5). While the reverse scan fails to yield the mirror wave form at slow scan rates v (the conditions allow a complete decomposition of the product), at a sufficiently high scan rate one can observe again the electrochemical reversibility of the investigated system because the reoxidation (or rereduction) takes place much faster than the chemical decomposition. The limited space of this article does not allow the author to go into details of this powerful method, which has been worked out in substantial detail both in theory and in the experimental approach. For the evaluation of experiments, pattern recognition methods were also applied.

The latest improvement of voltammetry is the use of ultramicroelectrodes, which are made of a glass-sealed platinum wire or carbon fiber having a diameter of the order of microns or even less. These electrodes have much smaller interfacial area than the conventional ones. Both the double-layer capacitance and the current generated at these electrodes are correspondingly smaller, which results in a signal considerably less distorted by the Ohmic resistance of the solution. Also, the smaller time constant of the cell makes possible the achievement of faster perturbation rates. The measurements can be made even in the absence of an indifferent electrolyte, making microelectrodes an attractive tool for sensing pollutants in water or for other applications in high-resistance media.

5. EXPERIMENTAL EQUIPMENT

Basic electrochemical equipment must deal with various problems specific for a given application. The most common questions are the choice of a suitable electrode material for the working electrode, elimination of a high Ohmic resistance of some samples, especially in nonaqueous solvents or at low temperatures, and an improvement of the signal-to-noise ratio at ultralow concentrations of electroactive material.

5.1 Working Electrodes, Solvents, Indifferent Electrolytes

For investigation of reduction processes in water or nonaqueous solvents containing strong acids, the electrode of choice is the mercury electrode. A very slow hydrogen evolution reaction on mercury in comparison with noble metals in concentration of acids as high as 1 $\text{mol} \cdot \text{l}^{-1}$ enables the measurements up to -1 V. Using low-proton media extends the range of accessible potentials to -2.5 V. The indifferent electrolytes are chosen according to the solubility in the given solvent. In aqueous solutions, common salts are the alkali metal halides or perchlorates (when complexation by halides has to be avoided) and a variety of *p*H-regulating buffer solutions. Nonaqueous electrochemistry uses mainly tetra-alkylammonium perchlorates, tetrafluoroborates, and hexafluorophosphates as indifferent electrolytes. Voltammetric measurements have been performed also in liquid gases (SO_2 and NH_3) and in low-temperature melts.

The facile oxidation of metallic mercury limits the useful potential range on the positive side to $+0.2$ to $+0.6$ V depending on the medium. For this reason noble metals, platinum and gold, are used in oxidation studies; however, in aqueous solutions both these metals become covered with a layer of oxides. An inert noble-metal electrode performs quite satisfactorily in nonaqueous solvents. The recently developed technique of preparing ultramicroelectrodes of diameters 0.5 to 20 μ solves the problems of the Ohmic drop of potential in the sample but requires a more sensitive detection of low-level currents. Microelectrodes enable one to perform measurements in solutions without indifferent electrolyte, which makes them promising tools in solvents of a low dielectric constant. Other popular electrodes are various forms of carbon: the glassy-carbon disk electrode and the carbon-paste electrode. All solid electrodes are used also in the form of a rotating disk embedded in an insulating Teflon rod. A special class is constituted by the *modified electrodes* designed in such a way that a solid electrode is covered by a layer of a polymer containing electroactive centers. Surface modifying techniques in most cases are based on oxidative polymerization, but surface casting is used as well. Modified layers containing zeolites, enzymes, or ion-selective polymers are described as special-purpose sensors. The main problem of modified electrodes is good stability and adhesion of a modifier to a metal substrate. The last type of electrodes to be mentioned here is optically transparent electrodes needed for a combination of electrochemical and spectroscopic techniques. The design is based either on a fine micromesh (about 1000 wires/inch) of Au or Pt electrodes, or on a thin transparent layer of conducting tin oxide or indium oxide on glass or quartz. Such electrodes make possible the identification of redox products by their spectral characterization *in situ.*

5.2 Instrumentation

As we said in the introduction, the instrumentation that sufficed for the Nobel prize experiment was the simplest that one can imagine. Low investment cost for electrochemistry still holds, and even now many laboratories rely on their own design of electronic equipment. The heart of the measuring system is a *potentiostat,* which is an analog feedback-controlled circuit performing an automatic compensation of the Ohmic drop of the potential in the cell in such a way that the working electrode is polarized to a desired value regardless of the amount of current that flows (Bard and Faulkner, 1980). The potentiostat in its simple form consists of three solid-state operational amplifiers (Fig. 6). An adder sums all the potential wave forms needed for a given method and a negative feedback loop senses the actual potential of the working electrode against the reference electrode. A current follower maintains the working electrode on the potential of a virtual ground and yields at its output a signal proportional to the measured current that is suitable for further conditioning or a direct recording. The third operational amplifier serves as an impedance buffer (a voltage follower), preventing the reference electrode from undesired loading. Programmable potential-wave forms are usually generated by a computer by means of a digital-to-analog converter having at least a 12-bit resolution. More sophisticated techniques like ac polarography or very fast voltammetry use correspondingly more expensive signal-conditioning instruments (lock-in amplifiers, transient recorders, digital oscilloscopes).

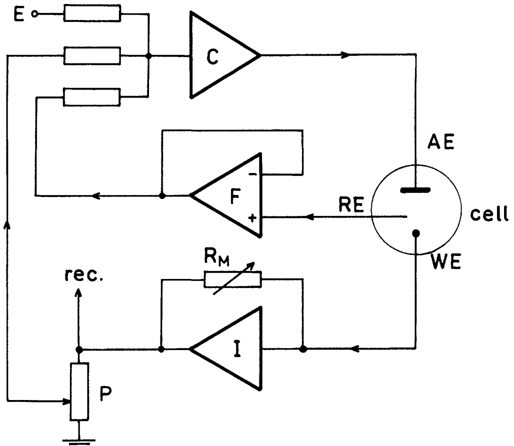

FIG. 6. Schema of a potentiostat: The potential *E* that has to be maintained is fed to a controlling amplifier *C* and to the auxiliary electrode *AE*. The working electrode *WE* is kept at the potential of a virtual ground; the current is measured by a current-to-voltage converter *I* (R_M is the measuring resistor) and led to a recorder. The voltage follower *F* senses the actual applied voltage vs the reference electrode *RE* and forms the negative-feedback loop. An additional compensation of the solution resistance can be achieved by a positive-feedback loop via a ten-turn potentiometer *P*. Passive elements stabilizing the circuit are not shown.

6. APPLICATIONS

The exceedingly large amount of electrochemical applications cannot be classified in a short paragraph. We can only refer to available encyclopedic or special literature (Baizer, 1973; Bard and Lund, 1973–80; Meites and Zuman, 1974). Analytical applications allow the determination of almost all elements that are required for monitoring either in industrial processes or in pollution control (Florence, 1989). Organic electroanalysis finds its place in food control, clinical tests, pharmacology, agrochemistry, pesticide control, and numerous other fields (Smyth and Vos, 1992). An equally important role is played by electrochemical techniques in research praxis because the redox characteristics of a new synthetic compound is information as important as its spectral, crystallographic, and other parameters.

INTRODUCTION

The polaron concept is of interest, not only because it describes the particular physical properties of an electron in polar crystals and ionic semiconductors, but also because it is an interesting field-theoretical model consisting of a fermion interacting with a scalar boson field.

The early work on polarons was concerned with general theoretical formulations and approximations, which now constitute the standard theory, and with experiments on cyclotron-resonance and transport properties.

Because of the more recent interest in the two-dimensional electron gas (2DEG), the study of the polaron in two dimensions became important. Cyclotron resonance, and therefore the behavior of polarons in magnetic fields, was a key issue.

1. THE POLARON CONCEPT AND THE FRÖHLICH POLARON

1.1 The Concept

A conduction electron (or hole) together with its self-induced polarization in a polar semiconductor or an ionic crystal forms a

quasiparticle, which is called a polaron (Fig. 1). The physical properties of the polaron differ from those of the band electron. In particular, the polaron is characterized by its binding (or self-) energy, its effective mass, and its response to external electric and magnetic fields (e.g., mobility and impedance). The general polaron concept was introduced by Landau (1933) in a paper of about one page. Subsequently, Landau and Pekar (see Pekar, 1951) investigated the self-energy and the effective mass of the polaron, for what was shown by Fröhlich (1954) to correspond to the adiabatic or strong-coupling regime.

The early work on polarons was devoted to the interaction between a charge carrier (electron, hole) and the long-wavelength optical phonons. The (now standard) field-theoretical Hamiltonian describing this interaction was derived by Fröhlich:

$$\mathrm{H} = \frac{p^2}{2m_b} + \sum_k \hbar\omega_{\mathrm{LO}} a_{\mathbf{k}}^{\dagger} a_{\mathbf{k}} + \sum_k (V_k a_k e^{i\mathbf{k}\cdot\mathbf{r}} + H.c.), \tag{1a}$$

where $\mathbf{r}$ is the position coordinate operator of the electron with band mass m_b, $\mathbf{p}$ is its canonically conjugate momentum operator, and $a_{\mathbf{k}}^{\dagger}$ and $a_{\mathbf{k}}$ are the creation (and annihilation) operators for longitudinal optical phonons of wave vector $\mathbf{k}$ and energy $\hbar\omega_{\mathrm{LO}}$. The V_k are Fourier components of the electron–phonon interaction:

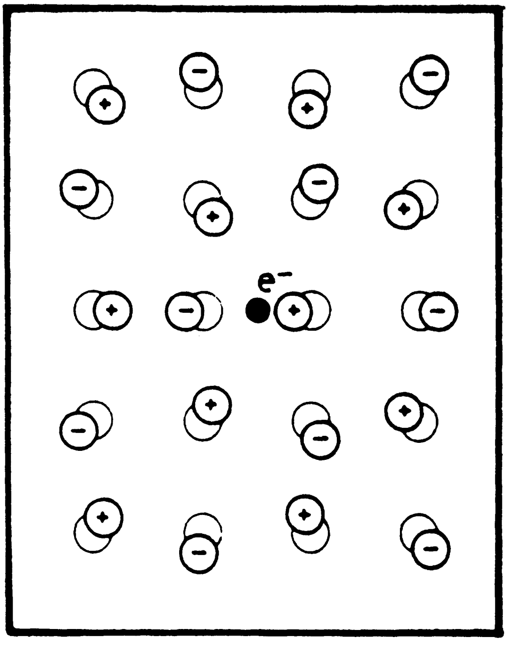

FIG. 1. A conduction electron (or hole) together with its self-induced polarization in a polar semiconductor or an ionic crystal forms a quasiparticle: a polaron.

$$V_k = -i\frac{\hbar\omega_{\mathrm{LO}}}{k}\left(\frac{4\pi\alpha}{V}\right)^{1/2}\left(\frac{\hbar}{2m_b\omega_{\mathrm{LO}}}\right)^{1/4}, \tag{1b}$$

$$\alpha = \frac{e^2}{\hbar c}\sqrt{\frac{m_b c^2}{2\hbar\omega_{\mathrm{LO}}}}\left(\frac{1}{\epsilon_\infty} - \frac{1}{\epsilon_0}\right). \tag{1c}$$

Here α is called the Fröhlich coupling constant; ϵ_∞ and ϵ_0 are respectively the electronic and the static dielectric constant of the polar crystal. In Table 1, a list is given of the coupling constants for a number of crystals.

In deriving the form of V_k, Eqs. (1b) and (1c), it was assumed that

1. the spatial extension of the polaron is large compared with the lattice parameters of the solid ("continuum" approximation);
2. spin and relativistic effects can be neglected;
3. the band electron has parabolic dispersion; and
4. in conjunction with the first approximation it is also assumed that the LO phonons of interest for the interaction are the long-wavelength phonons with constant frequency ω_{LO}.

The original concept of the polaron, as discussed above, has been generalized over the years to include polarization fields other than the LO-phonon field: the acoustical-phonon field, the exciton field, etc. For some materials, the continuum approximation is

Table 1. Fröhlich coupling constants.

Material	α	Material	α
CdTe	0.31	KI	2.5
CdS	0.52	RbCl	3.81
ZnSe	0.43	RbI	3.16
AgBr	1.53	CsI	3.67

InSb	0.02	GaP	0.201
KCl	3.5	InAs	0.052
KBr	3.05	$SrTiO_3$	4.5

not appropriate insofar as the polarization is confined to a region of the order of a unit cell; the so-called "small polaron" is a more adequate quasiparticle in that case (see Sec. 2).

It is customary to use the term "Fröhlich polaron" or "large polaron" for the quasiparticle consisting of the electron (or hole) and the polarization due to the LO phonons. The term Landau or Pekar or Landau–Fröhlich polaron would be more appropriate.

In this first section, the properties of Fröhlich polarons are reviewed; other realizations of the polaron concept (small polarons, spin polarons, etc.) are discussed in later sections. For reviews on polarons, see Kuper and Whitfield (1963), Appel (1968), Devreese (1972), and Devreese and Peeters (1984).

1.2 Standard Fröhlich-Polaron Theory. Self-Energy and Effective Mass of the Polaron

Historically, the first studies on polarons [the "Russian work": Landau (1933), Pekar (1951)] were based on a *Produkt-Ansatz* for the polaron wave function,

$$|\Phi\rangle = |\Psi(\mathbf{r})\rangle|\text{field}\rangle = |\Psi(\mathbf{r})\rangle|f\rangle, \tag{2a}$$

where $|\Psi(\mathbf{r})\rangle$ is the electron wave function. The field wave function parametrically depends on the electron wave function. Fröhlich showed that the approximation (2a) leads to results that are only valid as $\alpha \to \infty$ (the strong-coupling regime). It should be pointed out that a more systematic analysis of the strong-coupling polarons based on canonical transformations of the Hamiltonian (1a) was performed in pioneering investigations by Bogolubov (1950), Bogolubov and Tyablikov (1949), and Tyablikov (1951).

Fröhlich also found that Eq. (2a) is a poor *Ansatz* to represent actual crystals, which have α values typically ranging from $\alpha = 0.02$ (InSb) to $\alpha \sim 3$ to 4 (alkali halides). This work showed the need for a weak-coupling theory of the polaron, which in fact was provided originally by Fröhlich (1954). However, it turns out that for $\alpha \approx 3$ perturbation expansions in powers of α are not always sufficient; therefore an intermediate-coupling or—better—an all-coupling theory was necessary.

In what follows, the key concepts of the standard Fröhlich-polaron theories are reviewed.

1.2.1 Strong Coupling The *Produkt-Ansatz* (2a)—or Born–Oppenheimer approximation—implies that the electron adiabatically follows the motion of the atoms (Pekar, 1951). With the use of the canonical transformation

$$S = \exp\left[-\sum_{\mathbf{k}}\left(\frac{V_k^* \rho_{\mathbf{k}}^*}{e\hbar\omega_{\mathrm{LO}}} a_{\mathbf{k}} - H.c.\right)\right], \tag{2b}$$

where

$$\rho_{\mathbf{k}} = e\langle\Psi(\mathbf{r})|e^{i\mathbf{k}\cdot\mathbf{r}}|\Psi(\mathbf{r})\rangle, \tag{2c}$$

it leads to $|f\rangle = S|0\rangle$. The ket $|0\rangle$ describes the vacuum state. With Eqs. (2) and a Gaussian trial function for $|\Psi(\mathbf{r})\rangle$, the ground-state energy of the polaron E_0 (calculated with the energy of the uncoupled electron–phonon system as zero energy) takes the form

$$E_0 = -(\alpha^2/3\pi)\hbar\omega_{\mathrm{LO}} = -0.106\alpha^2\hbar\omega_{\mathrm{LO}}. \tag{3a}$$

At strong coupling, the polaron is characterized by Franck–Condon (FC) excited states, which correspond to excitations of the electron in the potential adapted to the ground state. The energy of the lowest FC state is, within the *Produkt-Ansatz*,

$$E_{\mathrm{FC}} = (\alpha^2/9\pi)\hbar\omega_{\mathrm{LO}} = 0.0354\alpha^2\hbar\omega_{\mathrm{LO}}. \tag{3b}$$

If the lattice polarization is allowed to relax or adapt to the electronic distribution of the excited electron (which itself then adapts its wave function to the new potential, etc., leading to a self-consistent final state), the so-called relaxed excited state (RES) results (Pekar, 1951). Its energy is (Evrard, 1965; Devreese and Evrard, 1966)

$$E_{\mathrm{RES}} = -0.041\alpha^2\hbar\omega_{\mathrm{LO}}. \tag{3c}$$

In fact, both the FC state and the RES lie in the continuum* and, strictly speaking, are resonances (Fig. 2).

The strong-coupling mass of the polaron,

---

*The RES lies in the continuum of so-called scattering states, not indicated in Fig. 2.

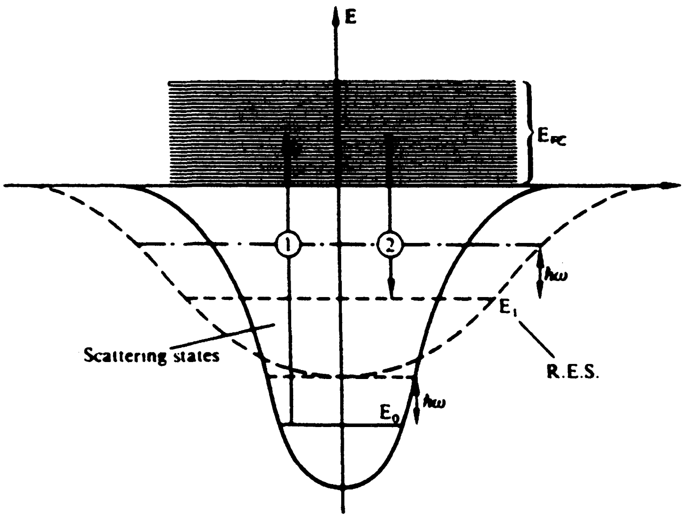

FIG. 2. Internal excitations at strong coupling: E_0, ground state; E_1, first relaxed excited state; E_{FC}, Franck–Condon state.

resulting again from the approximation (2), is given as

$$m^*/m_b = 1 + 0.0200\alpha^4. \tag{3d}$$

More rigorous strong-coupling expansions for E_0 and m^* have been presented in the literature (Miyake, 1975):

$$E_0/\hbar\omega_{\mathrm{LO}} = -0.108\,513\alpha^2 - 2.836, \tag{4a}$$

$$m^*/m_b = 1 + 0.022\,7019\alpha^4. \tag{4b}$$

The main significance of the strong-coupling theory is that it allows a test of "all-coupling" theories in the limit $\alpha \to \infty$. From the formal point of view, a deeper study of the status and uniqueness of the strong-coupling solutions was undertaken by Lieb (1977).

1.2.2. Weak Coupling Fröhlich (1954) has provided the first weak-coupling perturbation-theory results:

$$E_0 = -\alpha\hbar\omega_{\mathrm{LO}} \tag{5a}$$

and

$$m^* = \frac{m_b}{1 - \alpha/6}. \tag{5b}$$

Inspired by the work of Tomonaga, Lee *et al.* (1953) (usually cited as LLP) have derived Eq. (5a) and $m^* = m_b(1 + \alpha/6)$ from an elegant canonical transformation formulation. In fact, they perform two successive canonical transformations: first,

$$S_1 = \exp\left[\frac{i}{\hbar}\left(\mathbf{P} - \sum_{\mathbf{k}} \hbar\mathbf{k}a^\dagger_{\mathbf{k}}a_{\mathbf{k}}\right)\cdot\mathbf{r}\right], \tag{6a}$$

where $\mathbf{P}$ is the polaron total-momentum operator. The canonical transformation (6a) formally eliminates the electron operators from the Hamiltonian.

The second canonical transformation is of the "displaced-oscillator" form:

$$S_2 = \exp\left[\sum_{\mathbf{k}} (a^\dagger_{\mathbf{k}}f_{\mathbf{k}} - a_{\mathbf{k}}f^*_{\mathbf{k}})\right]. \tag{6b}$$

The $f_{\mathbf{k}}$ are treated as variational functions. The physical significance of Eq. (6b) is that it "dresses" the electron with the virtual phonon field that describes the polarization.

The LLP approximation has often been called "intermediate-coupling theory." However, its range of validity is in principle not larger than that of the weak-coupling approximation. The main significance of the LLP approximation is in the elegance of the canonical transformations S_1 and S_2, together with the fact that it puts the Fröhlich result on a variational basis.

In his basic article on polarons, Feynman (1955) found the following higher-order weak-coupling expansions:

$$E_0/\hbar\omega_{\mathrm{LO}} = -\alpha - 0.0123\alpha^2 - 0.00064\alpha^3 - \cdots \ (\alpha \to 0), \tag{7a}$$

$$m^*/m_b = 1 + \frac{\alpha}{6} + 0.025\alpha^2 + \cdots \ (\alpha \rightarrow 0). \tag{7b}$$

Since then a lot of theoretical work has been devoted to obtaining more exact coefficients in this expansion. Höhler and Müllensiefen (1959) calculated the coefficients for α^2 to be -0.016 in the energy and 0.0236 in the polaron mass. Röseler (1968) found the analytical expressions for the above-mentioned coefficients: $2\ \ln(\sqrt{2} + 1) - \frac{3}{2}\ \ln 2 - \frac{1}{2}\sqrt{2} \approx -0.015\,919\,62$ and $\frac{4}{3}\ \ln(\sqrt{2} + 1) - \frac{2}{3}\ \ln 2 - 5\sqrt{2}/8 + \frac{7}{36} \approx 0.023\,627\,63$, respectively. At present, the following most accurate higher-order weak-coupling expansions are known: for the energy (Smondyrev, 1986; Selyugin and Smondyrev, 1989),

$$E_0/\hbar\omega_{\mathrm{LO}} = -\alpha - 0.015\,919\,6220\alpha^2 - 0.000\,806\,070\,048\alpha^3 - \cdots, \tag{7c}$$

and for the polaron mass (Röseler, 1968),

$$m^*/m_b = 1 + \tfrac{1}{6}\alpha + 0.023\,627\,63\alpha^2 + \cdots, \tag{7d}$$

which are a striking illustration of the heuristical value of Feynman's path-integral approach in the polaron theory as follows from comparison of Eqs. (7a) and (7b) with Eqs. (7c) and (7d), respectively.

1.2.3 All-Coupling Theory. Feynman Path Integral In the early 1950s, H. Fröhlich gave a seminar at Caltech. In this seminar, he discussed the weak-coupling polaron mass as derived by him: $m^* = m_b/(1 - \alpha/6)$. He suggested that if the electron–phonon coupling could be accurately treated for intermediate coupling (in particular around $\alpha \approx 6$) this might lead to new insights in the theory of superconductivity (this was before BCS) (Feynman, 1973). Feynman was among the audience. He went to the library to study one of Fröhlich's papers on polarons (Fröhlich, 1954). There he got the idea to formulate the polaron problem into the Lagrangian form of quantum mechanics and then eliminate the field oscillators, "... in exact analogy to QED ... (resulting in) ... a sum over all trajectories. ..." The resulting path integral is of the form (Feynman, 1955)

$$\langle 0,\beta|0,0\rangle = \int \mathfrak{D}\mathbf{r}(\tau)\exp\left[-\tfrac{1}{2}\int_0^\beta \dot{\mathbf{r}}^2 d\tau + \frac{\alpha}{2^{3/2}}\int_0^\beta\int_0^\beta \frac{e^{-|\tau-\sigma|}}{|\mathbf{r}(\tau) - \mathbf{r}(\sigma)|}\,d\tau d\sigma\right], \tag{8}$$

where $\beta = 1/k_{\mathrm{B}}T$. This path integral (8) has a great intuitive appeal: It shows the polaron problem as an equivalent one-particle problem in which the interaction, nonlocal in time or "retarded," is between the electron and itself. Subsequently, Feynman showed (in fact to M. Baranger) how the variational principle of quantum mechanics could be adapted to the path integral and introduced a quadratic trial action (again nonlocal in time) to simulate Eq. (8). It may be noted that the elimination of the phonon field (or the boson field in general) introduced through Eq. (8) by Feynman has found many applications, e.g. in the study of dissipation phenomena.

Applying the variational principle for path integrals resulted in an upper bound for the polaron self-energy at all α, which at weak and strong coupling gave quite accurate limits. Feynman obtained the smooth interpolation between weak and strong coupling (for the ground-state energy). It is worth while to give the asymptotic expansions of Feynman's polaron theory. In the weak-coupling limit, they are given above by Eqs. (7a) and (7b). In another—strong-coupling—limit Feynman found for the energy

$$\frac{E_0}{\hbar\omega_{\mathrm{LO}}} \equiv \frac{E_{3\mathrm{D}}(\alpha)}{\hbar\omega_{\mathrm{LO}}} = -0.106\alpha^2 - 2.83 - \cdots \quad (\alpha \rightarrow \infty), \tag{9a}$$

and for the polaron mass

$$\frac{m^*}{m_b} \equiv \frac{m^*_{3\mathrm{D}}(\alpha)}{m_b} = 0.0202\alpha^4 + \cdots \quad (\alpha \rightarrow \infty). \tag{9b}$$

Over the years, the Feynman model for the polaron has remained in many respects the most successful approach to this problem. Only recently an equivalent Hamiltonian formulation of this path-integral approach has been realized ($\omega_c = 0$) by Devreese and Brosens (1992). [In one case (Yamazaki, 1983), the formal structure of the theory was reobtained in a Hamiltonian formulation—be it very artificial—but no variational principle leading to an upper bound for the energy could be found.]

The theory of polarons in semiconductors with degenerate bands and of statistical ensembles of polarons, related to many-polaron problems, is reviewed from the unified point of view of the path integration over the Wick symbols by Fomin and Pokatilov (1988).

1.2.4 Response Properties of Fröhlich Polarons. Mobility and Optical Properties

The transport properties of polar and ionic solids are influenced by the polaron coupling. Intuitively one expects that the mobility of large polarons will be inversely proportional to the number of real phonons present in the crystal:

$$\mu \sim \exp(\hbar\omega_{\mathrm{LO}}/k_{\mathrm{B}}T). \tag{10a}$$

The first to point out the typical behavior (characteristic for weak coupling) of Eq. (10a) was Fröhlich (1937). Kadanoff (1963) provided a derivation of the weak-coupling, low-temperature mobility starting from the Boltzmann equation; his result is

$$\mu = \frac{4}{3\pi^{1/2}}\,\frac{e}{m^{*}\alpha\omega_{\mathrm{LO}}}\,G(z)\exp\!\left(\frac{\hbar\omega_{\mathrm{LO}}}{k_{\mathrm{B}}T}\right)\left(\frac{k_{\mathrm{B}}T}{\hbar\omega_{\mathrm{LO}}}\right)^{1/2}, \tag{10b}$$

where $G(z)$, defined by Howarth and Sondheimer (1953), is of order 1.

Feynman *et al.* (1962) (usually referred to as FHIP) have elaborated a framework allowing the analysis of the response properties of a system, using path integrals. For low temperatures, they obtain the following expression for the dc mobility:

$$\mu \equiv \mu_{3\mathrm{D}}(\alpha) = \frac{e}{2m^{*}\omega_{\mathrm{LO}}\alpha}\,\frac{3}{2}\left(\frac{w}{v}\right)^{3} \times \exp\!\left(\frac{v^{2}-w^{2}}{w^{2}v}\right)\exp\!\left(\frac{\hbar\omega_{\mathrm{LO}}}{k_{\mathrm{B}}T}\right)\frac{k_{\mathrm{B}}T}{\hbar\omega_{\mathrm{LO}}}, \tag{10c}$$

where w and v are functions of α (also adequate for large α) deriving from the Feynman polaron model.* For the impedance of a polaron $Z(\nu) \equiv Z_{3\mathrm{D}}(\alpha,\nu)$ describing its response to the ac electric field of frequency ν, see Feynman *et al.* (1962).

Equation (10c) and related approximations allowed explanation of the experimental results of Brown and his co-workers (see Brown, 1963) on alkali halides and silver halides (see, e.g., Fig. 3) in the temperature region where the electron–LO-phonon scattering is the dominant process (at low temperatures $T < 50$ K the impurity scattering starts to prevail). Equation (10c) presupposed a "drifted-Maxwellian" velocity distribution of the polarons; this limits the validity of the treatment theoretically. However, because other scattering mechanisms than LO-phonon scattering might "conspire" to induce a Maxwellian distribution, the range of validity of Eq. (10c) seems to be larger than one would expect from electron–LO-phonon interaction only. A review on the mobility of Frölich polarons, written from a unified point of view, was presented by Peeters and Devreese (1984).

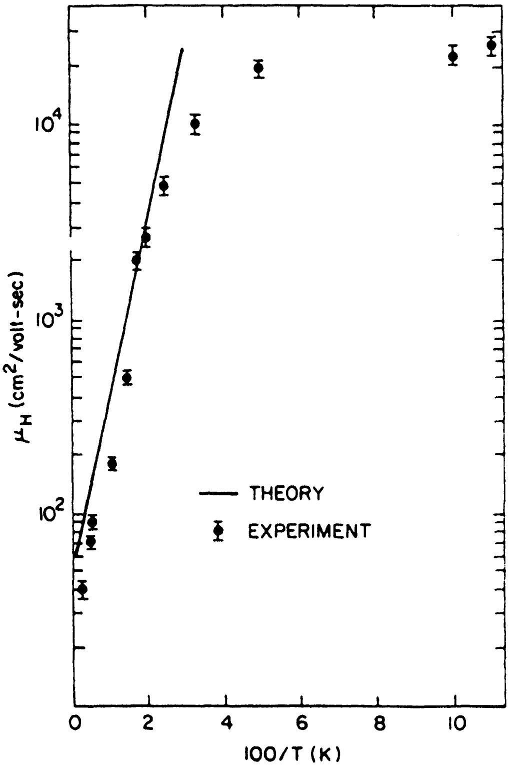

FIG. 3. Polaron mobility in AgBr (solid line) according to the low-temperature self-consistent approach of Devreese and co-workers (Kartheuser *et al.*, 1979) compared with the Hall data, from Brown (1981).

---

*It is noted that a misprint occurred in this formula in the *Encyclopedia of Physics* (Lerner and Trigg, 1991).

It was shown by the author and his coauthors (see Devreese, 1972) how the optical absorption of Fröhlich polarons, for all coupling, can be calculated starting from the FHIP scheme (which gives a derivation for the impedance function). This work led to the following expression for the optical absorption:

$$\Gamma(\nu) \sim \frac{\mathrm{Im}\Sigma(\nu)}{[\nu - \mathrm{Re}\Sigma(\nu)]^2 + [\mathrm{Im}\Sigma(\nu)]^2}, \qquad \text{(10d)}$$

where ν is the frequency of the incident radiation and $\Sigma(\nu)$ is the so-called "memory function" that contains the dynamics of the polaron and depends on α and ν. As an example, in Fig. 4 the optical-absorption spectrum of Fröhlich polarons for $\alpha = 6$ is shown.

It is remarkable that from Eq. (10d), in Devreese (1972) the three different kinds of polaron excitations, studied before only in asymptotic limits, are seen to appear in the spectra:

1. scattering states where, e.g., one real phonon is excited (the structure starting at $\nu = 1$);
2. RES; and
3. FC states.

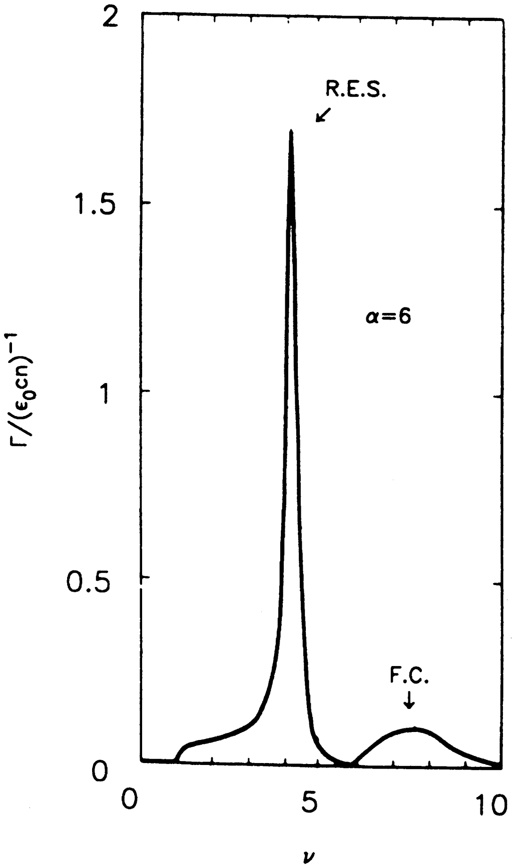

FIG. 4. Optical absorption Γ of polarons at $\alpha = 6$ as a function of frequency ν, expressed in units ω_{LO}, from Devreese (1972).

2 and **3** can be seen in the works of the author and co-workers [Kartheuser *et al.*, 1969 (KED); Devreese and Evrard, 1966; Evrard, 1965]. Experimentally only the "scattering states" have been observed for free polarons (Finkenrath *et al.*, 1969); the RES play a role for bipolarons (Devreese *et al.*, 1994). However, the full structure of Eq. (10d) has been revealed through cyclotron-resonance measurements for which $\nu - \mathrm{Re}\Sigma(\nu)$ is replaced by $\nu - \omega_c - \mathrm{Re}\Sigma(\nu)$ so that the resonance conditions can be tuned by changing ω_c (Peeters and Devreese, 1986).

The weak-coupling limit of Eq. (10d) coincides with the results by Gurevich *et al.* (1962), whereas the structure of the strong-coupling limit confirms the identification of the internal polaron excitations by Devreese and collaborators (KED).

In pioneering experimental studies, Brown and co-workers (see Brown, 1963) have combined mobility experiments and cyclotron-resonance measurements to demonstrate clearly the polaron effect. From a theoretical plot of mobility vs band mass in AgBr compared with experimental mobility data at a given temperature, they estimate the band mass. This allows them to calculate α and the polaron mass m^*. This value of m^* can then be compared with the measured cyclotron mass. The experimental value $m^*/m_b = 0.27 \pm 0.01$ is obtained for AgBr at 18 K, to be compared with a theoretical value $m^*/m_b = 0.27 \pm 0.05$.

1.3 Fröhlich Polarons in 2D

1.3.1 Introduction Today electron systems in reduced dimensions—e.g., in two dimensions like in GaAs–AlGaAs or MOSFETS—are of great interest. Also the electron–phonon interaction and the polaron effect in such systems receive much attention. For one polaron, confined to two dimensions, but interacting with a 3D phonon gas, the Fröhlich Hamiltonian remains of the form (1a) with the following modification for the V_k (Peeters *et al.*, 1986a):

$$V_k = -i\hbar\omega_{\mathrm{LO}}\left(\frac{\sqrt{2}\pi\alpha}{Ak}\right)^{1/2}\left(\frac{\hbar}{m_b\omega_{\mathrm{LO}}}\right)^{1/4}, \tag{11}$$

valid because the electron–polarization interaction is of the standard form $1/r$ in an arbitrary number of space dimensions. A possible dependence of the electron–phonon interaction on a concrete physical mechanism of the electron confinement to two dimensions was considered by Fomin and Smondyrev (1994). The self-energies $\Delta E/\hbar\omega_{\mathrm{LO}}$ for a polaron in 2D for $\alpha \to 0$ and $\alpha \to \infty$ were derived by Devreese and co-authors (Xiaoguang *et al.*, 1985, XPD) and Das Sarma and Mason (1985):

$$\frac{\Delta E}{\hbar\omega_{\mathrm{LO}}} \equiv \frac{E_{\mathrm{2D}}(\alpha)}{\hbar\omega_{\mathrm{LO}}} = -\frac{\pi}{2}\alpha - 0.063\,97\alpha^2 + O(\alpha^3) \quad (\alpha \to 0), \tag{11a}$$

$$\frac{\Delta E}{\hbar\omega_{\mathrm{LO}}} \equiv \frac{E_{\mathrm{2D}}(\alpha)}{\hbar\omega_{\mathrm{LO}}} = -0.4047\alpha^2 + O(\alpha^0) \quad (\alpha \to \infty). \tag{11b}$$

The corresponding results for the polaron mass in 2D are (XPD)

$$\frac{m^*}{m_b} \equiv \frac{m^*_{\mathrm{2D}}(\alpha)}{m_{\mathrm{2D}}} = \frac{\pi}{8}\alpha + 0.127\,2348\alpha^2 + O(\alpha^3) \quad (\alpha \to 0), \tag{11c}$$

$$\frac{m^*}{m_b} \equiv \frac{m^*_{\mathrm{2D}}(\alpha)}{m_{\mathrm{2D}}} = 0.733\alpha^4 + O(\alpha^2) \quad (\alpha \to \infty). \tag{11d}$$

The result $\Delta E/\hbar\omega_{\mathrm{LO}} = -(\pi/2)\alpha$ was first obtained by Sak (1972).

1.3.2 Scaling Relations Peeters and Devreese (1987) have derived several scaling relations connecting the polaron self-energy, the effective mass, the impedance Z, and the mobility μ in 2D to the same quantities in 3D. Those relations were derived on the level of the Feynman approximation and are listed here:

$$E_{\mathrm{2D}}(\alpha) = \tfrac{2}{3}E_{\mathrm{3D}}(3\pi\alpha/4), \tag{12a}$$

$$\frac{m^*_{\mathrm{2D}}(\alpha)}{m_{\mathrm{2D}}} = \frac{m^*_{\mathrm{3D}}(3\pi\alpha/4)}{m_{\mathrm{3D}}}, \tag{12b}$$

$$Z_{\mathrm{2D}}(\alpha,\nu) = Z_{\mathrm{3D}}(3\pi\alpha/4),\nu), \tag{12c}$$

where ν is the frequency of the external electromagnetic field, and

$$\mu_{\mathrm{2D}}(\alpha) = \mu_{\mathrm{3D}}(3\pi\alpha/4). \tag{12d}$$

Except for the investigations on polarons at the surface of liquid He (Jackson and Platzman, 1981; Peeters, 1987), the experimental studies performed at present are related to systems with weak electron–phonon coupling. Those studies have addressed a variety of physical properties including magnetophonon anomalies, optical absorption, plasmon–LO-phonon mode coupling, cyclotron resonance, mobility, many-body effects, etc. The reader is referred to Devreese and Peeters (1987) for more details and additional references. In what follows, some of these studies will be further discussed.

1.4 Fröhlich Polarons in a Magnetic Field

1.4.1 In 3D Fröhlich polarons have been most clearly manifested by investigations of their properties in magnetic fields. Therefore a special section is devoted to the study of polarons in magnetic fields.

1.4.1.1 Level Crossing, Pinning. In interpreting the (low field) cyclotron-resonance experiment of Brown *et al.* (1963), it was supposed that the zero-magnetic-field polaron mass is observed. Of course, there exists no *a priori* guarantee that this supposition is true, and theoretical studies of polarons in magnetic fields are necessary. Larsen (1972, 1991) has made important contributions to the theoretical study of polarons in magnetic fields. In particular, he was the first to point out the level repulsion close to the crossing of levels at $\omega_c = \omega_{\mathrm{LO}}$ (ω_c is the cyclotron-resonance frequency) and the pinning of Landau levels to the phonon continuum as $\omega_c \to \infty$ (see Fig. 5). Measurements on InSb (Johnson and Larsen, 1966) and CdTe (Waldman *et al.*, 1969) provided first indications for these level-crossing and pinning phenomena. Detailed line-shape studies for weak coupling

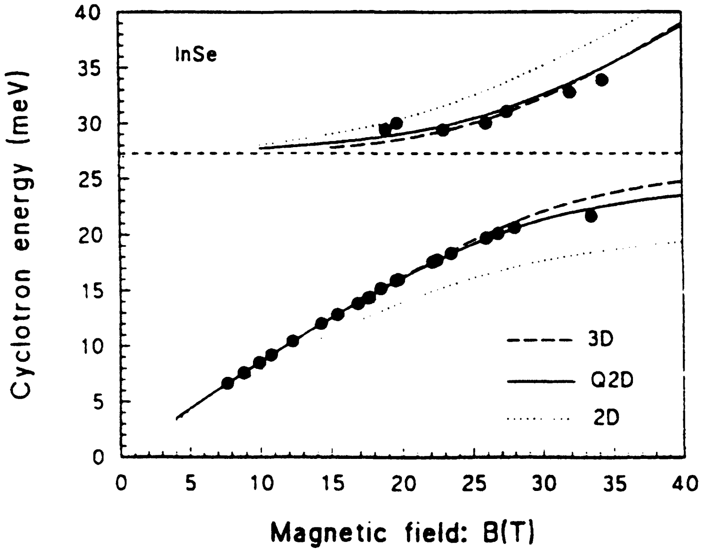

FIG. 5. The cyclotron-resonance position plotted as a function of magnetic field for InSe, from Nicholas *et al.* (1992).

of the cyclotron resonance, revealing a double-peak structure close to $\omega_c = \omega_{\mathrm{LO}}$, are displayed by Vigneron *et al.* (1978) and independently by Devreese and his co-workers (see Van Royen *et al.*, 1977).

1.4.1.2 Static and Dynamic Properties of Polarons in a Magnetic Field. Peeters and Devreese (1982) have generalized the Feynman model of the polaron to the case where a static external magnetic field is applied. The calculation is valid for all α, ω_c, and temperature described by the parameter $\beta = 1/k_BT$. The starting point is the expression of the free energy of the polaron as a path integral,

$$F = F_{\mathrm{ph}} - \frac{1}{\beta}\ln\left\{\int d\mathbf{r}\int_{\mathbf{r}(0)=\mathbf{r}}^{\mathbf{r}(\beta)=\mathbf{r}} \mathcal{D}\mathbf{r}(u)\exp(S[r(u)])\right\}. \tag{13a}$$

The "electron" contribution to the action S is

$$S_e = -\tfrac{1}{2}\int_0^\beta du\{\dot{\mathbf{r}}(u)^2 + i\omega_c[x(u)\dot{y}(u) - y(u)\dot{x}(u)]\}, \tag{13b}$$

where $\mathbf{r}$ is the position vector of the electron, with components x, y in the plane perpendicular to the magnetic field.

A quadratic, retarded model interaction was introduced (Peeters and Devreese, 1982) to simulate the polaron (retarded Coulomb) interaction and, in analogy to the zero-magnetic-field case, the Jensen–Feynman inequality was assumed to be valid:

$$F \le F_{\mathrm{ph}} + F_m - \frac{1}{\beta}\langle S - S_m\rangle_m. \tag{13c}$$

Here F_{ph} and F_m stand for the free energy of the phonon bath and the quadratic model, respectively, while $\langle\cdot\rangle_m$ denotes an evaluation of the corresponding average with

$$e^{S_m}\Big/\int d\mathbf{r}\int_{\mathbf{r}(0)=\mathbf{r}}^{\mathbf{r}(\beta)=\mathbf{r}} \mathcal{D}\mathbf{r}(u)e^{S_m} \tag{13d}$$

as weight factor. For details, the reader is referred to Peeters and Devreese (1982), where results for the energy and related properties of the polaron in a magnetic field for all α, ω_c, and β were derived both numerically and—in a variety of limiting cases—analytically.

A question of considerable significance has been raised about the validity of the inequality (13c) in the presence of a magnetic field. Feynman suggested that in a magnetic field this inequality remains valid, or might need a slight modification only (Feynman and Hibbs, 1965). Several works have been devoted to this challenging problem; see Brosens and Devreese (1988), Sec. 3.4 in Fomin and Pokatilov (1988), and Larsen (1991) for detailed reviews. Larsen (1985) revealed that the ground-state levels of a 2D polaron obtained "variationally" on the basis of Eq. (13c) for sufficiently high magnetic fields lie below those found within the framework of the adiabatic strong-coupling theory or the fourth-order–perturbation weak-coupling approach. Interpreting the latter ground-state level as the exact one, Larsen came to the conclusion that it would seem difficult to attach any particular sense to the variational ground-state level. However, it was pointed out that the adiabatic strong-coupling theory does not provide a rigorous asymptotic limit of high magnetic fields; see discussion in Devreese and Brosens (1991). It is also worth while to note that the perturbation ground-state energy can, however, itself be treated in some cases (see Fomin and Pokatilov, 1988, *loc. cit.*) as an upper bound for the exact energy. But when comparing various upper bounds for the exact energy, one should recall Feynman's (1955) warning that attempts to improve an upper bound by calculating the higher-order correction terms may indeed deprive the treatment of its variational nature! Using a model calculation, Brosens and Devreese (1988) rigorously demonstrated that for sufficiently small electron–phonon coupling the presence of a magnetic field is prohibitive for the application of the Jensen–Feynman inequality.

A generalization of the Jensen–Feynman inequality, which remains valid in the case of a nonzero magnetic field, was derived by Devreese and Brosens (1992) starting from the ordered-operator calculus. On these grounds, the conditions were determined to be imposed on the variational parameters in the model action S_m such that the Feynman upper bound in its original form of the inequality (13c) remains valid for a polaron in a magnetic field. Although so far it has not been conclusively established that a choice of the parameters in the trial action made in Peeters and Devreese (1982) limits them to the domain determined by the conditions derived in the above-cited work, it is interesting to note that most of the existing theories of polarons in a magnetic field (Hellwarth and Platzman, 1962; Marshall and Chawla, 1970; Evrard *et al.*, 1970; Lépine and Matz, 1976) are obtained as special cases of the results by Peeters and Devreese (1982) who simply accepted the inequality (13c) as a working hypothesis. A prediction by Peeters and Devreese (1982) is that some quantities characterizing the internal structure of the polaron [called, e.g., $(\nu_\perp/\omega_\perp)^2$ in the mentioned paper] undergo a drastic change for a well-defined magnetic field ("stripping transition"). Although high magnetic fields are needed (e.g., ~42 T in AgBr), it would be interesting to investigate this point experimentally.

1.4.1.3 Cyclotron-Resonance Spectra. The observation of the cyclotron mass of electrons in AgBr in the low-field case ($\omega_c \to 0$) gave evidence for the occurrence of polaron effects. However it concerns only one number (m^*/m_e) and involves the combination of two measurements (m_e is the mass of the electron in vacuum). It was therefore useful to analyze the magnetic-field dependence of the polaron mass in order to gain quantitative insight into the validity of the polaron picture.

An excellent occasion to realize such an analysis is provided by the more recent precise cyclotron-mass measurements (in AgBr and AgCl) by Hodby *et al.* (1987). These measurements, performed with the 5-cm-bore hybrid magnet at Oxford, cover the range from zero magnetic field to 16 T. These measurements are precise enough to distinguish between various polaron theories. Several theories were compared in analyzing the experimental data of Hodby *et al.* (1987).

First, the variational calculation of Larsen (1972) was considered. This approach is a so-called intermediate-coupling theory to calculate the energy levels (modified Landau levels) of a polaron in a magnetic field. The polaron mass is then defined from the energy differences between the polaron (Landau) energy levels.

In principle, it is better to calculate the magneto-optical absorption spectrum of the polaron (the quantity that is actually measured) and to define the polaron mass, in the same way as the experimentalist, from the peak positions in the spectrum. Starting from the results of Peeters and Devreese (1982), the magneto-optical absorption of polarons for all α and ω_c at $T = 0$ was calculated by Peeters and Devreese (1986). They used the memory-function formalism to generalize the study of the response of a Feynman polaron in a magnetic field. The magneto-absorption is then obtained from

$$\lim_{\epsilon \to 0} \frac{1}{\nu - \omega_c - \Sigma(\nu + i\epsilon)}, \tag{14a}$$

where ν is the frequency of the incident radiation and $\Sigma(\nu + i\epsilon)$ is the memory function. The key ingredient of $\Sigma(\nu + i\epsilon)$ is the space Fourier transform of the density–density correlation function:

$$\langle e^{i\mathbf{k}\cdot\mathbf{r}(t)} e^{-i\mathbf{k}\cdot\mathbf{r}(0)} \rangle, \tag{14b}$$

where $\langle \cdot \rangle$ can be expressed as a path integral. $\Sigma(\nu + i\epsilon)$ is an intricate function that takes into account all the polaron internal states and all the Landau levels. It turns out that the magneto-absorption calculated by Peeters and Devreese (1986) leads to the best quantitative agreement between theory and experiment as was analyzed for AgBr and AgCl (Hodby *et al.,* 1987). It should be pointed out that the weak-coupling theories (Rayleigh–Schrödinger perturbation theory, Wigner–Brillouin formulation and its improvements) fail (and are all off by at least 20% at 16 T) to describe the experimental data for the silver halides. The analysis of Hodby *et al.* (1987) based on the theory of magnetoabsorption by Peeters and Devreese (1986) provides a confirmation of the Fröhlich description of the polaron in a case where weak-coupling approximations are not adequate.

An interesting case is provided by the cyclotron-resonance data for CdTe (Johnson and Larsen, 1966). The early analysis (Larsen, 1972) of these experiments as well as subsequent cyclotron-resonance measurements of the polaron effective mass in *n*-CdTe (Litton *et al.,* 1976) seemed to suggest that a Fröhlich coupling constant as large as $\alpha = 0.4$ could explain the data for the polaron mass as a function of magnetic field. This gave rise to a long-standing challenge about the adequacy of the dielectric continuum model for the magneto-bound polarons in CdTe, which maintains the value $\alpha \sim 0.3$ of the coupling constant. But it turns out that the experimental data on the Zeeman splitting in the $1s \to 2p$ shallow-donor–impurity transitions in CdTe at high magnetic fields obtained by Cohn *et al.* (1972) can be precisely described in the framework of a second-order perturbation theory with band nonparabolicity taken into account using the value $\alpha = 0.286$ for the Fröhlich coupling constant following from Eq. (1c) (Shi *et al.,* 1995). It has been revealed in the latter work that Cohn *et al.* (1972) had to use as a fitting parameter the value $\alpha = 0.4$, higher than the above-mentioned Fröhlich coupling constant, in order to compensate for the underestimation of the polaron effects in the calculation of the transition energies.

1.4.2 Cyclotron Resonance of Polarons in 2D Cyclotron-resonance experiments have been performed on the 2DEG, e.g., in InSb inversion layers and in GaAs–$\text{Al}_x\text{Ga}_{1-x}$As heterostructures (Scholz *et al.,* 1983; Seidenbusch *et al.,* 1984; Sigg *et al.,* 1985; Merkt, 1985; Hopkins *et al.,* 1989). Several theoretical studies have been presented to analyze these experimental results for the 2DEG. In those works, the cyclotron mass was obtained from the positions of the energy levels (Das Sarma, 1984; Larsen, 1984a,b; Peeters and Devreese, 1985; Peeters *et al.,* 1986b,c).

The theory of cyclotron resonance in the 2DEG for cases where the electron–phonon interaction plays a significant role is reviewed by Devreese and Peeters (1987). Like in 3D (Peeters and Devreese, 1986), the theory is expressed in terms of the memory-function formalism. In this treatment, the magneto-optical absorption itself is calculated and the transition frequencies (rather than the individual energy levels) are obtained directly.

Some results of this work are the following:

1. First the magneto-absorption spectrum was calculated, at weak coupling, for one polaron in 2D. A Landau-level broadening parameter is introduced phenomenologically in order to remove the divergences in the magneto-optical absorption spectrum. The effect of the nonzero width of the 2DEG is incorporated along with nonparabolicity. The experimental data for *p*-InSb inversion layers can be adequately explained by this theory.
2. To account for the cyclotron-mass data in GaAs–$\text{Al}_x\text{Ga}_{1-x}$As heterostructures it is essential to include many-body effects. Both the "occupation effect" (Pauli principle) and the effects of screening were included, on top of the effect included in the one-polaron studies under **1**.

It is also worth mentioning that, although for one electron the polaron effect is enhanced by the 2D confinement, in reality—e.g., in GaAs–Al$_x$Ga$_{1-x}$As with $n_e \geq 1.4 \times 10^{11}$ cm^{-2}—screening helps to reduce the polaron effect in 2D so that it becomes smaller than its 3D counterpart. For sufficiently large densities, Peeters *et al.* (1988a,b) revealed that the polaron mass in 2D is not a monotonically increasing function of ω_c but shows structure where the filling factor becomes an integer.

It is obvious, in both the case of InSb and that of GaAs–Al$_x$Ga$_{1-x}$As, that polaron effects do occur, even if these are weak-coupling materials.

A nice example, clearly demonstrating the polaron coupling, is provided using the memory-function approach by the author and his colleagues (Peeters and Devreese, 1985, 1986c; Devreese and Peeters, 1986) through the analysis of the cyclotron resonance in a 2DEG that naturally occurs in InSe where $\alpha \approx 0.3$ (Nicholas *et al.*, 1992). One clearly sees, over a wide range of magnetic fields, the two distinct polaron branches separated by as much as $0.4\omega_{\mathrm{LO}}$ at resonance (Fig. 5). Polaron cyclotron resonance has even been observed in n-type ZnS up to 220 T by Miura *et al.* (1994).

A quantitative interpretation of the cyclotron-resonance measurements in n-GaAs and AlGaAs–GaAs heterojunctions was obtained by Peeters *et al.* (1988a,b) on the grounds of the polaron theory with three factors taken into account: dimensionality, band nonparabolicity, and screening. Impurity-bound resonant magnetopolarons have been clearly observed in bulk GaAs and GaAs–Al$_x$Ga$_{1-x}$As multiple quantum wells (Cheng *et al.*, 1993).

1.4.3 Formal Developments Also to treat Fröhlich polarons in a magnetic field the Feynman path integral proved to be a most powerful method extending the possibilities of perturbation theory and Hamiltonian variational calculations.

From the methodological point of view, the introduction of the total angular-momentum operator of the polaron,

$$\hat{L}_z = \hat{l}_z + i\hbar \sum_{\mathbf{k},\mathbf{k}'} a^\dagger_{\mathbf{k}'} a_{\mathbf{k}} \left(k_x \frac{\partial}{\partial k_y} - k_y \frac{\partial}{\partial k_x} \right) \delta_{\mathbf{k},\mathbf{k}'} \tag{15}$$

(with $\hat{l}_z$ denoting the electron angular momentum), is useful for Hamiltonian treatments of polarons in a magnetic field performed by Evrard *et al.* (1970). Later this operator was used in studies on excitons.

An operator-algebra method was developed by Larsen (1984a), useful to study higher-order effects for polarons in magnetic fields, when expanding in powers of α.

1.5 The Bound Polaron

A polaron can be bound to a charged vacancy or to a charged interstitial. To a first approximation, this system can be approximated by adding the Coulomb potential energy operator ($-e^2/\epsilon_\infty|\mathbf{r}| \equiv -\beta/|\mathbf{r}|$, where $\mathbf{r}$ is the vector operator characterizing the electron position with respect to the center of the vacancy or of the interstitial) to the Fröhlich Hamiltonian.

Intuitively one expects that the weak-coupling polaron spectrum for the bound polaron is approximately given by a Bohr formula adapted to take into account the polaron mass:

$$E_n = -\alpha\hbar\omega_{\mathrm{LO}} - \frac{m_b e^4}{2\hbar^2 n^2 \epsilon_0^2} - \frac{\alpha}{12}\frac{m_b e^4}{\hbar^2 n^2} + O(\alpha^2)\ (n = 1, 2, \cdots). \tag{16}$$

Expansions refining Eq. (16) were derived first using approximate schemes for perturbation theory (Bajaj, 1972); later a rigorous result for the binding energy E_n up to order α was obtained (Engineer and Tzoar, 1972).

Further schemes to treat the ground-state energy of the bound polaron (and approximations for some of the excited states) have been developed by Platzman (1962), Larsen (1969), Devreese *et al.* (1982), and Adamowski (1985).

Brandt and Brown (1969) have interpreted some structure in their infrared optical absorption spectra of AgBr as caused by the bound polaron; in particular the 168-cm^{-1} absorption line has been analyzed as a transition between a 1s and a 2p state (modified by the polaron interaction). Also higher excited states and LO-phonon sidebands play a role in this spectrum (see e.g., Bajaj, 1972) (Fig. 6). The bound polaron is related to the F center. In Tables 2 and 3, some energy levels of the bound polaron are tabulated.

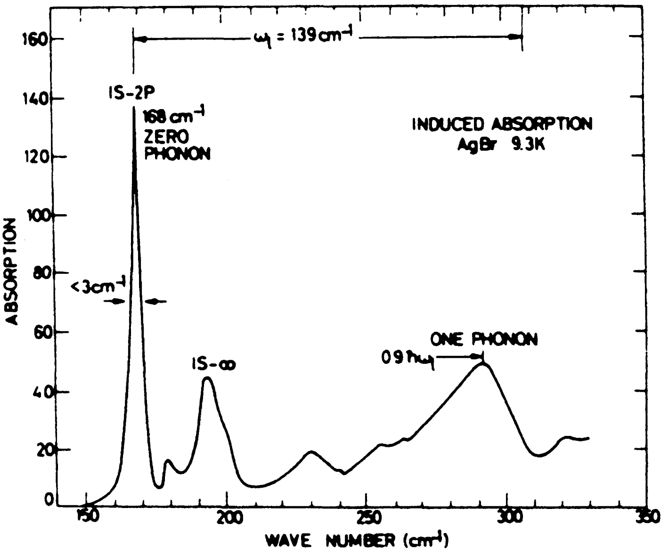

FIG. 6. Induced absorption in AgBr at 9.3 K from 150 to 320 cm^{-1}. The exciting light was in the region of the direct-absorption edge. From Brandt and Brown (1969), reproduced by courtesy of The American Physical Society.

2. THE SMALL POLARON

2.1 The Small-Polaron Concept. Role of Localization

An electron or a hole trapped by its self-induced atomic (ionic) displacement field in a region of linear dimension ("radius") that is of the order of the lattice constant is called a *small polaron* (Fröhlich, 1957; Sewell, 1958; Fröhlich and Sewell, 1959; Holstein, 1959; Emin and Holstein, 1976). An excellent survey of the small-polaron physics relevant to conduction phenomena in noncrystalline materials and to metal–insulator transitions has been given by Mott (1987, 1990). As distinct from large polarons, small polarons appear as a result of overall short-range forces. Thus, in certain materials, in particular in some oxides, the induced lattice polarization is essentially localized in a volume of the order of a unit cell. Hence, the charge carrier is localized on an individual lattice site during a time that can become large compared with the *localization time* describing the relaxation of the lattice to the small-polaron state. The localization time is of the same order of magnitude as the period of a lattice vibration, ω_{LO}^{-1}.

Because for small polarons the lattice polarization is mostly confined to one unit cell, the atomicity of the solid is felt by the car-

Table 3. Calculated energy of the first excited $2p$ state (in units $\hbar\omega_{\text{LO}}$) of the bound polaron for several values of α and $\tilde{\beta}$ as obtained by Devreese *et al.* (1982).

	E_{2p}		
α	$\tilde{\beta} = 0$	$\tilde{\beta} = 1$	$\tilde{\beta} = 2$
1	−0.7626	−0.8775	−1.113
3	−1.971	−2.237	−2.628

7	−4.600	−5.214	−5.955
9	−6.199	−6.996	−7.922
11	−8.029	−9.014	−10.13

rier; a complete treatment of small polarons should therefore start from an *ab initio* calculation that takes into account the detailed local structure of the solid; the Fröhlich continuum approximation would not be adequate. Nevertheless, actual small-polaron theories as developed, e.g., by Yamashita and Kurosawa (1958), Holstein (1959), and others are based on analytical approximations as a starting point. Thus, the adiabatic eigenstates of an electron placed in a deformable continuum were shown to depend drastically on the character of the electron–lattice interaction as well as on the dimensionality of the system (Emin and Holstein, 1976). As distinct from the case of the long-range interaction with a stable large-polaron state, for the short-range interaction in a three-dimensional system there exist two stable states, namely, an unbound electron in an undeformed continuum and an electron collapsed in an infinitesimally localized self-induced potential well. The former is analogous to the band-electron state in a rigid lattice; the latter models a small-polaron state. It is also worth while noting that the common action of a long-range and of a short-range force was found to yield always a small-polaron–like state and—in a certain region of the interaction strengths—a large-polaron state. Thus, even from the early analysis the possibility of *coexistence* of both types of polarons can be distinctly deduced.

In the modern theories (see, e.g., Alexandrov and Mott, 1994), the small-polaron energy is regarded to consist of the following parts:

1. the kinetic energy of the charge carrier in a rigid lattice, which, as distinct from large polarons, is considered to originate from the intersite transfer due to tunneling;
2. the energy of the atomic (ionic) displacements field, describing the lattice distortion; and
3. the potential energy of the charge carrier in the potential well formed by these displacements.

The interaction of the localized electron (hole) with the lattice vibrations then induces the charge carrier to jump from one atom (or ion) to a neighboring one. This process is called *hopping*. The detailed physical picture of hopping (Lang and Firsov, 1962) suggests a sequence of the acts of small-polaron disintegration and reappearance as follows. At sufficiently high temperatures $k_BT > \hbar\omega_{LO}/4$, the typical time interval between jumps Δt satisfies the inequalities $t_0 \ll \Delta t \ll t_p$, where $t_0 \sim \hbar/(W_H k_B T)^{1/2}$ (with W_H the thermal activation energy for hopping) denotes the *jump-over* time and $t_p \sim \hbar/\Delta E_p$ (with ΔE_p the small-polaron bandwidth) is the tunneling time. Hence, an electron remains most of the time at a site, undergoing a hopping transition from site to site rather rarely, but on average earlier than a tunneling occurs. If the jump-over time is much shorter than the period of a lattice vibration, $t_0 \ll \omega_{LO}^{-1}$, under a hopping transition the electron "jumps out of" the old potential well due to its self-induced lattice deformation, thus initiating a multiphonon process due to the lattice relaxation: The small-polaron state disappears. But the time interval between jumps is much larger than the localization time: $\Delta t \gg \omega_{LO}^{-1}$. This inequality describes the *anti-adiabatic limit:* the atoms (ions) can adiabatically follow the motion of an electron, in contrast with the case of a large polaron (see Sec. 1.2.1). Thus, a new potential well due to the lattice deformation adapted to the new position of the electron is formed. A small-polaron state reappears.

Also in the case of small polarons the relevant phonons are commonly the LO phonons. A simple estimate of the temperature dependence of the mobility can be obtained starting from the following. The larger the number of LO phonons n_{ph} present in the solid, the larger the mobility μ_{SP} of the small polaron:

$$\mu_{SP} \sim n_{ph}. \tag{17}$$

For sufficiently low temperatures $n_{ph} = \exp(\hbar\omega_{LO}/k_BT)$ and, as a consequence, we find

$$\mu_{SP} \sim \exp(\hbar\omega_{LO}/k_BT). \tag{18}$$

It should be emphasized that the mobility of small polarons is therefore *thermally activated* and its temperature dependence is totally different from that of Fröhlich polarons [compare, e.g., Eq. (18) with Eq. (10a)].

A more detailed theoretical treatment of the small-polaron mobility (see Lang and Firsov, 1962; Reik, 1972) leads to the following formula, valid for $T > \theta_D/2$ (θ_D is the Debye temperature of the crystal):

$$\mu_{\mathrm{SP}} = \frac{ea^2\omega_{\mathrm{LO}}}{6k_{\mathrm{B}}T}\exp\left(-\frac{W_H}{k_{\mathrm{B}}T}\right), \tag{19}$$

where a is the lattice constant of the crystal in which the small polaron occurs; W_H is the thermal activation energy for hopping and is given by $\frac{1}{2}$ the small-polaron binding energy.

The Arrhenius-type activated behavior of the form (19) of the mobility has been used as a fingerprint to identify small-polaron behavior in solids. The earliest studies concerned one of the uranium oxides, UO_{2+x} (Devreese, 1963; Nagels *et al.*, 1964). Subsequently, small polarons were invoked to interpret the conductivity in many oxides (Mott and Davis, 1979), in particular in transition-metal oxides. It should be mentioned that often the measured quantity is the Hall mobility rather than the drift mobility. The theory of the Hall mobility of small polarons due to hopping (Friedman and Holstein, 1963; Austin and Mott, 1969) leads to

$$\mu_{\mathrm{Hall}} \propto T^{-1/2}\exp\left(-\frac{W_H}{3k_{\mathrm{B}}T}\right). \tag{20}$$

The relation between Hall and drift mobility is not simple, and the Hall mobility depends, e.g., on the interference between several hopping processes [see a comprehensive review by Austin and Mott (1969)]. For s carriers, the Hall coefficient turns out to be always negative.

2.2 Standard Small-Polaron Theory

As shown above, small polarons—at sufficiently high temperature—are characterized by diffusive motion and the band picture with its Bloch states breaks down; in the low-temperature limit the band picture reappears in the theoretical description, although experimental evidence for band conduction has been limited.

The fact that the Bloch-band picture breaks down is connected with the narrowing of the band gap that develops as the carrier becomes more and more localized, resulting in an increasing effective mass and, in the limit, in self-trapping. For example, in KCl the material characteristics are such that a valence-band hole gets self-trapped because of its polaron interaction with the lattice (Stoneham, 1979). The self-trapping of the hole is a subtle process, but the evidence is that it is related to the polaron formation in interplay with the Jahn–Teller effect (Stoneham, 1979).

For the quantitative treatment of small polarons, the so-called molecular-crystal model of Holstein (1959) is perhaps most illuminating. Without going into the mathematical details of this model, we mention its basic ingredients: a linear (1D) chain is considered with N diatomic molecules in which an excess electron is moving. With this model, the occurrence of two regimes, separated by a characteristic temperature typically of order (0.4 to 0.5)$\hbar\omega_{\mathrm{LO}}/k_{\mathrm{B}}$, is established theoretically: (a) hopping induced by phonons and (b) Bloch-type band motion. For the hopping motion of small polarons, Holstein derived the following expression for the mobility:

$$\mu = \frac{ea^2}{k_{\mathrm{B}}T}\frac{J^2}{\hbar^2\omega_{\mathrm{LO}}}\left[\frac{\pi}{\gamma\cosh(\hbar\omega_{\mathrm{LO}}/4k_{\mathrm{B}}T)}\right]^{1/2} \times \exp\left[-2\gamma\tan\left(\frac{\hbar\omega_{\mathrm{LO}}}{4k_{\mathrm{B}}T}\right)\right], \tag{21}$$

where J is a two-center overlap integral and γ is a measure for the electron–phonon coupling strength for small polarons, to be distinguished from the large-polaron coupling constant α ($2J$ corresponds to the width of the electronic Bloch band, which is supposed to be relatively small in small-polaron theory).

An important role in small-polaron theory belongs to the distinction between adiabatic and nonadiabatic hopping transitions [roughly speaking, the adiabatic regime is characterized by the fact that the electron follows the atomic (ionic) motion instantaneously]; see for the details the monograph by Klinger (1979).

The formation of small bipolarons by coupling of electrons to acoustic phonons and in disordered media was examined by Cohen *et al.* (1984). The study of small-polaron properties has been extended and studied in depth by Mott (1990), who identified and analyzed many instances of small-polaron transport including variable-range hopping, in which electrons hop over a range of distances and not only between nearest neighbors. He revealed the role of small polarons in amorphous semiconductors. The coherence and dynamics of small polarons in the presence of disorder were represented in terms of two characteristic energies: The polaron bandwidth specifies the energy scale of disorder at which the polarons become localized as composite particles, while the bare-electron bandwidth defines the energy scale at which the polaron ceases to be a composite particle (Spicci *et al.*, 1994).

In the theory of small polarons there are still some open fundamental questions that have been a subject of considerable recent investigation. Among the urgent issues, we note

1. the problem of the relevance of the Bloch-like states for a single small polaron in spite of the retardation, and
2. the study of the nature and properties of quasiparticles in many-polaron systems, which are of especial interest for the polaron, bipolaron, and hybrid polaron–bipolaron pictures of high-T_c superconductivity (see Sec. 5).

2.3 Experimental Evidence

Experimentally small-polaron effects have been analyzed, e.g., in UO_{2+x}, KCl, LiF, NiO, MnO, TiO_2, $BaTiO_3$, $SrTiO_3$, $LaCoO_3$, etc. We refer to the reviews by Appel (1968) and Firsov (1975) for more details. More recently, de Jongh (1988), Micnas *et al.* (1990), Alexandrov and Krebs (1992), and Alexandrov and Mott (1994) surveyed in detail both the principles and the main results of the small-polaron theory in the context of the (bi)polaronic approach in the physics of high-T_c superconductors and tried to interpret some experimental data in different materials in terms of small polarons and small bipolarons.

The study of the optical absorption for small polarons is complex. A representative example is shown in Fig. 7, where the real part of the ac conductivity, describing the small-polaron absorption, as derived from the Kubo formula, is shown for various Γ ($\Gamma = \hbar/4\tau_0 k_B T$, where τ_0 is $\frac{1}{4}$ times the "hopping time") (Reik and Heese, 1967). Note the completely different character of the optical absorption for small polarons as compared with large polarons (see Fig. 4).

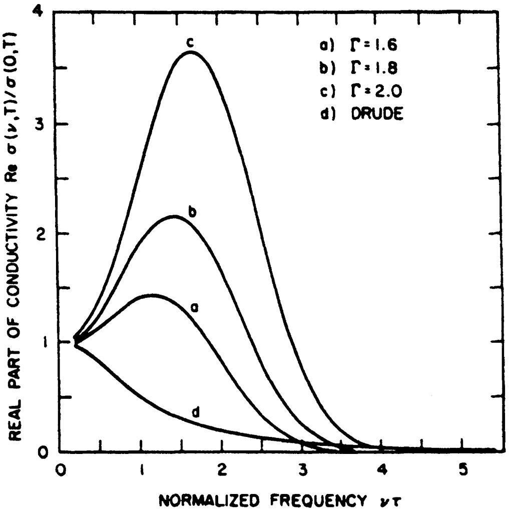

FIG. 7. Real part of the conductivity vs normalized frequency $\nu\tau$ for different values of the parameter Γ; from Reik and Heese (1967), reproduced by courtesy of Pergamon Press Ltd.

In analyzing experimental transport data also thermoelectric-power measurements are used; the theoretical study of the thermopower for small polarons has revealed that no polarization energy is transferred by the polaron motion.

Mobile polarons, observed in WO_{3-x} by Gehlig and Salje (1983), were shown to exhibit at 130 K a transition from a regime of hopping conductivity, characterized by a constant activation energy, to a regime of band conductivity, in which the process is not activated. With increasing carrier density, small polarons are formed up to a density that is equal to the concentration of the sites at which they can be localized. At this critical density, the dc electrical conductivity shows a phase transition, which these authors interpret as an Anderson-type transition: A change from a thermally activated small-polaron behavior to a metallic temperature dependence occurs. The critical density was found to be about 3.7×10^{21} cm^{-3} in WO_{3-x} (Salje and Güttler, 1984) and 1.7×10^{21} cm^{-3} in $NbO_{2.5-x}$ (Rüscher *et al.*, 1988). At higher densities, two type of carriers are suggested to coexist: small polarons, on the one hand, and, on the other hand, conducting carriers that can be regarded as

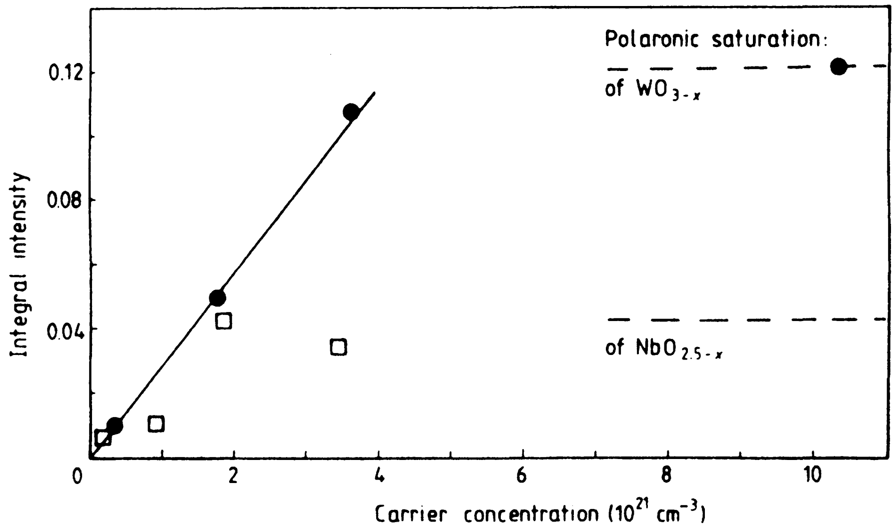

FIG. 8. Integral intensities of the polaronic absorption in dependence on the degree of reduction of $NbO_{2.5-x}$ (●) and WO_{3-x} (□); from Rüscher *et al.* (1988), reproduced by courtesy of Institute of Physics Publishing.

large polarons. The crossover from small-polaronic to metallic temperature dependence of the conductivity is consistently demonstrated by the Arrhenius plot for five different chemical compositions $NbO_{2.5-x}$. A thermally activated small-polaron conductivity seems to occur at lower degrees of reduction than that of $NbO_{2.49}$. This crossover scenario is strongly supported by the fact that close to the same critical densities as mentioned above, a saturation of the "integral intensity" of the polaronic absorption occurs; see Fig. 8.

Quite recently, the dc electrical conductivity of a slightly hyperstoichiometric sample of polycrystalline UO_{2+x} was interpreted (Casado *et al.,* 1994) in the framework of small-polaron theory, where some discrepancies between the semiempirical values of the small-polaron self-energy and the thermal activation energy, from the one side, and those obtained as a result of a fully microscopic calculation, from the other side, are revealed.

The recent measurements of the Seebeck coefficient of $BaBi_{0.25}Pb_{0.75}O_{3-\delta}$ with an oxygen deficiency by Hashimoto *et al.* (1995) suggest the coexistence between band charge carriers of high mobility, on the one side, and localized charge carriers of low mobility, on the other side (Fig. 9). Namely, in the low-temperature region, $T < 200$ K, the decrease of the (negative) Seebeck coefficient with T is supposed to be due to large electron polarons, while a temperature-activated behavior of the (positive) Seebeck coefficient above room temperature is attributed by the authors to small-hole polarons. A nonphenomenological interpretation of such experi-

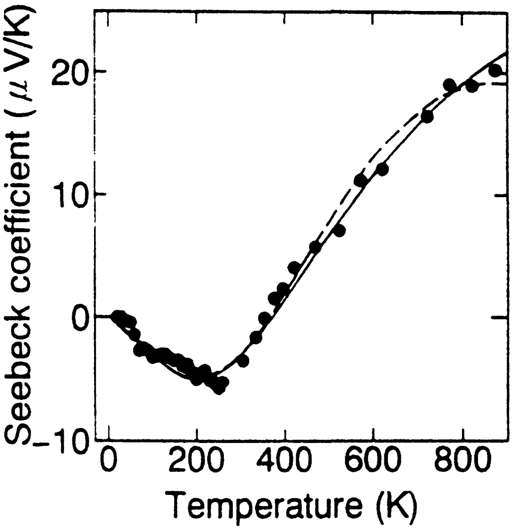

FIG. 9. Seebeck coefficient of $BaBi_{0.25}Pb_{0.75}O_{3.00}$: measured data (●) and phenomenological estimates (solid and dashed lines); from Hashimoto *et al.*, 1995, reproduced by courtesy of The American Physical Society.

ments requires a theoretical approach that would combine the large- and the small-polaron concepts.

A complex of experimental results on dielectric relaxation and ac and dc conductivities of $La_{1-x}Sr_xFeO_3$ with $0.05 \leq x \leq 0.3$ obtained by Jung and Iguchi (1995) was self-consistently explained in terms of small polarons (see, e.g., the Arrhenius plot for conductivity in Fig. 10).

3. BIPOLARONS AND POLARONIC EXCITONS

When two electrons (or two holes) interact with each other simultaneously through the Coulomb force and via the electron–phonon–electron interaction, either two independent polarons can occur or a bound state of two polarons—the *bipolaron* (Pekar, 1951)—can arise (Vinetskii, 1961; Hiramoto and Toyozawa, 1985; Adamowski, 1989). Whether bipolarons originate or not depends on the competition between the repulsive forces (direct Coulomb interaction) and the attractive forces (mediated through the electron–phonon interaction).

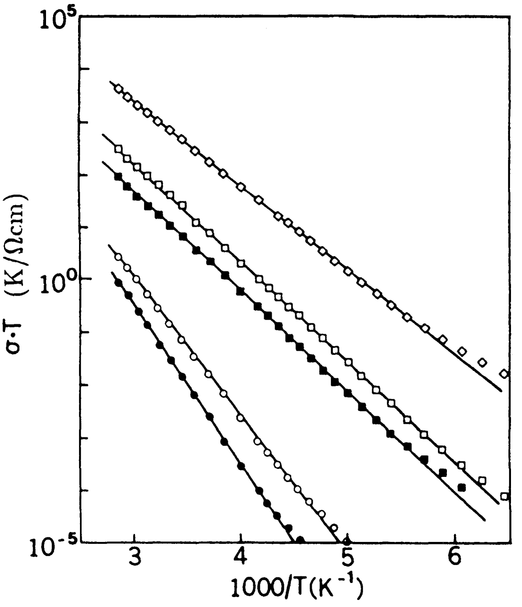

FIG. 10. Arrhenius plot for conductivity in $La_{1-x}Sr_xFeO_3$ with $x = 0.05$ (●), $x = 0.10$ (○), $x = 0.20$ (solid boxes), $x = 0.25$ (□), $x = 0.30$ (◇) in comparison with small-polaron theory (solid lines); from Jung and Iguchi (1995), reproduced by courtesy of Institute of Physics Publishing.

The bipolaron can be *free* and characterized by translational invariance, or it can be *localized.* According to Alexandrov and Ranninger (1981a,b), the many-electron system on a lattice coupled with any bosonic field turns out to be a charged Bose liquid, consisting of small bipolarons in the strong-coupling regime.

Similarly to the case of a bipolaron, an electron and a hole in a polarizable medium interacting with each other simultaneously both through the Coulomb force and via the electron–phonon–hole interaction form a quasiparticle—the *polaronic exciton.*

3.1 Fröhlich Bipolarons

In this section, the case of free bipolarons for electrons or holes interacting with longitudinal-optical phonons is discussed for the case of the continuum limit. They are referred to as Fröhlich bipolarons.

Fröhlich bipolarons are described by the following Hamiltonian:

$$\mathrm{H} = \sum_{j=1,2}\left[\frac{p_j^2}{2m_b} + \sum_{\mathbf{k}}\left(V_k a_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{r}_j} + V_k^* a_{\mathbf{k}}^\dagger e^{-i\mathbf{k}\cdot\mathbf{r}_j}\right)\right] + \sum_{\mathbf{k}} \hbar\omega_k a_{\mathbf{k}}^\dagger a_{\mathbf{k}} + U(\mathbf{r}_1 - \mathbf{r}_2), \tag{22}$$

where $\mathbf{p}_j$, $\mathbf{r}_j$ characterize the jth electron ($j = 1,2$), the potential energy for the Coulomb repulsion equals

$$U(\mathbf{r}) = e^2/\epsilon_\infty|\mathbf{r}| \equiv U/|\mathbf{r}|, \tag{23}$$

ϵ_∞ is the high-frequency dielectric constant, and the other symbols in Eq. (22) are the same as those in Eq. (1a). Note that one always has

$$U > \sqrt{2}\alpha \tag{24}$$

($\hbar = \omega_{LO} = m_b = 1$): This inequality expresses the obvious fact that $\epsilon_0 > \epsilon_\infty$.

In the discussion of bipolarons, often the ratio

$$\eta = \epsilon_\infty/\epsilon_0 \tag{25}$$

of the electronic and static dielectric constant is used ($0 \leq \eta \leq 1$). It turns out that bipolaron formation is favored by smaller η.

To estimate the order of magnitude of the quantities involved, one may express α and U as follows:

$$\alpha = \sqrt{\lambda}(1/\epsilon_\infty - 1/\epsilon_0), \tag{26a}$$

$$U = \sqrt{2\lambda}(1/\epsilon_\infty), \tag{26b}$$

with

$$\lambda = \frac{m_b}{m_e}\frac{R_y^*}{\hbar\omega_{\text{LO}}}. \tag{26c}$$

The effective Rydberg is characterized by the electron (hole) band mass m_b:

$$R_y^* = m_b e^4/2\hbar^2. \tag{27}$$

Devreese and associates (Verbist *et al.*, 1990, 1991) (VPD) analyzed the Fröhlich bipolaron using the Feynman path-integral formalism. Quite analogously to the above-discussed relations (12a) to (12d), a scaling relation was derived between the free energies F in two dimensions, $F_{2\text{D}}(\alpha,U,\beta)$, and in three dimensions, $F_{3\text{D}}(\alpha,U,\beta)$:

$$F_{2\text{D}}(\alpha,U,\beta) = \tfrac{2}{3}F_{3\text{D}}\left(\frac{3\pi}{4}\,\alpha,\ \frac{3\pi}{4}\,U,\beta\right). \tag{28}$$

This is the generalization to bipolarons of the scaling relation for a single Fröhlich polaron (Peeters and Devreese, 1987). Physically the scaling relation implies that bipolaron formation will be facilitated in 2D as compared with 3D. (The critical value for bipolaron formation α_c will be scaled with a factor $3\pi/4 \approx 2.36$; or $\alpha_c^{(2\text{D})} = \alpha_c^{(3\text{D})}/2.36$).

Smondyrev *et al.* (1995) derived an analytical strong-coupling asymptotic expansion in inverse powers of the electron–phonon coupling constant for the large bipolaron energy at $T = 0$:

$$E_{3\text{D}}(\alpha,u) = -(2\alpha^2/3\pi)A(u) - B(u) + O(\alpha^{-2}), \tag{29a}$$

where the coefficients are closed analytical functions of the ratio $u = U/\alpha$:

$$A(u) = 4 - 2\sqrt{2}u\left(1 + \frac{u^2}{128}\right)^{3/2} + \tfrac{5}{8}u^2 - \frac{u^4}{512}, \tag{29b}$$

and for $B(u)$ see the above-cited paper.

The scaling relation (28) allows one to find the bipolaron energy in two dimensions as

$$E_{2\text{D}}(\alpha,u) = \tfrac{2}{3}E_{3\text{D}}\left(\frac{3\pi}{4}\,\alpha,u\right). \tag{30}$$

A "phase diagram" for the polaron–bipolaron system was introduced by VPD. It is based on the generalized trial action. This phase diagram is shown in Fig. 11 for the 3D case. A Fröhlich coupling constant as high as 6.8 is needed to allow for bipolaron formation. No definite experimental evidence has been provided for the existence of materials with such high Fröhlich coupling constant. (One of the highest α's reported is for RbCl where $\alpha \approx 3.8$ and for CsI where $\alpha \approx 3.7$; see Table 1.)

Materials with sufficiently large α for Fröhlich bipolaron formation in 3D might exist, but careful analysis (involving, e.g., the study of cyclotron resonance), like the one executed for AgBr and AgCl (Hodby *et al.*, 1987), is in order to confirm this. Presumably some modifications to the Fröhlich Hamiltonian are also necessary to describe such high coupling because of the more localized character of the carriers in this case, which makes the continuum approximation less valid.

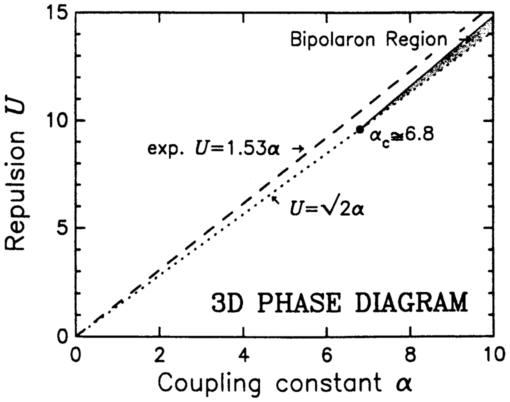

FIG. 11. The stability region for bipolaron formation in 3D from Verbist *et al.* (1990). The dotted line $U = \sqrt{2}\alpha$ separates the physical region ($U \geq \sqrt{2}\alpha$) from the nonphysical ($U \leqslant \sqrt{2}\alpha$). The stability region lies below the full curve. The shaded area is the stability region in physical space. The dashed line is determined by $U = \sqrt{2}\alpha/(1 - \epsilon_\infty/\epsilon_0)$ where we took the experimental values $\epsilon_\infty = 4$ and $\epsilon_0 = 50$. The critical point $\alpha_c = 6.8$ is represented as a full dot.

The confinement of the bipolaron in 2D facilitates bipolaron formation at smaller α. From Fig. 12 it is seen that bipolarons can now be stable for $\alpha \geq 2.9$, a domain of coupling constants that is definitely realized in several solids. Intuitive arguments suggesting that bipolarons are stabilized in going from 3D to 2D had been given before, but the quantitative analysis based on the path integral was presented by VPD.

The stability of bipolarons has also been examined with the use of operator techniques where the center-of-gravity motion of the bipolaron was approximately separated from the relative electron (hole) motion (see Bassani *et al.*, 1991). The results by Bassani *et al.* (1991) and by VPD tend to confirm each other.

The bipolaron was also approached (Hiramoto and Toyozawa, 1985) in the path-integral representation using a special case of the trial action of VPD; in this work the combined effect of LO phonons, acoustic phonons, and deformation potential was analyzed.

Early work on bipolarons had been based on strong-coupling theory, in which case the bipolaron stability can be expressed with η as the sole parameter. ($\eta < 0.08$ is a typical strong-coupling result for bipolaron stability.) It turns out that the numerical stability criteria of VPD can be adequately formulated analytically for all α, for which the bipolaron is stable.

A very clear representation of experimental evidence for bipolarons, e.g., from the data on magnetization and electric conductivity in Ti_4O_7, as well as in $Na_{0.3}V_2O_5$ and polyacetylene, given by Mott (1990) is to be mentioned.

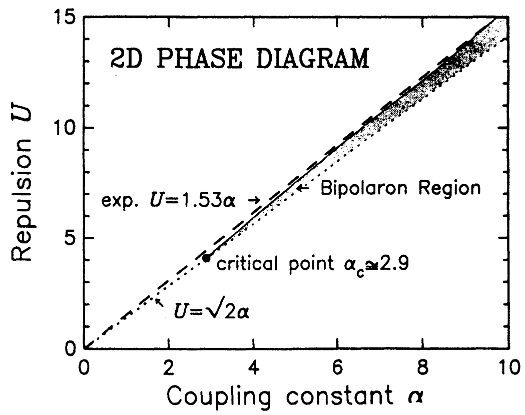

FIG. 12. The same as Fig. 11, but now for 2D, where the critical point is $\alpha_c = 2.9$; from Verbist *et al.* (1990).

Recently, the effect of a high magnetic field on bipolarons was examined both for singlet and triplet states (Fomin and Devreese, 1995).

3.2 Polaronic Excitons

Excitons (*q.v.*) constitute very interesting physical entities, which in polarizable media are relevant to polarons: In polar systems they can be conceived as two interacting polarons of opposite charges (Haken, 1956; Toyozawa, 1963, 1964; Knox, 1963; Bassani and Baldereschi, 1973; Bassani and Pastori Parravicini, 1975; Adamowski *et al.*, 1981; Wallis and Balkanski, 1986).

The exciton ground-state energy in a polar crystal was determined by Pollmann and Büttner (1975, 1977) and by Aldrich and Bajaj (1977) taking into account the fact that the potential energy of the electron–hole interaction depends on the quantum state of the interacting particles as a result of the polaronic effect. Later on, many works were devoted to this problem. Similar considerations were applied by Petelenz and Smith (1981) to explain the dependence of the binding energy of an exciton-ionized donor complex on the electron-to-hole mass ratio in CdS and TlCl, and by Larsen (1981) to show that the ratio of the binding energy of the D^- centers to that of neutral donors in AgBr and AgCl is as much as one order of magnitude larger than in a nonpolar crystal. The binding enhancement is due to the *attraction* between the electrons and the static polarization charge induced by them in the central part of the ion. Experimental data on the spectral photoconductivity in the systems Ca–Sr–Bi–Cu–O (Masumi *et al.*, 1988a) and Ba–Pb–Bi–O (Masumi *et al.*, 1988b) have been interpreted as due to an exciton-mediated bipolaronic mechanism. Recent experimental data on the reflectivity and its temperature dependence in La_2CuO_4 were interpreted in terms of polaronic excitons by Falck *et al.* (1992).

3.3 Localized Bipolarons

Localized bipolarons tend to be *small* bipolarons, characterized by a radius of the order of the lattice constant. For a small bipolaron, both constituting polarons can be localized either at the same lattice site (intrasite, or Anderson, bipolaron; see Anderson, 1975) or at two different lattice sites, e.g., at two neighboring lattice sites (intersite bipolaron).

For two electrons (holes) on the same site, the direct Coulomb repulsion is governed by the potential energy U. Whether or not two electrons remain at the same site is determined by U_{eff}, the effective potential that arises if both the Coulomb repulsion and the electron (hole)–phonon or polaron interaction are taken into account. If the polaron interaction dominates ($U_{\text{eff}} < 0$) the Coulomb repulsion, one speaks of *negative-U behavior* and two carriers can be occupying the same site ("double occupancy of a lattice site"); a bipolaron localized on one site arises. Negative-U bipolarons have been suggested to occur, e.g., in *chalcogenide glasses* (Anderson, 1975; Mott, 1990).

The intersite bipolaron can form *singlet* (bonding as well as antibonding) or *triplet* states (Fig. 13). Intersite singlet bipolarons are usually referred to as Heitler–London bipolarons (see, for example, de Jongh, 1988).

Localization of bipolarons was investigated by many authors including Lannoo *et al.* (1959), Hubbard (1964), Stoneham and Bullough (1971), Anderson (1975), and Mott (1990), to name a few. An extensive literature exists, and a more complete discussion is given by Fisher *et al.* (1989). Localized bipolarons have been studied in numerous oxides including Ti oxides, vanadium bronzes, $LiNbO_3$, and WO_3.

Hybridization between coexisting localized bipolarons and itinerant electrons leads to a possibility of the coherent motion of bipolarons and their phase transition into a superfluid state upon lowering the temperature to a certain critical temperature (Ranninger, 1994), which seems to be relevant to the phenomena occurring in cuprates, bismuthates, and fullerenes.

4. SPIN POLARONS

Just as electrons or holes interact with the Bose field of phonons, they can, because of the exchange interaction, interact with the magnon field. This gives rise to the formation of the *spin polaron* (or magnetic polaron). One of the first studies related to spin polarons is due to de Gennes (1960).

Intuitively one can imagine that, e.g., in an antiferromagnet, the carrier spin polarizes the spins of the surrounding magnetic ions. The spin polaron consists of the carrier with its spin together with the lattice magnetization created by the carrier spin. Similar to the case of the dielectric polaron, the physical properties of the carrier are influenced by the self-induced magnetization cloud. The mechanism for the formation of spin polarons can be easily understood for

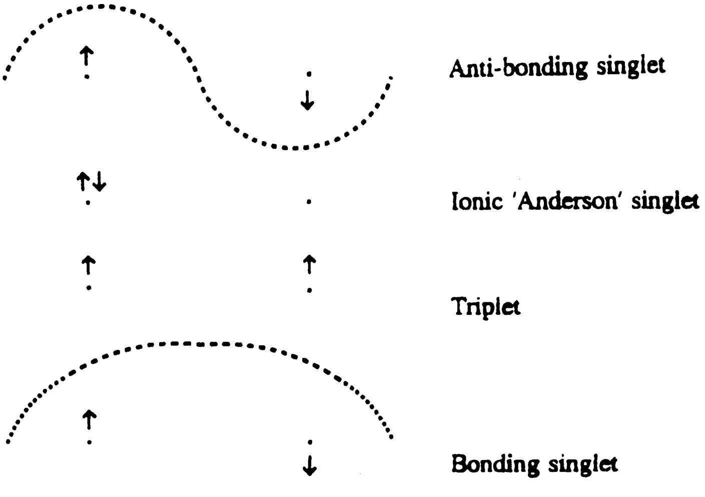

FIG. 13. States of a model two-site, two-electron system where the electrons are coupled to the interatomic coordinate; from Fisher *et al.*, (1989), reproduced by courtesy of Institute of Physics Publishing.

materials with preference for antiferromagnetic alignment; the kinetic energy of a carrier can be reduced if reversing the spins of the surrounding ions allows the carrier to move more easily around these ions (Wood, 1991).

In principle, spin polarons can arise in ferromagnets as well. Also the induced magnetic polarization can be characterized by ferromagnetic as well as antiferromagnetic alignment.

In general, it is accepted that the evidence for the occurrence of *bound magnetic polarons* is more convincing than that for *free magnetic polarons* (Benoit á la Guillaume, 1993). Bound magnetic polarons occur when the carriers are localized (e.g., because they are bound to a donor or to an acceptor).

The bound magnetic polaron has been studied primarily in Mn-based semimagnetic semiconductors (SMSC). The bound magnetic polaron then originates from the exchange interaction between a rather localized unpaired carrier and the $\frac{5}{2}$ spin of the surrounding Mn^{2+} ions. In the bound magnetic polaron, ferromagnetic order occurs within the orbit of the bound carrier and the magnetic exchange leads to an increase of its binding energy. For spin polarons, e.g., in the case of EuS doped with GdSe (Mott, 1990), the basic interaction energy between a conduction-electron spin and the surrounding magnetic moments is given by

$$J_{sf} sS |\Psi_s(0)|^2 V; \tag{31}$$

here J_{sf} is the energy of the ferromagnetic coupling between the spin s of the conduction electron and the europium ion spin S, $\Psi_s(0)$ is the wave function of the conduction electron at the origin, and V is the atomic volume.

A transparent intuitive consideration due to Mott (1990) leads to a simple expression for the spin-polaron radius:

$$R = \left(\frac{\hbar^2 \pi a^3}{4m^* J_N}\right)^{1/5}, \tag{32}$$

where J_N is the energy, per moment, needed for a transition from the antiferromagnetic alignment to the ferromagnetic alignment, m^* is the effective mass of the carrier, and a the lattice parameter of the host solid.

For the effective mass of the spin polaron, the following expression has been derived (Mott, 1990):

$$m^*_{sp} = m^* e^{\gamma R/a}, \tag{33}$$

with $\gamma \approx 1$.

5. BIPOLARONS AND HIGH-TEMPERATURE SUPERCONDUCTIVITY

Dielectric or Fröhlich bipolarons as well as spin bipolarons have been considered as possibly playing a role in superconductivity. Also the "small-polaron" interaction was studied in the framework of superconductivity.

In fact, already the charged bosons of Schafroth (1955) could be thought of as Fröhlich bipolarons. However, although the London equation indeed results from a bipolaron-gas model, a continuous behavior of the specific heat C_V was found at the superconducting transition temperature in contradistinction from experiment. After the success of the BCS theory with its Cooper pairs consisting of electrons coupling in **k** space, $|\uparrow, \mathbf{k}; \downarrow, -\mathbf{k}\rangle$, the bipolaron gas and the pairing in real space became a less central issue.

Nevertheless, theoretical models incorporating small bipolarons [localized Cooper pairs with electrons (holes) of opposite spins on nearest-neighbor sites] and small bipolarons in narrow bands and characterized by hopping conductivity were still studied (Alexandrov and Ranninger, 1981a,b; Chakraverty *et al.*, 1987). These models had not predicted high-T_c superconductivity, however.

After the discovery of high-T_c superconductivity, alternative models (with respect to BCS) for superconductivity received renewed attention. It is experimentally clear that also in the high-T_c materials, pairing of carriers in the superconducting phase takes place. However, different coupling mechanisms might be at the basis of the pairing; e.g., coupling through acoustic plasmons has been considered.

In the present context, a preliminary question is whether Fröhlich or spin bipolarons do form in high-T_c materials. This question has been investigated by Verbist *et al.* (1991), and the polaron–bipolaron phase diagram was applied, e.g., to La_2CuO_4 (see Fig.

12). In this figure the existence line for bipolarons in $YBa_2Cu_3O_6$ corresponds to $U \approx 1.49\alpha$. On the basis of the existing experimental data, it can be stated that the characteristic point in the polaron–bipolaron phase diagram for La_2CuO_4 and $YBa_2Cu_3O_6$ lies on the straight line through the origin and is shown in the figure. Presumably the Fröhlich coupling is large enough in these materials that their α overlaps with the bipolaron existence region with reference to α. It is remarkable that the existence line for bipolarons lies very close to (La_2CuO_4) or penetrates ($YBa_2Cu_3O_6$) the very narrow existence domain for large bipolarons. It seems therefore *safe to assume* that Fröhlich bipolarons do occur in some of the high-T_c materials in the normal phase; see Verbist *et al.* (1990) and Devreese *et al.* (1994).

It should be reiterated that the precise α value characterizing the high-T_c materials is not known as long as the band mass has not been determined. It may also be observed that most other "polaron materials" (alkali halides, etc.) find their characteristic points in the polaron–bipolaron phase diagram far away from the bipolaron-stability area.

Cataudella *et al.* (1992) and Iadonisi *et al.* (1995) have undertaken the study of the many-body physics of the bipolaron gas in an approximation comparable to that by Verbist *et al.* (1990), but based on a Hamiltonian formulation. Although the mathematics of this problem is complex and the studies are far from finalized, some promising features arise; especially the variation of T_c for the high-T_c materials as a function of the doping is well reproduced, be it with one fitting parameter.

On the basis of results by Verbist *et al.* (1991), also the optical spectra of bipolarons were analyzed (Devreese *et al.*, 1994); it was suggested that the mid-IR peak characterizing the high-T_c solids is related to relaxed excited states of the bipolaron.

Emin and Hillery (1989) studied the interplay between short- and long-range polaron interaction in the adiabatic (strong-coupling) approximation. This work joins the ideas of Schafroth and examines in more detail the character of the mobile charged bosons as bipolarons. (It should be noted that—in fact—the adiabatic theory does not lead to the existence of strong-coupling large Fröhlich bipolarons.)

In discussing bipolaronic superconductivity as a candidate theory for high-T_c superconductivity, one should mention the analysis by Mott in terms of *spin bipolarons.* Mott (1991) has emphasized how a metal–insulator transition occurs in several of the high-temperature superconductors, the metal being superconducting. In analyzing this transition, he suggests the formation of spin polarons and the possibility that they combine to form bipolarons. Those bipolarons could replace the Cooper pairs. Alexandrov *et al.* (1994a) have also analyzed the nondegenerate gas of bosons above T_c. In particular, the linear T behavior of the resistivity above T_c was accounted for. Mott envisaged the possibility of two different mechanisms for superconductivity depending on the hole concentration (for one of the mechanisms, the bosons do not overlap; for the other they do) and stressed the analogy of high-T_c superconductors to the behavior of superfluid ^{4}He. The quantitative formulation of this fact goes back to Alexandrov and Ranninger (1992), who used a mapping of the electronic specific heat of high-T_c superconductors onto that of ^{4}He to show that its λ-like temperature dependence may be described in terms of charged bosons.

A spin-bipolaron model has been invoked by Alexandrov *et al.* (1994b) to explain the experimental data on the Hall effect and resistivity in underdoped $YBa_2Cu_3O_{7-\delta}$ (Carrington *et al.*, 1993), based on the assumption that at zero temperature a part of the spin bipolarons are in Anderson localized states due to disorder. The agreement between theory and experiment exists at least in the region of temperatures higher than the temperature T^* at which the slope of resistivity changes. This is illustrated in Figs. 14 and 15, representing the temperature dependence of the Hall coefficient and of the resistivity for different values of the degree of reduction in $YBa_2Cu_3O_{7-\delta}$.

Also, the Cooper pairing of small polarons has been regarded as a possible mechanism of high-T_c superconductivity; see, e.g., a comprehensive review by Alexandrov and Mott (1994) and an extensive list of references therein. It was shown that there exists an intermediate region of the coupling constant, where the energy of interaction between small polarons (resulting from the interplay between the Coulomb repulsion and the at-

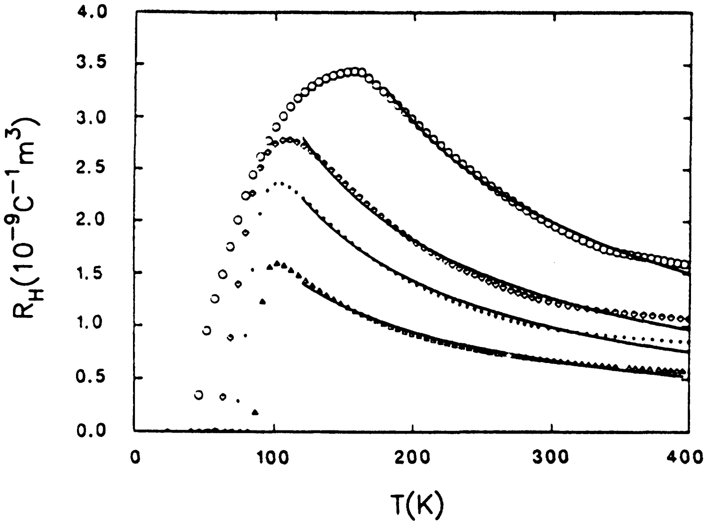

FIG. 14. Hall coefficient of YBa$_2$Cu$_3$O$_{7-\delta}$ for various degrees of reduction: $\delta = 0.05$ (△), $\delta = 0.19$ (●), $\delta = 0.23$ (◇), $\delta = 0.39$ (○) (Carrington *et al.*, 1993) in comparison with theory; from Alexandrov *et al.*, (1994b), reproduced by courtesy of Elsevier Science Publishers.

traction due to their interaction with the lattice) is smaller than, or of the same order as, the small-polaron bandwidth, both being less than or comparable to the phonon frequency. In this region, the BCS theory predicts superconductivity even for on-site repulsion, provided that it is weaker than the total intersite attraction of small polarons. It is the *polaronic narrowing* of the band that increases the estimated maximum value for the critical temperature when the interaction with high-frequency phonons is dominant. This maximum occurs for an intermediate value of the coupling constant which is situated at the boundary between the above-described polaronic superconductivity region, on the one hand, and the bipolaronic superconductivity region, on the other hand. The latter mechanism is considered to be relevant for values of the coupling constant high enough to make the energy of attraction between small polarons much larger than the small-polaron bandwidth. In this case, the ground state of the system of small polarons can be—in first approximation—regarded as consisting of a phonon field and a set of immobile small *bipolarons,* the hopping term treated as a perturbation producing the bipolaronic motion.

A serious alternative to the picture devel-

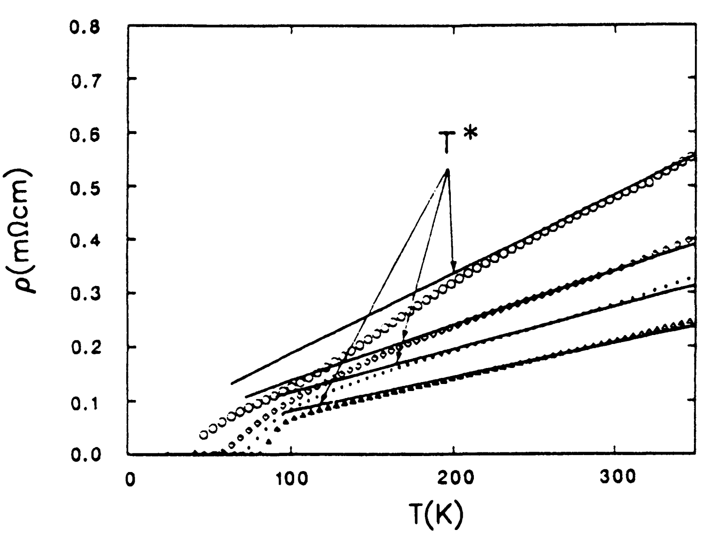

FIG. 15. Resistivity of YBa$_2$Cu$_3$O$_{7-\delta}$ for various degrees of reduction in the same denotations as in Fig. 14 (Carrington *et al.*, 1993) in comparison with theory. T^* stands for the temperature at which the change in the slope of resistivity occurs; from Alexandrov *et al.* (1994b), reproduced by courtesy of Elsevier Science Publishers.

oped by Alexandrov and Mott (1994) is the fermion–boson model considering a possibility of exchange between localized bipolarons and itinerant electrons, which goes back to Ranninger and Robaszkiewicz (1985). Depending on the filling, this model gives either a BCS-like state or a superfluid state of bipolarons with a dramatic increase of T_c beyond a critical concentration.

In summary of this section, it is realized that no definite theory for high-T_c superconductivity (whether or not it involves bipolarons) is available as yet; nevertheless dielectric bipolarons, spin-bipolaron gases, and polaron–bipolaron mixtures seem to be systems of significant promise in attempting to construct such a theory.

6. FURTHER DEVELOPMENTS OF THE POLARON CONCEPT

6.1 Polarons and Bipolarons in Polymers. Solitons

Many conjugated polymers (e.g., *trans*-polyacetylene) behave as quasi-1D semiconductors (where the energy gaps are between 1.5 and 3.0 eV). The carrier transport in those systems seems to take place through *charged defects* originating as a result of doping. These charged defects are influenced by the polaronic interaction with the surroundings. At low temperature, the transport is dominated by the motion of the defects; at higher doping levels hopping conductivity occurs. As is well known, the possible application of those polymers (including, e.g., those in aerospace technology) has attracted wide attention.

Su *et al.* (1980) have proposed a model Hamiltonian to study the physics of conjugated polymers. In analyzing the polaronic localized states related to the charged defects, nonlinear behavior, characteristic of solitons, is revealed. Polaron-type excitations were experimentally observed in polyacetylene by Su and Schrieffer (1980).

Polarons in conjugated polymers constitute a challenging and vast subject; in the context of this article only its significance and main ingredients are pointed out; the reader is referred to comprehensive reviews by Yu (1988) and Fisher *et al.* (1989). Bipolarons might occur in polymers at higher dopant levels, and the question of polaron–bipolaron conversion rates is a central one.

6.2 Modeling Systems Using the Polaron Concept

Originally the polaron was mainly studied to describe the electron–LO-phonon interaction. The concept has been generalized to several systems where one or many fermions interact with a bath of bosons or to instances where such an approximation is meaningful. Table 4 lists several such cases. The fundamental concepts concerning a piezopolaron—this is a name for a quasiparticle arising from the piezoelectric interaction between an electron and acoustic phonons—were displayed by Mahan (1972) and Lax (1972). More recently, convincing experimental evidence on the significant role of piezopolarons in the electronic transport properties of CdS has been presented by Mahan (1990).

Other examples include the motion of a ^{3}He atom through superfluid helium considered by Bardeen *et al.* (1969) and by Brosens *et al.* (1991), or the dynamics of electrons (2DEG) at the surface of liquid He—"ripplonic polaron" (Jackson and Platzman, 1981; Peeters, 1987).

Charges moving through liquids (many of which are characterized by polarizable atoms) have been modeled as "hydrated polarons" (Laria *et al.*, 1991). Even an electron in-

Table 4. Extensions of the polaron concept.

Concept	"Candidates"
Acoustic polaron	Hole in AgCl
Piezoelectric polaron	ZnO, ZnS, CdS
Electronic polaron	Band structure of all semiconductors
Spin polaron	Magnetic semiconductors
Bipolarons:	
One center	Amorphous chalcogenides
Two center	Ti_4O_7, vanadium-bronzes
Small polarons and hopping	Transition-metal oxides, polyacetylenes
Superconductivity and (bi)-polarons ("Localized electron pairs")	$BaPb_{1-x}$ (1981) Bi_xO_3 $LiTi_2O_4$ (1985) "High-T_c superconductivity"

teracting with plasmons ("plasmaron") was invoked to study the electron gas. A new subject concerns the occurrence of polarons in fullerenes (Matus *et al.*, 1992).

These extensions of the polaron concept are not treated in any detail here, but they illustrate the richness of the polaron concept.

A valuable extension of the polaron concept arises by considering the interaction between a carrier and the exciton field. One of the early formulations of this model was by Toyozawa (1963). The resulting quasiparticle is called the *electronic polaron.* The self-energy of the electronic polaron (which is almost independent of wave number) must be taken into account when the band gap of an insulator or semiconductor is calculated using pseudopotentials. For example if one calculates, with Hartree–Fock theory, the band gap of an alkali halide, one is typically off by a factor of 2. This was the original problem that was solved conceptually with the introduction of the electronic polaron (Toyozawa, 1963; Kunz, 1974). Also in the soft x-ray spectra of alkali halides exciton sidebands have been observed that seem to be due to the electronic polaron coupling (Devreese *et al.*, 1972). The standard "local density approximation" (LDA) does not provide the correct band gap for semiconductors. The solution to this problem (Hybertsen and Louie, 1987; Godby *et al.*, 1988) via the so-called GW approximation of Hedin (1965) is analogous in its basic interaction to Toyozawa's solution of the gap problem for strongly ionic crystals.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to several colleagues for many stimulating discussions and contributions on polarons over the years: R. Evrard, F. Peeters, F. Brosens, L. Lemmens. He also wishes to acknowledge recent interactions and fruitful discussions in particular with V. Fomin, and also with M. Smondyrev.

This work has been partially supported by the E.E.C. Human Capital and Mobility Program under Contract No. CHRX-CT93-0124.

GLOSSARY

Anderson Bipolaron: See **Intrasite Bipolaron.**

Bipolaron: A composite quasiparticle consisting of a bound state of two conduction electrons (or holes) and the surrounding common cloud of virtual phonons.

Electronic Polaron: A quasiparticle that arises as a result of the interaction between a charge carrier and the exciton field.

Ferron: See **Magnetic Polaron.**

Free Bipolaron: A **bipolaron** characterized by translational invariance, which can move as a free particle of enhanced mass (bipolaron mass).

Free Polaron: A **polaron** characterized by translational invariance, which can move as a free particle of enhanced mass (polaron mass).

Fröhlich Bipolaron: A **large bipolaron** formed through the electron–LO-phonon interaction in a polarizable continuum.

Fröhlich Polaron: A **large (radius) polaron** formed through the electron–LO-phonon interaction in a polarizable continuum.

Heitler–London Bipolaron: A singlet **intersite bipolaron.**

"Hydrated Polaron": A quasiparticle modeling charges that move through liquids (many of which are characterized by polarizable atoms).

Intersite Bipolaron: A **bipolaron** in which the two constituent small polarons are localized at two different lattice sites.

Intrasite Bipolaron: A **small bipolaron** in which the two constituent polarons are localized at the same lattice site.

Large Bipolaron: A **bipolaron** with a **Radius** much larger than the lattice constant.

Large (Radius) Polaron: A **polaron** with a radius considerably larger than the lattice constant of the solid.

Landau Polaron: See **Fröhlich Polaron.**

Magnetic Polaron: A quasiparticle consisting of an electron together with a group of magnetic moments oriented antiparallel to the electron spin as a result of the exchange interaction of the electron with the magnon field.

Pekar Polaron: See **Fröhlich Polaron.**

Piezopolaron: A quasiparticle arising from the piezoelectric interaction between an electron and acoustic phonons.

"Plasmaron": A quasiparticle sometimes considered as consisting of an electron (or hole) interacting with plasmons in the electron gas.

Polaron: A quasiparticle consisting of a conduction electron (or hole) together with

- its self-induced polarization in a polar semiconductor or an ionic crystal;
- the self-induced lattice deformation field in a nonionic material;
- the self-induced perturbation of a Bose field (in the modern extensions of the polaron concept).

Polaronic Exciton: A composite quasiparticle, which is formed by two charge carriers of opposite sign and a surrounding cloud of virtual phonons.

Radius of a bipolaron: A characteristic size of the common cloud of virtual phonons, surrounding two electrons (or holes) in a **bipolaron.**

Radius of a polaron: A characteristic size of the fluctuations in space of an electron in a **polaron** due to emission and absorption of virtual phonons.

"Ripplonic Polaron": A quasiparticle describing the dynamics of electrons at the surface of liquid ^{4}He.

Small Bipolaron: A **bipolaron** with a **radius** of the order of the lattice constant. A small bipolaron can move by hopping from one localization position to another.

Small (Radius) Polaron: A **polaron** with a radius of the order of the lattice constant. A small polaron can move by hopping from one lattice site to another.

Spin Polaron: See **Magnetic Polaron.**

INTRODUCTION

This work is restricted to the dynamics of polymers at microscopic length scales in both dynamic equilibrium and nonequilibrium systems. Macroscopic dynamics of polymeric liquids is also considered, but only insofar as it is predicted from microscopic models. Continuum-mechanical considerations are otherwise ignored. The properties of flexible chains are considered in both dilute and concentrated regimes. An emphasis is placed on those properties that are largely independent of chemical detail. Exceptions are chain architecture, and the consideration of solvent quality for solutions. Special properties of liquid-crystalline polymers (which can form polycrystalline phases), or biological polymers, such as proteins, are not considered. A discussion of static equilibrium properties is limited to those properties that are important for dynamics. However, time-independent conformational properties in flows are discussed. Modeling is primarily restricted to stochastic, mean-field theories for intermediate to long time scales. Given the extremely large number of competing models, theories are broadly categorized, and many details are necessarily omitted.

1. OVERVIEW OF POLYMER DYNAMICS

Polymers are large chains made up of repeating monomers (chemical units) and have molecular weights exceeding roughly 10^4. Synthetic polymers may contain all identical monomer units, whereas biological poly-

mers, such as proteins, are made up of many different subunits attached in various arrangements. The specific sequence of subunits on a protein may give each protein its individual conformations in the folded shape, such as α sheets, or $\alpha\beta$ barrels. Since we are concerned here with the large-scale, universal behavior of polymers, we do not consider the specific properties of proteins further, although some of the properties outlined here may also describe biological polymers.

Depending on the chemical structure, monomers of synthetic polymers may be attached in linear or branched fashions; examples of simple branched polymers are comb-shaped and star-shaped molecules. A batch of synthesized polymers is never *monodisperse* (all chains having identical molecular weights), but has a distribution of weights, and is hence called *polydisperse.* The details of the distribution of molecular weights may be found by chromatography, but are usually not known for a given batch. Oftentimes, the only information available about the distribution is the single dimensionless quantity called the *polydispersity index* (>1), which is the ratio of the weight-averaged molecular weight of chains M_w to the number-averaged weight M_n,

$$M_n := \frac{1}{n_c}\sum_{i=1}^{nc} M_i, \quad M_w := \frac{1}{n_c M_n}\sum_{i=1}^{nc} M_i^2, \tag{1}$$

where M_i is the molecular weight of chain i in a sample of n_c chains. A monodisperse batch of chains has polydispersity index of unity, and the broader the distribution, the greater the value.

Because of the large molecular weight and the more or less linear fashion in which the chains are constructed, polymers are orders of magnitude longer than they are wide, regardless of the chemical structure of the monomer. This feature suggests the existence of an intermediate length scale that is larger than a monomer, but shorter than the entire chain. If we probe only the dynamics of the chain on this length scale or larger, we expect to find results that are independent of the specific chain chemistry. These intermediate length scales are probably the ones that give rise to important macroscopic behavior. Therefore, we coarse grain the information on specific chemical structure into a few simple ideas:

1. the architecture of the chain (e.g., linear, star shaped, ring),
2. the *Kuhn step length* of the chain, and
3. the polymer–solvent interaction parameter.

The first two ideas are important for both undiluted chains and polymer solutions, whereas the last is applicable only to solutions.

Roughly speaking, the Kuhn step length (Flory, 1969, p. 12) is the average distance necessary to travel from one monomer along the chain to another monomer that has orientation statistically independent from that of the first monomer when the liquid is at equilibrium. Its value will depend upon the polymer chemistry: Molecules with stiff backbones will have values larger than those of flexible chains. A related quantity is the *persistence length* (Doi and Edwards, 1986). If two monomers separated by a distance s along the contour have orientations $\mathbf{u}_0$ and $\mathbf{u}_s$, then the correlation of the orientations falls with increasing s. If we assume that the decrease is exponential, then the persistence length is l_p, where

$$\langle \mathbf{u}_0 \cdot \mathbf{u}_s \rangle = \exp(-s/l_p). \tag{2}$$

To a good approximation, one can assume that the Kuhn step length is twice the persistence length.

The polymer–solvent interaction can be divided roughly into three categories: *good, theta,* and *poor solvents.* The quality of solvent can be described by a single quantity, such as the *Flory interaction parameter* $\chi := \chi_{\text{MS}} - \frac{1}{2}(\chi_{\text{MM}} + \chi_{\text{SS}})$, where χ_{MS} is the energy of interaction between a monomer and the solvent, for example (Flory, 1969; Yamakawa, 1971; de Gennes, 1979; des Cloizeaux and Jannink, 1990). Crudely put, the solvent is called good (poor) when it is energetically more (less) favorable for a monomer to be adjacent to a solvent particle than another monomer and $\chi < \frac{1}{2}$ ($\chi > \frac{1}{2}$). In addition to energetic interactions between monomers, there are also steric interactions. When steric and energetic interactions are balanced, the solvent is called a theta solvent. Since the quality of the solvent is temperature dependent, the *theta temperature* is that at which the solvent is a theta solvent for a given system. Static equilibrium properties of dilute polymer chains in theta solvents can be modeled as a random walk, whereas dilute polymer chains in good solvents are closer to self-avoiding random walks.

Because of the large number of degrees of freedom of the polymer chain, the chain may take effectively an infinite number of possible configurations. The size of the polymer chain may be described by the average

$$\langle R_G^2 \rangle := \frac{1}{N} \sum_{\mu=1}^{N} \sum_{\nu=1}^{N} \langle \mathbf{R}_\mu \cdot \mathbf{R}_\nu \rangle, \tag{3}$$

where R_G is the *radius of gyration*, the angular brackets represent an ensemble average of chains in the system, N is the number of Kuhn steps in a chain, and $\mathbf{R}_\nu$ is the vector from the center of mass of the chain to the νth Kuhn step.

Polymers in good solvents can be categorized as dilute, semidilute, or concentrated. In dilute solutions, polymers exist as independent coils that do not overlap. In a theta solvent, a chain's mean square radius of gyration scales as $\langle R_G^2 \rangle \sim N$, which is consistent with modeling the coarse-grained chain as a random walk. In a good solvent, the coil swells to a larger size and no longer behaves like a random walk, but $\langle R_G^2 \rangle$ scales roughly as $N^{2\nu}$, $\nu \approx \frac{3}{5}$. In a poor solvent, the coil shrinks in size and also no longer scales like a random walk.

A semidilute solution is characterized by the onset of overlap between different coils. Thus, if we call c^{**} the critical number concentration where chains begin to overlap, we can estimate its magnitude by

$$\tfrac{4}{3}\pi \langle R_G^2 \rangle^{3/2} \approx 1/c^{**}. \tag{4}$$

It is believed that chains in the semidilute region do not substantially interpenetrate.

As the concentration is increased further past the critical, molecular-weight- and chemistry-dependent *entanglement concentration* c^*, the chains begin to become entangled with one another, and the kinematics of the chains becomes much slower, and scaling dependence on molecular weight becomes much more pronounced (Graessley, 1974). There is also a minimum *entanglement molecular weight* M_e, below which the chains are not entangled. The presence of the entanglement is evident in a plateau region of the relaxation modulus described in Sec. 2.4.1. At about twice this molecular weight, the zero–shear-rate viscosity scales more strongly with molecular weight.

Brownian forces cause the subunits of the chain to rearrange continually, even at equilibrium, while the center of mass of the polymer chain exhibits Brownian motion. The instantaneous mobility of a chain depends upon its configuration, which may result in anisotropic diffusion for any given configuration. However, the average configuration of chains at equilibrium results in an overall isotropic diffusion for the entire system. The rearrangement of smaller length scales in the polymer results in a spectrum of relaxation times, one for each length scale. The simplest model that exhibits the relaxation of various length scales is the Rouse model described in Sec. 3.1.1.

Through interactions with the solvent or with surrounding chains, the dynamics of the polymer on the *microscopic* length scale can be influenced by *macroscopic* deformations of the fluid, and the average conformation of the polymer chain can be greatly distorted from that at equilibrium. In turn, the anisotropic orientation of the chains leads to anisotropic macroscopic stresses in the fluid. Thus, mechanical experiments that deform the fluid and simultaneously measure the resulting stresses can be used to infer information about the dynamics of the chains.

On the other hand, optical techniques can directly probe the average orientation and dynamics of polymer segments, either in dynamic equilibrium experiments or in nonequilibrium flow fields. When these two techniques are used together, complementary information is obtained.

After describing the goals of research in polymer dynamics in the next section, we explain the method of measuring some of the properties discussed above, as well as additional experimental observations.

1.1 Goals of Polymer Dynamics

The goals of polymer dynamics can be separated into the following broad questions:

1. What is the microscopic dynamics of the polymer chains *at equilibrium?*

2. What is the microscopic polymer dynamics *in flow fields?*
3. How does the microscopic dynamics affect the *macroscopic properties of the flowing continuum?*

The first two questions remain ongoing fields of research both theoretically and experimentally. Much greater progress has been made on the last question for optical and stress properties. Less progress has been made on thermodynamic and mass-transport properties of chains in flow fields.

From the macroscopic point of view, if one applies the idea of momentum balance to a continuum, the equation of motion, or Cauchy's equation, arises (Bird *et al.*, 1960):

$$\rho \frac{\partial \mathbf{v}_f}{\partial t} + \rho \mathbf{v}_f \cdot \nabla \mathbf{v}_f = -\nabla p - \nabla \cdot \boldsymbol{\tau} + \rho \mathbf{g}, \tag{5}$$

where ρ is the density of the fluid, $\mathbf{v}_f$ is the velocity of the fluid, t is time, p is the pressure, $\mathbf{g}$ is the gravity vector, and $\boldsymbol{\tau}$ is the extra stress tensor. To close the equation, we need a constitutive equation relating the stress $\boldsymbol{\tau}$ to the flow field $\mathbf{v}_f$.

For a Newtonian fluid, one assumes that the stress tensor depends linearly on the components of the instantaneous, local velocity-gradient tensor only. To be objective, if the fluid is incompressible and isotropic, the stress tensor depends only upon a single material constant called viscosity. If this Newtonian constitutive equation is inserted into Eq. (5), the Navier–Stokes equation results.

On the other hand, it is easily shown that polymeric fluids do not obey Newton's constitutive equation. For example, if a flow field is suddenly switched off after being applied for some time, the stress field of a polymer fluid decays to zero only slowly, whereas that for a Newtonian fluid decays to zero instantaneously. Thus, the Navier–Stokes equation does not apply, and we need to find the proper constitutive equation for $\boldsymbol{\tau}$. *No single constitutive equation has been found that correctly describes the stresses arising in all flow fields for polymeric fluids.* For this reason, this field of research is primarily experimental. We discuss below some of the progress made from a microscopic viewpoint to derive a proper constitutive equation.

Qualitatively, we know that the constitutive equation must depend upon the kinematic history of the deformation for any given material element. Thus, experiments that probe the continuum must be careful to insure that the history of the deformation of the material is known in order to infer the relationship between stress and strain. Here we focus on those flows that are homogeneous deformations at all times throughout the entire region of the sample being tested.

The deviation from Newtonian behavior is not surprising, given the above observations: Polymer chains can extend in space and exert stresses over distances, their conformations are distorted away from isotropic in flow fields, and the various length scales of the polymer rearrange on different time scales. Therefore, it may also not be surprising that if we know the dynamics of the polymer chain, it is relatively straightforward to know the polymer contribution to the stress field. Derivation of these relations is outside the scope of this article, but is based on either statistical-mechanical (Bird *et al.*, 1987) or thermodynamic (Beris and Edwards, 1994; Jongschaap, 1991; Grmela, 1985) arguments. The two approaches often yield complementary insight into polymer dynamics.

For example, if the polymer chain in a melt is modeled as elastic "connectors" whose orientations and lengths are given by the set of vectors $\{\mathbf{Q}_i\}$, then the polymer contribution to the stress tensor is called the *Kramers form for the stress tensor,*

$$\boldsymbol{\tau}_p = -n \sum_i \langle \mathbf{Q}_i \mathbf{F}_i^{(c)} \rangle, \tag{6}$$

where n is the number density of polymer chains and $\mathbf{F}_i^{(c)}$ is the force exerted by the ith connector.

We note here that linear-optical measurements probe the second moment of the chain segment orientations $\langle \mathbf{Q}_i \mathbf{Q}_i \rangle$. If a particular theory predicts that the connector force is linear in segment orientation $\mathbf{Q}_i$, then optical measurements provide a consistency check with the theory. On the other hand, if the theory predicts a tension nonlinear in $\mathbf{Q}_i$, then optical measurements provide additional information about average orientations.

Not considered further here is the fact that other linear flux laws do not apply for polymer melts. For example, anisotropic orientation leads to non-Fickian diffusion of the polymer, and it is expected that heat flux is not described by Fourier's law. Microscopic models are already giving insight into generalizations of these laws to polymeric liquids (Curtiss and Bird, 1995).

1.2 Universality of Experimental Results

Many properties of a given polymeric fluid show behavior similar to other polymers in its class (same chain architecture, and same solvent quality if in solution) when the results are properly rescaled. For example, polymer melts have a zero–shear-rate viscosity that scales with molecular weight to the 3.4 power, for long chains. All polymers exhibit a spectrum of relaxation times. However, when time is rescaled by the longest relaxation time, the results often look quite similar for all polymers in that class. Likewise, the viscosity as a function of shear rate gives similar results for all polymer melts. The results given below are meant to be indicative of all polymers in a given class.

2. EXPERIMENTAL TECHNIQUES

2.1 Conformation Studies

Scattered radiation can be used to measure static or dynamic properties of polymers in melt or solution. The general theory of scattering for polymers applies to light, x-ray, or neutron scattering. However, the details of each method often make one more suitable than the others for either melts or solutions. Here we discuss light scattering by solutions, and neutron scattering by melts.

2.1.1 Light Scattering As lucidly described in the classic text by Berne and Pecora (1976), radiation scattering can be conceptually divided into two steps: scattering from a medium whose index of refraction is fluctuating in time and the influence of a scattering center on the local index of refraction. The first step is made from a macroscopic viewpoint, whereas the second makes the connection between microscopic dynamics and macroscopic observation.

If we assume that the radiation field is weak, so that the medium's response is linear, the intensity of scattered light depends upon the fluctuations in the dielectric constant found using Maxwell's laws of radiation. If the medium has average (constant) dielectric constant ϵ_0, and a fluctuating (in general, anisotropic) tensorial component $\Delta\boldsymbol{\epsilon}(\mathbf{r},t)$, then the total dielectric tensorial field $\boldsymbol{\epsilon}$ is

$$\boldsymbol{\epsilon}(\mathbf{r},t) = \epsilon_0\boldsymbol{\delta} + \Delta\boldsymbol{\epsilon}(\mathbf{r},t), \tag{7}$$

where $\mathbf{r}$ is the position in space and $\boldsymbol{\delta}$ is the unit tensor. The intensity of scattered radiation a distance R away from the *scattering volume* (volume of the sample on which the light impinges) is given by

$$\begin{aligned} I_{if}(\mathbf{q},\omega_f - \omega_i,R) = {}& \left[\frac{I_0 k_f^4}{16\pi^2 R^2 \epsilon_0^2}\right] \\ & \times \frac{1}{2\pi}\int_{-\infty}^{\infty} \langle \Delta\epsilon_{if}(\mathbf{q},0)\Delta\epsilon_{if}(\mathbf{q},t)\rangle \\ & \times \exp[i(\omega_f - \omega_i)t]dt, \end{aligned} \tag{8}$$

where I_0 is the intensity of incident light, and ω_i (ω_f) is the frequency of incident (scattered) light. The vector $\mathbf{q}$ is the difference between the incident and scattered wave vectors,

$$\mathbf{q} := \mathbf{k}_i - \mathbf{k}_f, \tag{9}$$

where $\mathbf{k}_i$ ($\mathbf{k}_f$) is the wave vector of the incident (scattered) light, which has orientation in the direction of propagation, and magnitude ω_i/c (ω_f/c). The function $\Delta\epsilon_{if}(\mathbf{q},t)$ is the component of the spatial Fourier transform of the fluctuating part of the tensorial dielectric constant in the incident and scattered directions:

$$\Delta\epsilon_{if} := \mathbf{n}_i \cdot \left[\int \exp(i\mathbf{q}\cdot\mathbf{r})\Delta\boldsymbol{\epsilon}(\mathbf{r},t)d^3r\right]\cdot \mathbf{n}_f, \tag{10}$$

where $\mathbf{n}_i$ ($\mathbf{n}_f$) is the direction of travel of the incident (scattered) wave.

Because a laser is used for light scattering, or a collimator for neutron scattering, the incident radiation is monochromatic, so that a single value is sufficient to describe ω_i. Measuring the scattered intensity at all frequencies is equivalent mathematically to integrating $I_{if}(\mathbf{q},\omega,R)$ over all ω. When this integration is performed on Eq. (8), the exponential inside the integral on the right-hand side becomes a delta function, and the total intensity contains information about the second moment of the fluctuations in the dielectric field. Intensities measured at specific frequencies contain information about the autocorrelation function $\langle \Delta\epsilon_{if}(\mathbf{q},0)\, \Delta\epsilon_{if}(\mathbf{q},t)\rangle$. If the scattering process is elastic (i.e., $\omega_i \approx \omega_f$), then one can show that

$$q \equiv |\mathbf{q}| = (4\omega_i/c)\sin(\theta/2), \qquad (11)$$

where θ is the angle between $\mathbf{k}_i$ and $\mathbf{k}_f$. By holding the incident wave and scattering volume stationary, and moving the position of the detector that measures the intensity of scattered radiation, the magnitude of the vector $\mathbf{q}$ can be varied. In addition, one can vary the frequency of the incident radiation to vary q. The scalar q is sometimes mislabeled the "scattering vector," so that discussions are often seen on "the value of the scattering vector."

To extract information about the molecular dynamics from the fluctuations in the dielectric constant extracted from radiation-scattering measurements, one needs a model to predict the influence of molecules on the dielectric field. This step of the procedure is not nearly as "clean" as the first for polymeric systems—one typically must make several simplifying approximations that can be justified only *a posteriori* by quantitative comparison with data.

For light scattering, the scattering target is the electron cloud, which is polarizable. Hence, the effective scattering length increases monotonically with molecular weight of the atom, and most scattered light is coherent. Ability to scatter is directly proportional to the polarizability of the molecule, so that polymers are more effective scatterers than solvent molecules. Also, since polymers relax on time scales much longer than those for solvent particles, one can usually separate the influence of polymer dynamics from that of the solvent. Typical length scales for light scattering are in the range 0.025–0.2 μm.

It is generally assumed that a segment of a polymer chain can be treated as a point (or spherical) scatterer, if the size of the segment is much less than q^{-1}. The concentration and volume size are chosen so that multiple scatterings are negligible. Then, the mathematical problem is reduced to finding the scattering intensity of a single point particle. Utilizing the solution to this simpler problem, one can find the intensity of scattered light from n_c chains of N segments of point scatterers. If the chains are also identical and noninteracting, then there is no correlation between the scatterers on different chains. If we further assume that each chain segment has the same polarizability, then Eq. (8) can be simplified to depend upon the scattering from a single polymer:

$$\begin{aligned} I_{if}(\mathbf{q},\omega_i,\omega_f,R) = {} & \left[\frac{I_0\omega_f^4 N c' \alpha_m'^2 V}{16\pi^2 R^2 \epsilon_0^2 \bar{c}^4 \tilde{N}_{\mathrm{A}}}\right] \\ & \times (\mathbf{n}_i \cdot \mathbf{n}_f)^2 \frac{1}{2\pi}\int_{-\infty}^{\infty} S(\mathbf{q},t) \\ & \times \exp[i(\omega_f - \omega_i)t]dt, \end{aligned} \qquad (12)$$

where $\bar{c}$ is the speed of light, V is the volume of the scattering sample, c' is the mass concentration of polymer, α_m' is the polarizability per unit mass of polymer, $\tilde{N}_{\mathrm{A}}$ is Avogadro's number, and $S(\mathbf{q},t)$ is the *dynamic structure factor* for a single polymer,

$$S(\mathbf{q},t) := \frac{1}{N}\sum_{lm} \langle \exp\{i\mathbf{q}\cdot[\mathbf{r}_l(t) - \mathbf{r}_m(0)]\}\rangle. \qquad (13)$$

If the scattered light is detected at all frequencies, then the only contribution from the structure factor is $S(\mathbf{q},0)$, the *static structure factor*. All other quantities in Eq. (12) except polymer molecular weight M are measurable physical quantities, or are estimated from calibration. For small values of q, by expanding the exponential in Eq. (13), one can show that

$$1/S(\mathbf{q},0) \approx 1 + \tfrac{1}{3}q^2\langle R_G^2\rangle. \qquad (14)$$

Therefore, by measuring the intensity of scattered light at several small angles and small concentrations, and performing a double extrapolation in both concentration and q (a so-called *Zimm plot*), one can obtain both the molecular weight M and the radius of gyration $\langle R_G^2\rangle$. Generalization of this derivation shows that for a polydisperse mixture of chains, the weight-averaged molecular weight is obtained, but then no simple relation exists for the second-order term in q.

Experimentally, Debye showed by light scattering that $\langle R_G^2\rangle \sim M$ for a linear chain in theta solvent, and $\sim M^{6/5}$ for a good solvent, in agreement with the predictions of Sec. 1.

By measuring the intensity of the scattered light at various frequencies, information can be obtained about the time dependence of the dynamic structure factor. From its definition Eq. (13), one sees that, in general, the dynamic structure factor will depend in complicated ways upon the dynamics of the polymer chain. Therefore, to extract useful information one begins with a model for polymer dynamics and predicts the resulting structure factor to compare with experiment. However, some information can be extracted from the experiments when the scattering angle is very small. For sufficiently small values of q, the entire molecule acts as a scatterer, if interference from intramolecular length scales is negligible. Then, one can show that $S(\mathbf{q},t) \sim \exp(-q^2Dt)$, where D is the binary solvent/polymer diffusion coefficient.

Caroline and Jones (1980) studied polystyrene in cyclohexane (at theta temperature) to find that the diffusion coefficient scales as $\sqrt{M_w}$ at infinite dilution. The largest time constant of relaxation by normal-mode analysis yielded a molecular-weight dependence to the 1.4 power.

In flow, the average chain orientation is deformed into an ellipsoid with a preferred direction. In shear flow, the major axis points in a direction somewhere between the direction of flow and 45° toward the direction of the shear gradient. If light scattering is performed in different directions relative to the flow, information can be obtained about the shape of the ellipsoid. For example, light-scattering experiments by Link and Springer (1993) on polystyrene dissolved in dioctyl phthalate (nearly a theta solvent) have found the sizes of the three principal axes and the orientation of the ellipsoid relative to the flow direction describing the average conformation of the chains during shear flows. By extrapolating their results to zero polymer concentration, they find that the orientation angle α of the ellipsoid varies with shear rate as

$$\alpha = \tfrac{1}{2}\tan^{-1}\left(\frac{2.1 + 0.1\beta}{\beta}\right), \qquad (15)$$

where β is the shear rate made dimensionless by $RT/\eta_{p,0}M_w$ and $\eta_{p,0}$ is the zero–shear-rate polymer contribution to viscosity defined in Sec. 2.4.1. They were also able to measure the three ellipsoid lengths. They find that the ellipsoid axis perpendicular to both flow and shear directions does not change in length from its equilibrium value. The major axis grows nearly linearly with shear rate, and the overall radius of gyration made dimensionless by its equilibrium value is (Link and Springer, 1993)

$$\frac{\langle R_G^2\rangle}{\langle R_G^2\rangle_{\mathrm{eq}}} = 1 + 0.017\beta^{1.4}. \qquad (16)$$

They point out, however, that the data of Cottrell *et al.* (1969) indicates that polyisobutylene in decalin has a deformability $\langle R_G^2\rangle/\langle R_G^2\rangle_{\mathrm{eq}}$ that grows nearly linearly with β.

2.1.2 Small-Angle Neutron Scattering

Small-angle neutron scattering differs from light scattering in two important ways: Neutrons at room temperature have a frequency such that they can probe length scales down to 2 Å, and they are scattered by nuclei rather than electrons. The first difference suggests that neutron scattering may be used as a tool complementary to light scattering, since it can probe smaller length scales. The second property makes neutron scattering appropriate for melts and concentrated solutions (as well as dilute solutions) for the following reasons.

For effective study of chain dynamics in the melts, it is necessary to make most of the chains "invisible" to the incident radiation, while making a few chains effective scatterers. Since light scattering relies on the electron density for scattering size, labeling a few chains in a melt requires substantial change in the chemical structure of the labeled chains, which risks changing the dynamics of the chains being probed. Since the neutron is scattered by the nucleus of the atom, isotopes can be used to create scattering contrast, without changing chemistry appreciably. Such a contrast exists, for example, between hydrogen and deuterium. However, one must be careful not to increase the temperature above a critical value causing separation of the undeuterated and deuterated chains into different phases (Bates *et al.*, 1986).

Neutron scattering on polymer melts has confirmed that the radii of gyration of polymethylmethacrylate, polystyrene, and polyethylene have dimensions comparable to dilute polymers in theta solvents, with ratios of $\sqrt{\langle R_G^2\rangle}/M_w$ equal to 0.31, 0.23, and 0.45, respectively (Higgins, 1979).

To date, neutron-scattering experiments on polymers in flow fields have been accomplished in two flow cases: scattering by solutions during flow, and scattering by melt samples that have been quenched during deformation. The latter experiment was performed by Muller *et al.* (1993) on a polystyrene melt that had been quenched during a creep experiment. By slicing the quenched sample in different planes, the coil orientations could be studied in all directions. By varying the magnitude of the scattering vector to probe different length scales, they find that the principal directions of orientation in the shear plane depend upon the length scale of the polymer; smaller length scales show less anisotropy in orientation. This is not surprising, since the small-angle neutron-scattering experiment is able to probe length scales smaller than the Kuhn length. They find that the direction perpendicular to the flow plane is unaffected by flow as in the polystyrene theta solution, and the deformation of the coil in the flow plane is less than that predicted by affine motion of the segments.

2.1.3 Flow Birefringence When polymer chains are oriented by electrical, magnetic, or mechanical means, the (tensorial) index of refraction of the fluid **n** can be made anisotropic. By careful control of the perturbing force, the anisotropic effect can be made homogeneous throughout the sample. If polarized light is made to impinge on the sample, and the intensity of light that exits from the sample is measured for different orientations of polarization, information can be obtained about the index-of-refraction tensor. Since the orientation of the chains causes the anisotropy of **n**, information is indirectly obtained about the instantaneous conformations of the chains.

Flow birefringence is the study of the anisotropy of the index of refraction of polymeric liquids that are undergoing flow (Fuller, 1995). Linear-optic theory can be used to interpret the results of such experiments. For example, consider light that travels in the z direction relative to a laboratory-fixed reference frame, and is polarized in the x direction prior to passing through a birefringent medium. The light will "see" three components of the index of refraction projected on the plane perpendicular to the direction of propagation of the impinging light. By a suitable rotation of the coordinate system, these components can be made diagonal. Thus, the components describe an ellipse of major axis, minor axis, and orientation. The intensity of light transmitted through an analyzer oriented along the y axis is given by (Riande and Saiz, 1992)

$$I = I_0 \sin^2 2\beta_e \sin^2(\delta_R/2), \tag{17}$$

where I_0 is the intensity of polarized light impinging on the sample, β_e is the angle of the ellipse relative to the x axis, called the *extinction angle*, and δ_R is the *retardation* of the medium defined by

$$\delta_R := 2\pi l \Delta n/\lambda, \tag{18}$$

where $\Delta n = n_I - n_{II}$ is the difference between the major and minor components of the index of refraction in the plane, l is the length of sample through which the light passes, and λ is the wavelength of light. By rotating the polarizer and analyzer in tandem, β_e can be varied. When the intensity of the light becomes zero, then the orientation of the index-of-refraction ellipse is known, and δ_R can be calculated from Eq. (17). Since the other variables appearing in Eq. (18) are easily measured, Δn can be found.

Janeschitz-Kriegl (1983) has shown that for all experiments involving shear flows, the stress tensor for polymer melts is, within a constant, given by the index-of-refraction tensor. The relation is called the *stress-optic law,*

$$\mathbf{n} = C\boldsymbol{\tau}, \tag{19}$$

where C is called the *stress-optic coefficient,* and, in general, is a function of material and temperature, but is not a function of strain or strain history. Theoretically, such an equivalence is predicted for any model that predicts that the stress tensor and the index-of-refraction tensor depend, within a constant, upon the same averages of the orientation of the polymer chain. Since simple, physical arguments suggest that $\mathbf{n} \sim \Sigma_i\langle\mathbf{Q}_i\mathbf{Q}_i\rangle$, it is believed that the Kramers form for the stress tensor, Eq. (6), is the proper one for polymeric melts with $\mathbf{F}_i^{(c)} \sim \mathbf{Q}$.

Practically, the stress-optic law means that some rheological measurements can be performed optically rather than mechanically. Since measuring normal stress differences can be rather difficult, the stress-optic law allows us to infer normal stress differences more easily. Many experimental data determined by flow birefringence may be found in Janeschitz-Kriegl (1983).

2.2 Diffusion in Melts

There are three different methods for defining a diffusion coefficient that are not necessarily equivalent. Each method involves the average distance that a chain may move when experiencing a given driving force. When the driving force is a concentration gradient, the diffusion coefficient may be "cooperative," whereas when the driving force is Brownian motion, and a single chain is followed, it is called the "self-diffusion coefficient." Chains may also diffuse from an external force, say an electric field. Cooperative diffusion may behave quite differently from self-diffusion, since entangled chains moving collectively may have a large contribution to the coefficient. In fact, the cooperative diffusion coefficient for semidilute chains increases with concentration to the power $\frac{2}{3}$ (de Gennes, 1979, p. 211).

Self-diffusion in polymer melts is difficult to measure because of the very long time scales associated with diffusion over very small length scales, and because of the difficulty in isolating the dynamics of a single chain from the melt. For example, neutron scattering cannot be used to measure the diffusion coefficient directly, because the time scales and length scales probed are too small for diffusion; light scattering is problematic, because isolating a chain from the others requires that the chemical structure of the polymer being probed be different from the bulk of chains.

The advantages and disadvantages of a number of methods are reviewed in an article by Tirrell (1984), where experimental diffusion results are compiled. We focus here on a single method, *forced Rayleigh scattering* (FRS), because the method appears to be the most useful and least problematic, and many other methods (e.g., fluorescence redistribution after pattern photobleaching, indirect neutron scattering, and isorefractive quasi-elastic light scattering) use analogous principles.

In FRS, one labels a small number of chains with a dye (e.g., fluorescein) that changes its adsorption spectrum when exposed to light of a particular wavelength. Since the dye group is much smaller than the chain, it is hoped that the dynamics of the labeled chains is not perceptibly altered. One then uses crossed beams of a split writing laser to alter the dye group on some of the chains. A sinusoidal interference pattern is created in the beams so that sandwiched layers of altered and unaltered chains in the melt result. Once the writing laser is switched off, the melt relaxes to a homogeneous mixture of altered and unaltered chains by diffusion. A second laser whose light is absorbed by the altered dye (but not the unaltered dye) is used to "read" the distribution in the melt, which now acts like a diffraction grating. By following with time the ability of the grating to diffract, one can calculate the diffusion coefficient (assuming Fickian diffusion over these time scales).

It is necessary to make the thickness of each layer sufficiently small that no appreciable amount of the dye decays back to its unaltered state before diffusion makes the sample homogeneous. By varying the crossing angle of the writing lasers, different layer thicknesses can be created, thereby allowing different times of diffusion to be studied.

Other techniques use asymmetric interfaces, such as a sample of large chains adjacent to a sample of small chains, by following the movement of the interface. Backscattering of tracer particles, infrared spectroscopy, or electron microscopy is used to follow the concentration profiles at the interface.

The bulk of experiments reveal some general trends (Tirrell, 1984). The self-diffusion coefficient of entangled chains in the melt scales with molecular weight as $D \sim 1/M^2$ for nylon 12, polystyrene, and polyethylene. The results for polyethylene, the most flexible of the three, are rather conclusive. However, some of the data for polystyrene suggest that the diffusion coefficient may scale with molecular weight as $1/M^{2.7}$ for long chains. Some data reported since the review of Tirrell have also suggested that D falls with increasing molecular weight more rapidly than $1/M^2$ for some systems (Nemoto *et al.*, 1984, 1985; Kim *et al.*, 1986).

If molecular-weight dependence is studied for chains at and below the entanglement length, it is found that the $1/M^2$ dependence holds well below the entanglement length. Very short chains show $D \sim 1/M$, which is consistent with the Rouse dynamics discussed in Sec. 3.1.1 when chain segment concentration is held constant.

The diffusion coefficient of star-shaped chains with three arms in the melt exhibits a dependence consistent with $D \sim M^{-1} \times \exp(-bM)$ for chains of medium length, but deviates from this form for higher molecular weights. When polyisobutylene, polystyrene, or polybutylene are unentangled, branching was found to have no important effects on the dependence of the diffusion coefficient on molecular weight.

When a single chain of weight M is probed as it diffuses through a matrix of longer chains M_m far above the glass transition temperature, the diffusion coefficient of the short chain is independent of M_m. However, when the matrix chains are much shorter than the probe chain, $D \sim 1/M$, and the matrix molecular weight becomes important if $M > M_m \approx M_e$. If a single chain is diffusing through a fixed network, its diffusion coefficient is approximately three times the self-diffusion coefficient. If the mixture is polydisperse, then $D \sim 1/M_n M_w$.

The diffusion coefficient of concentrated polystyrene in good and theta solvents has been studied extensively. The concentration dependence appears to be nearly the same in both solvents, and no simple scaling law was seen; the diffusion coefficient decreased strongly with concentration c. The slope of $\log D$ vs $\log c$ appears to be greater than -10 at the highest concentration.

2.3 Macroscopic Flow Studies

2.3.1 Optical Techniques Because polymeric liquids do not obey the Navier–Stokes equation, the flow patterns resulting in complex geometries can be dramatically different from those of Newtonian fluids. These flow patterns can give clues to the importance of shear thinning or elastic properties on the stability of roll cells or vortices, for example. When predictions are made by solution of Cauchy's equation together with the proposed constitutive equation, the results can be compared with the measured flow field.

Streamlines can be followed quite cheaply and easily by flow-visualization techniques, which use video images, or long-time exposure of photographs to follow the trajectories of brightly reflecting particles. Some beautiful photographs of these effects can be seen in Boger and Walters (1993). In these series of photographs, one sees, for example, that

1. when a rotating rod is inserted through a free surface into a container of polymeric fluid, the polymer climbs the rod;
2. upon exit from a die, the stream of a polymeric fluid expands so that the exit stream has a much greater radius than the die radius;
3. a liquid fiber can be continuously drawn from the container, and wound onto a drum;
4. if the driving force for a steady flow is suddenly switched off, the fluid *recoils* backward some substantial distance; and
5. the addition of small amounts of polymer to a solution can significantly affect the range of stable flow past a cylinder.

Macroscopically, many of these effects can be described qualitatively by the presence of a first normal-stress difference (**1**,**2**,**3**,**5**), by the concept of "memory" (**2**,**4**,**5**), or by shear-rate-dependent viscosity (**5**). None of these effects occurs for Newtonian fluids.

If more precise measurements of fluid velocities are desired, *laser Doppler anemometry* (LDA) can be used to measure the velocity of the fluid at any point in space. *Laser Doppler velocimetry* is an application of light scattering described in Sec. 2.1.1, in which quasi-elastic scattering of light from particles in the fluid is used to measure the local flow field.

There is a growing trend to measure the flow field and the stress field simultaneously in complex geometries by combining multiple techniques. For example, in a recent work, LDA experiments were used to track particles in a 10:1 contraction. The particle trajectories were then used to compute predicted stress fields and compared with data (Feigl and Öttinger, 1994). Rajagopalan *et al.*

(1992) compared finite-element predictions with birefringence measurements in flow between eccentric rotating cylinders using a multimode Giesekus model.

2.3.2 Nuclear Magnetic Resonance Techniques Nuclear magnetic resonance imaging (NMR or MRI) techniques provide an alternative way to obtain velocity fields in complex geometries, by tracking the NMR signals of nuclei in the fluid, typically hydrogen atoms. This technique does not require that all solid objects be optically transparent to light or other probing radiation, and provides a three-dimensional picture of fluid motion. The method was originally developed to track blood flow in living bodies.

The flowing sample is placed in an electric field to align the H nuclei. Then, an rf signal of narrow width is used to flip the spins of the protons in a very thin cross section of the flow, thus labeling those protons in the cross section. The protons begin to precess back to their original orientations in the field. After a chosen time t_0, a second rf signal is used to flip the protons in the cross section again. The protons that have entered the cross section after the first signal have orientation different from the protons that were present in the cross section during the first rf signal. By following the spatial dependence of the NMR signal in the cross section, it is possible to infer which sections of the region have been replenished by new fluid. By changing t_0 it is hence possible to infer the fluid velocity. This method has been used by Li and McCarthy (1994) to map the flow field in a straight pipe of circular cross section for aqueous polyacrylamide solutions. They were able to measure the axial velocities in laminar flow, and mean axial velocities in turbulent flow. By combining pressure-drop measurements with the measured shear rate at the walls, viscosity curves as functions of shear rate could be constructed. Since the pressure varies down the length of the tube, the method might be used to give pressure dependence of viscosity by measuring the shear rate at various axial positions.

2.4 Stress Measurements

Model-independent rheological measurements can be obtained in flow fields that are homogeneous, i.e., flow fields in which the velocity gradient is independent of position. Most important homogeneous flow fields can be divided into the two types: shear (transient or steady state) or shear-free (transient only) flows.

2.4.1 Shear Flows Shear flows are anisotropic, and therefore have vorticity. They can be described in the appropriate coordinate system by $dv_y/dx = \dot{\gamma}$, all other gradient components zero, where $\dot{\gamma}$ is the *shear rate.* Important measured quantities are the shear stress τ_{yx}, the first normal-stress difference $\tau_{xx} - \tau_{yy}$, and the second normal-stress difference $\tau_{yy} - \tau_{zz}$. The ratio of shear stress to shear rate is the viscosity $\eta := \tau_{yx}/\dot{\gamma}$. Important time-dependent flows are single-step strain $\dot{\gamma} = \gamma\delta(t)$ (also multiple-step strains), inception of steady shear flow $\dot{\gamma} = \dot{\gamma}_0\mathrm{H}(t)$, cessation of steady shear $\dot{\gamma} = \dot{\gamma}_0\mathrm{H}(-t)$, and small-amplitude oscillatory shear flow $\dot{\gamma} = \dot{\gamma}^0 \cos(\omega t)$. $\mathrm{H}(t)$ is the Heaviside step function. The other parameters are all held constant during an experiment, but can be varied arbitrarily from experiment to experiment, except for the strain $\dot{\gamma}^0$, for which we require that $\dot{\omega}\gamma^0 \lll 1$. Other flows are not considered here, such as exponential shearing flow: $\dot{\gamma} = \mathrm{H}(t)A \exp(\alpha t)$, where A and α are arbitrarily chosen constants for a given experiment.

Linear-viscoelastic theory (Ferry, 1980) relates all experiments of very small deformation to a single material property called the *relaxation modulus* $G(t)$. The function $G(t)$ is defined from the single-step strain experiment in the limit that $\gamma \to 0$:

$$G(t) := \tau_{yx}(t,\gamma)/\gamma, \quad \text{step strain: } \gamma \to 0. \qquad (20)$$

The relaxation modulus exhibits three regimes for polymer melts: an initial, rapidly decaying regime, a plateau, and a second decay. The plateau's height is independent of molecular weight, but its temporal location depends upon molecular weight to the 3.4 power, i.e., the longest relaxation time constant scales with molecular weight to the 3.4 power.

At higher (nonlinear) strains, the shear stress is found to be separable into a strain-dependent part $h(\gamma)$ called the *damping function,* and the time-dependent relaxation modulus:

$$\tau_{yx}(t,\gamma) = \gamma h(\gamma)G(t), \quad \text{single-step strain.} \tag{21}$$

The damping function is a dimensionless quantity that is unity at vanishingly small strain and is found to decrease monotonically with strain γ. The separability is often not observed at the shortest times. Empirically, we find that many data are described by a function of the form

$$h(\gamma) = 1/(1 + a_d\gamma^2), \tag{22}$$

where a_d is a material constant. For example, a highly branched low-density polyethylene was found by Khan and Larson (1987) to have $a_d \approx 0.07$. Concentrated solutions of linear polystyrene exhibit values of a_d between 0.11 and 0.22. The first normal-stress difference is observed to decay with the same time dependence as the viscosity; the observation is referred to as the Lodge–Meissner rule. Such experiments are typically not performed for dilute solutions.

Experiments of multiple-step strains that are multidirectional have also been performed (Meissner, 1984; Hürlimann, 1991; Venerus and Kohvand, 1994). For example, one imposes an instantaneous shearing step strain, waits a period of time, and then performs a second step in the opposite direction. Alternatively, the second step could be performed in a direction perpendicular to the first step. The results of these experiments are not easily given in a brief description, and hence we do not discuss them further here. However, it is believed that these experiments are very important to distinguish between competing molecular theories, since many theories predict results quite different from each other, and no theory has successfully described all observed multistep-strain results to date.

Small-amplitude oscillatory shear flow is thought to probe the relaxation dynamics of the chain at equilibrium, and is effectively studied using linear viscoelastic theory. From linear viscoelastic theory, and experimentally, it is found that the results of the small-amplitude oscillatory shear flow experiment can be related to $G(t)$. The first normal stress is second order in strain, and does not play a role in linear viscoelasticity. The shear stress responds with a part that is in phase with the deformation, and a part that is out of phase. If we write the shear stress in the form

$$\tau_{yx} = -\dot{\gamma}^0\mathcal{R}\{\eta^* e^{i\omega t}\}, \tag{23}$$

then the in-phase part of the shear stress is described by the real part η' of η^*, and the out-of-phase part is described by negative of the imaginary part η''. Experimentally and theoretically, it is found that the complex viscosity η^* is the Fourier transform of the relaxation modulus $G(t)$. Thus, the small-amplitude oscillatory shear flow experiment mechanically probes the various relaxations on different time scales by varying the frequency of the experiment.

The relaxation modulus is often fitted by a finite sum of exponentials: $G(t) = \Sigma_n a_n \times \exp(t/\lambda_n)$, where the $\{a_n\}$ represent the weighting factors for each of the time constants $\{\lambda_n\}$. Baumgärtel *et al.* (1990) have found a general trend for the weighting factors $\{a_i\}$ with time constants $\{\lambda_i\}$ for linear, nearly monodisperse polymer melts. They studied entangled polystyrene and polybutadiene with polydispersity indices between 1.02 and 1.13 just above the glass transition temperature. Plots of $\{\log a_n\}$ vs $\{\log \lambda_n\}$ show a general V shape. The initial linear, downward-sloping portion of the curve was found to be universal for all chains studied, and had slope of -0.84. This portion of the curve at short time constants was attributed to the glassy modes of the polymers. The final linear, upward-sloping portion of the plot depended on molecular weight and chemical structure of the chains. Polystyrene showed a slope of 0.22 (all M_w), whereas polybutadiene revealed a slope of 0.42. On the basis of these results, the authors recommended representing the relaxation modulus as a sum of $N_1 + N_2$ exponentials,

$$\begin{aligned} G(t) = &\sum_{i=1}^{N_1} g_1 a_1^{n_1(i-1)} \exp\left(\frac{-t}{a_1^{i-1}\lambda_1}\right) \\ &+ \sum_{i=1}^{N_2} g_2 a_2^{-n_2(i-1)} \exp\left(\frac{-t}{a_2^{i-1}\lambda_2}\right), \end{aligned} \tag{24}$$

where g_1, g_2, a_1, a_2, λ_1, and λ_2 are material parameters. The parameters n_1 and n_2 are the slopes described above.

Polymer melts and polymer solutions exhibit qualitatively similar behavior for η^*. That is, η' is independent of frequency ω at low frequencies and drops off with increasing ω; at high frequencies dilute solutions may show a second leveling off of η'. The out-of-phase part η'' initially rises linearly with ω, goes through a maximum, and eventually falls with increasing ω. Polydispersity tends to broaden the shapes of these curves.

The steady-state viscosity $\eta := -\tau_{yx}/\dot{\gamma}$ has many universal features for polymer melts. The initial plateau value η_0 increases with molecular weight to the first power for unentangled chains, and to the 3.4 power for entangled chains. The shear-thinning regime obeys a power law $\eta \sim \dot{\gamma}^b$, where b is between 0 and -1. This *power-law region* is independent of molecular weight or polydispersity. The dependence of viscosity η on shear rate $\dot{\gamma}$ is found to be nearly identical to the dependence of the magnitude of the complex viscosity $|\eta^*|$ on frequency ω. This observation is called the *Cox–Merz rule.*

Figure 1 shows steady-state viscosity as a function of shear rate for high-density polyethylene (HDPE, linear chains) and low-density polyethylene (LDPE, branched chains) melts of several molecular weights. The data are taken from Wales (1976). The HDPE samples have polydispersity indices of 4 and 14.5 for the samples with molecular weight 4.4×10^4 and 1.6×10^5, respectively, whereas the LDPE samples have polydispersity indices of 5, 16.7, and 4.62 for the lowest to highest molecular weights, respectively.

The first normal-stress coefficient $\Psi_1 := -(\tau_{xx} - \tau_{yy})/\dot{\gamma}^2$ exhibits a shape similar to the viscosity, but has a much stronger shear-thinning dependence. The second normal-stress coefficient, which is difficult to measure, has sign opposite to that of the first normal-stress coefficient, and approximately one-tenth the magnitude.

Figure 2 shows steady-state first normal-stress coefficient as a function of shear rate for concentrated polystyrene (linear chains) solutions of two molecular weights at a temperature of 25 °C. The data are taken from Kulicke and Wallbaum (1985). The samples have molecular weights of 9.15×10^6 and 3.2×10^6 with polydispersity indices of 1.3 and 1.1, respectively.

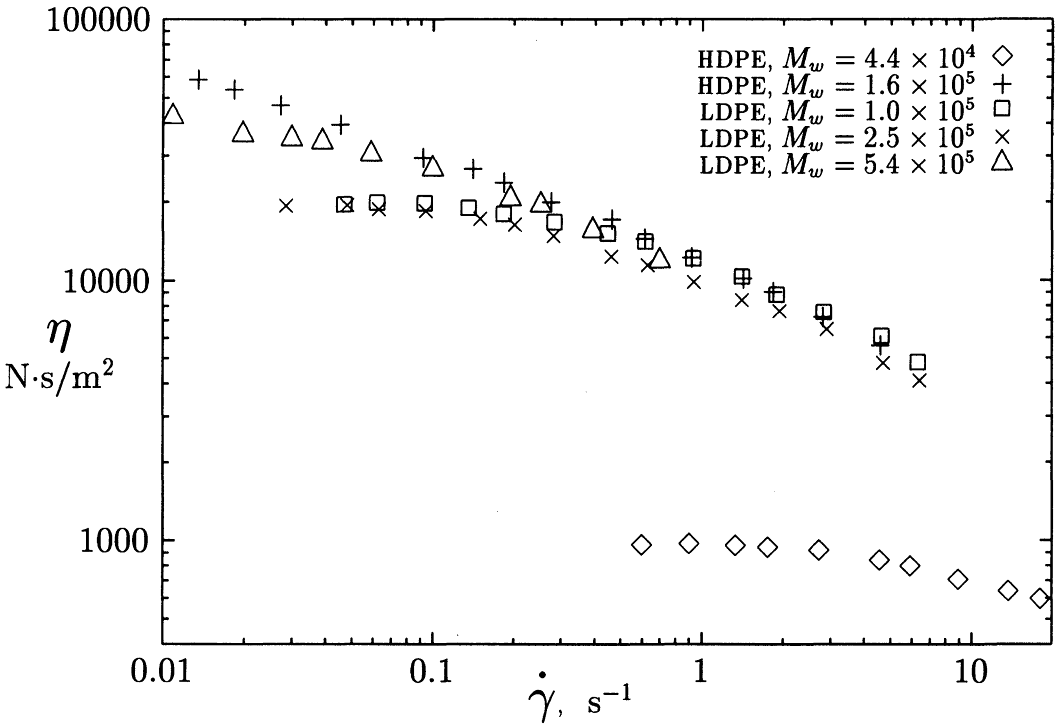

FIG. 1. Viscosity data of Wales (1976) for samples of high-density polyethylene (HDPE) and low-density polyethylene (LDPE) melts of various molecular weights; the polydispersity indices are given in the text. The data were taken using a cone-and-plate rheometer at 150 °C.

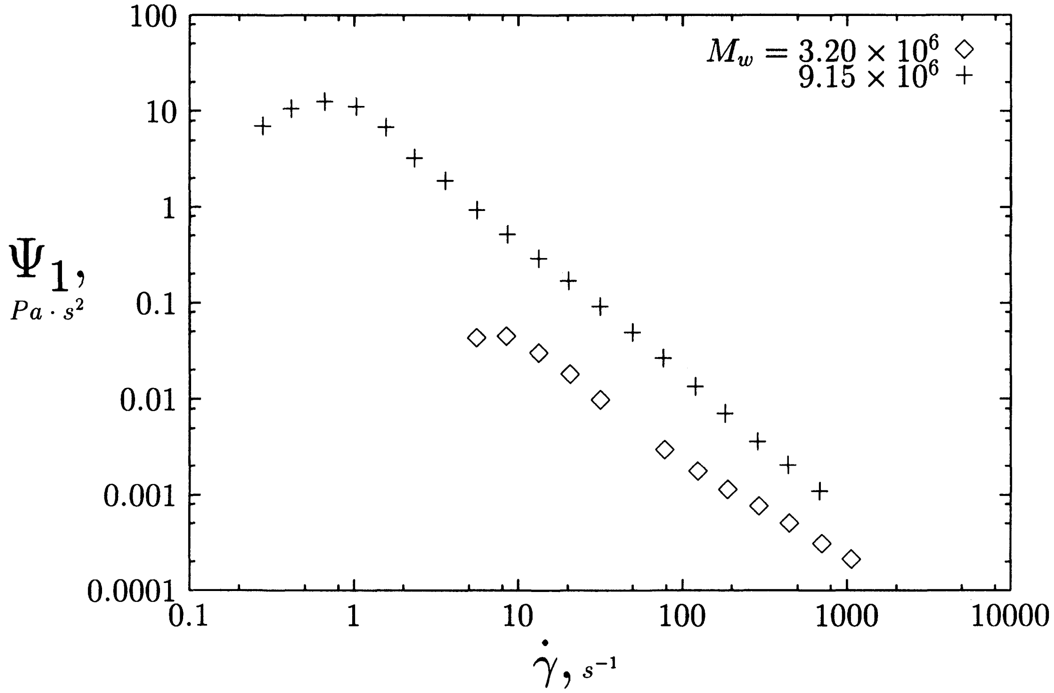

FIG. 2. First normal-stress coefficient data of Kulicke and Wallbaum (1985) for concentrated polystyrene solutions at 25 °C. The samples have molecular weights of 9.15×10^6 and 3.2×10^6 with polydispersity indices of 1.3 and 1.1, respectively.

Dilute polymer solutions again are qualitatively similar, but the steady-state viscosity reaches a second plateau at high shear rates, and at zero shear rate scales as $M^{3\nu}$ ($\nu = \frac{1}{2} \Rightarrow$ theta solvent; $\nu = \frac{3}{5} \Rightarrow$ good solvent).

Before reaching steady state, these material functions can also be studied as transient quantities. Transient material properties can be defined in a manner similar to the ones defined above. We indicate the transient property either by the addition of a superscript "+" to indicate the stress following inception of steady shear, or by a superscript "−" to indicate the stress following the cessation of steady shear flow. For example, $\eta^+(\dot{\gamma},t)$ represents the shear stress divided by the shear rate following the inception of shear rate $\dot{\gamma}$ at $t = 0$.

Both shear-stress and first normal-stress differences can be studied. It is found that both η^+ and Ψ_1^+ go through three different regimes as the shear rate is increased. At lowest shear rates, the stress growth is strictly monotonic, and the curve for the lowest shear rate forms a maximum upper curve for all experiments. At somewhat higher shear rates, an overshoot can be observed. At yet higher shear rates, an overshoot followed by at least one oscillation is observed. The first normal-stress coefficient experiences a relatively higher maximum value. The second normal-stress difference follows the behavior of the first normal-stress difference quite closely for all times.

Similar to the Cox–Merz rule, the *Gleissle mirror relation* relates the steady-state viscosity curve to the transient measurement: $\eta(\dot{\gamma}) = \eta_0^+(t = 1/\dot{\gamma})$.

After steady state has been attained, two different experiments can be performed. The first holds the sample stationary while the resulting stress is measured, whereas the second applies no stress and measures the resulting flow. The first experiment is referred to as *cessation of steady shear flow,* and the second is called *constrained recoil after steady shear flow.* The former experiment on polymer melts reveals that all stresses relax monotonically, but that the transient shear-stress coefficient η^- decays more rapidly than the first normal-stress coefficient Ψ_1^- (Gleissle and Ohl, 1990). Also, the shear and normal stresses decay more rapidly the higher the shear rate $\dot{\gamma}_0$.

In the constant-recoil experiment, after the stresses have reached steady state in the shear flow, the shear stress at the boundaries is turned off, and the sample reverses the direction of flow for some time. Results can be described by the *ultimate recoil,* which is defined as the final total strain achieved by the sample after the shear stress is turned off. The time for total recoil is comparable to the longest relaxation time of the fluid, found either by zero–shear-rate viscosity, or time required to attain steady state. In the linear viscoelastic regime, the ultimate recoil is equal in magnitude to the zero–shear-rate first normal stress divided by the zero–shear-rate shear stress, $\Psi_{1,0}\dot{\gamma}/\eta_0$. At higher shear rates, the value of ultimate recoil for linear low-density polyethylene increases linearly with shear rate, before leveling off at a strain near 3 to become independent of shear rate.

Many shear-flow data can be found to fit master curves that are temperature independent, when the time is rescaled appropriately. The principle is referred to as *time-temperature superposition,* and the temperature- and material-dependent factor necessary for rescaling is called the *time-temperature superposition shift factor,* defined as

$$a_T := \frac{\eta_0(T)T_0\rho(T_0)}{\eta_0(T_0)T\rho(T)}, \tag{25}$$

where T_0 is a reference temperature, η_0 is the zero–shear-rate viscosity, and ρ is the density. The shift factor appears to be rather universal in shifting many different curves. The factor's functional form is often fitted by either an Arrhenius expression or the so-called *WLF equation* (Williams–Landel–Ferry; see p. 274 of Ferry, 1980).

2.4.2 Shear-Free Flows Incompressible shear-free flows are described by the velocity gradient in the appropriate coordinate system as

$$\nabla \mathbf{v}_f = \begin{bmatrix} -\frac{1}{2}(1+b)\dot{\epsilon}_0 & 0 & 0 \\ 0 & -\frac{1}{2}(1-b)\dot{\epsilon}_0 & 0 \\ 0 & 0 & \dot{\epsilon}_0 \end{bmatrix} \mathrm{H}(t), \tag{26}$$

where b is a constant that specifies the type of flow field and $\dot{\epsilon}_0$ is the *elongation rate,* which can be varied from experiment to experiment. For $b = 0$ and $\dot{\epsilon}_0 > 0$, the flow is called *elongational,* and is something like stretching a filament with a rate that increases the length of the filament exponentially with time. For $b = 0$ and $\dot{\epsilon}_0 < 0$, the flow is called *biaxial stretching.* Such a flow is the opposite of elongational, and can be viewed as stretching a sheet equally in both directions, such that the width and length of the sheet increase exponentially with time. When $b = 1$, the flow is called *planar elongational,* and can be achieved by stretching the length of a rectanguloid exponentially with time, while constraining the width to stay constant, and allowing the thickness to decrease.

Important material functions in these experiments are coefficients of the normal-stress differences:

$$\begin{aligned} \bar{\eta}_1 &:= (\tau_{xx} - \tau_{zz})/\dot{\epsilon}_0, \\ \bar{\eta}_2 &:= (\tau_{xx} - \tau_{yy})/\dot{\epsilon}_0. \end{aligned} \tag{27}$$

At least one of these stresses is conveniently found by measuring the forces necessary to pull the sample in the directions described above.

These measurements are notoriously difficult, and have been successfully accomplished in very few laboratories with one very notable exception (Meissner *et al.,* 1982). In fact, a homogeneous flow field described by Eq. (26) has not been successfully achieved for polymer solutions, although some very clever experiments have been designed to impose flow fields with predominantly elongational components. We do not consider them here, although these experiments are very important in understanding the stresses arising in many complex geometries.

Achieving steady state in elongation of polymer melts has also been rather difficult, and there is evidence that steady state is rarely achieved in nonlinear strains. However, at very small strain rates linear viscoelastic theory is useful, which predicts that the steady-state value of $\bar{\eta}_1$ is three times the zero–shear-rate viscosity as $\dot{\epsilon}_0 \to 0$. This prediction is consistent with experiment.

The approach to steady state of the *elongational stress growth function* $\bar{\eta}_1^+$ (transient analog of $\bar{\eta}_1$) at small elongational rates is monotonic, and the curve forms the lower bound for results at higher elongational rates. At higher rates, the elongational viscosity initially follows the linear-viscoelastic curve at short times, but then deviates sharply upward, exhibiting an extreme *strain-hardening* effect. The strain hardening occurs at strains of approximately unity, independent of elongation rate. For sufficiently long measurement times, the coefficient goes through a maximum.

Figure 3 shows $\bar{\eta}_1^+$ data in simple elongation flows as a function of time for a branched low-density polyethylene melt at 150 °C from Zülle *et al.* (1987). The polydispersity index is not reported. However, the sample is industrial, and so presumably has a broad distribution. The different curves are various elongational rates $\dot{\epsilon}_0$.

Transient measurements during other shear-free flows have been accomplished, but are not discussed here.

3. THEORETICAL MODELING

3.1 Dilute-Solution Polymers

3.1.1 Models of Kuhn and Kuhn, Rouse, and Kramers Kinetic-theory models for dilute polymer solutions are mean-field models that treat the solvent as a continuum. However, the discrete segments of the chain are sufficiently small that Brownian forces are important, so that the equations of motion for the polymer segments are stochastic. The approach to making predictions involves two steps: solving for the microscopic dynamics, and making the connection to macroscopic observables. We begin with the former.

The chain is subdivided into discrete segments or "beads" that interact with one another and the solvent. One begins by writing the equation of motion for bead i on the chain ($i = 1,2,\ldots$):

$$m_i \frac{d}{dt}\left[\frac{d}{dt}\mathbf{r}_i - \mathbf{v}_f(\mathbf{r}_i)\right] = \mathbf{F}_i^{(c)} + \mathbf{F}_i^{(h)} + \mathbf{F}_i^{(ev)} + \mathbf{F}_i^{(b)}, \qquad (28)$$

where m_i is the mass and $\mathbf{r}_i$ is the position of bead i, $\mathbf{v}_f(\mathbf{r})$ is the solution velocity at $\mathbf{r}$, and the terms on the right-hand side of Eq. (28) are the various forces that act on the bead. The term $\mathbf{F}_i^{(c)}$ represents the "connector forces" between beads that are near one another along the contour of the chain. $\mathbf{F}_i^{(h)}$ is

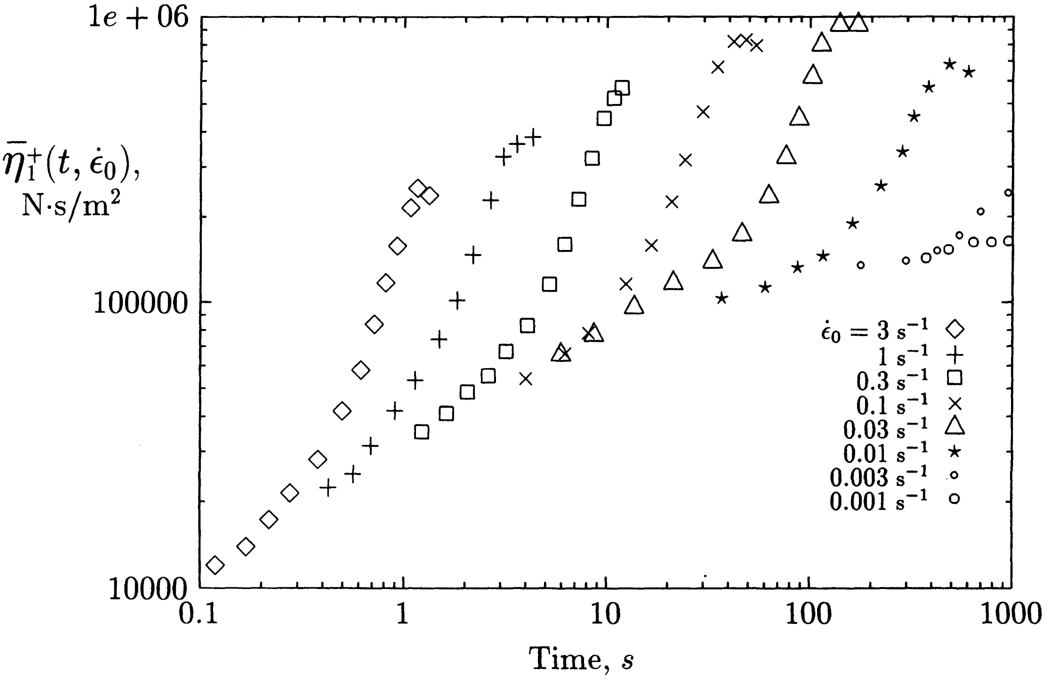

FIG. 3. Simple elongational stress data $\bar{\eta}_1^+$ as a function of time for branched polyethylene melts at 150 °C from Zülle *et al.* (1987). The different curves are various elongational rates $\dot{\epsilon}_0$.

the "hydrodynamic force," which represents the drag force exerted by the solvent on the bead. $\mathbf{F}_i^{(ev)}$ is the "excluded-volume" force that accounts for interactions between beads that may be far apart along the contour of the chain, but are near in space, and hence prevents two beads from occupying the same space. Such an effect can also be used to prevent different segments of the chain from passing through each other, or to account for the effects of a good solvent. $\mathbf{F}_i^{(b)}$ is the random, fluctuating Brownian force on the bead, whose form is fixed by statistical-mechanical considerations.

The simplest model that incorporates some of these ideas is the model of Kuhn and Kuhn (1945). Kuhn and Kuhn began with a thread model and considered only the end-to-end vector of the thread. The model is mathematically equivalent to a dumbbell model that neglects the inertia of the beads, so that the left-hand side of Eq. (28) may be set equal to zero. Only two beads are used, so that $i = 1, 2$. Excluded volume is neglected, and so we assume $\mathbf{F}_i^{(ev)} = \mathbf{0}$. The hydrodynamic force that accounts for bead–solvent interaction is assumed to be a simple Stokes's law drag with coefficient ζ,

$$\mathbf{F}_i^{(h)} = -\zeta\left[\frac{d}{dt}\mathbf{r}_i - \mathbf{v}_f(\mathbf{r}_i)\right]. \tag{29}$$

The connector force is assumed to be linear in displacement, with constant H, which is found from statistical-mechanical arguments in Sec. 3.1.2:

$$\mathbf{F}_1^{(c)} = -\mathbf{F}_2^{(c)} = H(\mathbf{r}_2 - \mathbf{r}_1). \tag{30}$$

In general, the Brownian force must be chosen to satisfy the fluctuation–dissipation theorem (Berne, 1977), which provides a relation between the Brownian force and the dissipative polymer–solvent forces. When the dissipative forces depend only upon the instantaneous velocities of the beads (i.e., when they have no "memory"), satisfaction of the equipartition of energy is usually sufficient to satisfy the fluctuation–dissipation theorem. For the Kuhn–Kuhn model, the Brownian forces are required to have an autocorrelation function that is delta-correlated in time, has no cross correlations among the different components, and has magnitude $2kT\zeta$:

$$\langle \mathbf{F}_i^{(b)}(t)\mathbf{F}_j^{(b)}(t')\rangle = 2kT\zeta\delta_{ij}\delta(t - t')\boldsymbol{\delta}, \tag{31}$$

where δ_{ij} is the Kronecker delta and $\delta(t)$ is the Dirac delta function. It is convenient to introduce the "connector vectors" to describe the orientation of the chain, $\mathbf{Q}_i := \mathbf{r}_{i+1} - \mathbf{r}_i$. For the dumbbell, a single vector is sufficient, $\mathbf{Q} \equiv \mathbf{Q}_1$. The parameters introduced give rise to a single time constant $\lambda_H := \zeta/4H$, and a single length scale $\sqrt{kT/H}$. We assume that the local velocity gradient is not large on the length scale of the size of the polymer, so that the difference in the solution velocities at the two beads can be determined from the first spatial derivative of $\mathbf{v}_f$. Using the above definitions and simplifications, and solving explicitly for $\dot{\mathbf{Q}}$, the equation of motion for a Hookean dumbbell model becomes a Langevin equation. Just as the dynamics of a Brownian particle can be explained by both a Langevin equation and Einstein's diffusion equation, the dynamics of the Hookean dumbbell can equivalently be described by a Fokker–Planck equation. Using standard techniques (Gardiner, 1985), the Fokker–Planck equation equivalent to the Langevin equation is found to be

$$\frac{\partial\psi(\mathbf{Q},t)}{\partial t} = -\frac{\partial}{\partial\mathbf{Q}} \cdot\left\{\mathbf{Q}\cdot\nabla\mathbf{v}_f - \frac{1}{2\lambda_H}\mathbf{Q} - \frac{kT}{2H\lambda_H}\frac{\partial}{\partial\mathbf{Q}}\right\}\psi, \tag{32}$$

where $\psi(\mathbf{Q},t)$ is the polymer end-to-end vector probability distribution. Note that Eq. (32) implies that the stress tensor is a functional of the history of the velocity gradient $\nabla\mathbf{v}_f$. Since the model is frame invariant (Schieber and Öttinger, 1994), it is a specific case of a viscoelastic fluid as proposed by VanArsdale (1995). In fact, nearly all kinetic-theory models to date, except liquid-crystalline polymers that can have preferred direction, are examples of such fluids.

When one measures macroscopic properties of polymer solutions, one is typically measuring certain moments of $\mathbf{Q}$. For example, light scattering measures the radius of gyration, which is proportional to $\langle Q^2\rangle = \mathrm{tr}\langle\mathbf{QQ}\rangle$. To find moments of $\mathbf{Q}$, one can take several different approaches for a given Langevin or Fokker–Planck equation. The most difficult to perform, but conceptually easiest to see, is first to solve the Fokker–Planck equation for ψ, and take the necessary integration:

$$\langle f(\mathbf{Q})\rangle = \int f(\mathbf{Q})\psi(\mathbf{Q},t)d^3Q, \tag{33}$$

where f is an arbitrary function of **Q**. The solution to Eq. (32) is a multivariate Gaussian distribution of zero moments. The second moment is more easily found by the method described next.

Alternatively, in the case where the Fokker–Planck equation is linear in **Q**, one can use Eq. (32) to generate a series of ordinary differential equations in the averages. For example, multiplying Eq. (32) by the dyadic product **QQ**, integrating both sides over all possible configurations of **Q**, and using integration by parts for the integrals on the right-hand side, one obtains

$$\begin{aligned}\frac{d}{dt}\langle\mathbf{QQ}\rangle + (\nabla\mathbf{v}_f)^{\dagger}\cdot\langle\mathbf{QQ}\rangle + \langle\mathbf{QQ}\rangle\cdot\nabla\mathbf{v}_f \\ = -\frac{1}{\lambda_{\mathrm{H}}}\langle\mathbf{QQ}\rangle + \frac{kT}{H\lambda_{\mathrm{H}}}\boldsymbol{\delta}.\end{aligned} \tag{34}$$

For any given flow field, Eq. (34) has a formal solution that contains an exponential matrix involving the integral of the velocity gradient.

If the Fokker–Planck equation derived for some model is nonlinear in **Q**, the above methods cannot be used to find an ordinary differential equation for $\langle\mathbf{QQ}\rangle$. If one attempted to create an ordinary differential equation involving the second moment of **Q**, higher moments of **Q** would arise in the equation. Attempts to write equations of the higher moments result in yet higher moments, and a closed set of differential equations would never result. When this impasse occurs, either one resorts to approximations, or the "exact" solution can be found numerically. Using a pseudorandom-number generator, one can generate stochastic trajectories of a discretized version of the Langevin equation for an ensemble of dumbbells. Then, at any point in the simulation, any desired average can be estimated by taking an ensemble average of this finite-sized ensemble of dumbbells. This *Brownian dynamics* method is used to find "exact" numerical results of many of the models discussed in the next section. A detailed discussion of stochastic simulations of polymer dynamics is given by Öttinger (1995).

To make a connection between the proposed mechanical model and measurements of stresses, one needs an expression for the extra stress tensor $\boldsymbol{\tau}$ and averages of the configuration of the chain. Statistical-mechanical arguments lead to the Kramers–Kirkwood expression for the polymer contribution to the extra stress,

$$\boldsymbol{\tau}_p = -n\sum_i \langle\mathbf{F}_i^{(\mathrm{h})}\mathbf{r}_i\rangle, \tag{35}$$

where n is the number density of polymer chains. The Kramers–Kirkwood expression has been found to be "thermodynamically consistent" for a large number of models and appears to be very generally true (Jongschaap, 1991). In this context, "thermodynamically consistent" means that the expression leads to a positive dissipation of mechanical energy in all flow fields. The Kramers–Kirkwood expression, Eq. (35), simplifies to the less general Kramers expression, Eq. (6), for the dumbbell considered here.

In contrast to experiment, the Hookean dumbbell leads to shear-rate–independent viscosity, no overshoot in the transient viscosity, and a length that can stretch without bounds in strong flows. On the other hand, the model does yield a first normal-stress coefficient, albeit shear-rate independent, and a qualitatively reasonable-looking complex viscosity in small-amplitude oscillatory shear flow.

The Hookean dumbbell predicts that the average orientation angle of the polymer coil in shear flow is $\alpha = \frac{1}{2}\tan^{-1}(m_0/\beta)$ with $m_0 = 1$. The radius of gyration is predicted to go as $1 + 2\beta^2/3m_0$. These predictions can be compared with the empirical results in Eqs. (15) and (16). The orientation predictions are qualitatively reasonable at low shear rates, but the predictions of coil stretching at high shear rates are overestimates.

An early attempt to improve this simple model is to give the chain additional degrees of freedom to allow more complex orientations than a single vector. The Rouse model allows the number of beads to be arbitrarily large, but maintains the other approximations. Such a generalization can be shown to be mathematically equivalent to using an equimolar mixture of dumbbells with different time constants. Instead of a single time constant, there is a discrete spectrum of $N_b - 1$ time constants for N_b beads,

$$\lambda_i = \zeta/8H \sin^2(i\pi/2N_b), \quad i = 1, 2, \cdots, N_b - 1. \tag{36}$$

Rouse's generalization leads to an improved complex viscosity prediction, and improves the quantitative fit for the coil stretching and orientation in shear ($m_0 = \frac{5}{2}$), but does not correct the other drawbacks of the Hookean dumbbell. Also, the Rouse model predicts that the zero–shear-rate viscosity scales as $\sim M^2$, and the diffusion coefficient scales as $\sim 1/M^2$. Both of these results are inconsistent with the experimental work, for which the scaling exponents were found to be $\frac{3}{2}$ and $\frac{1}{2}$, respectively. The model is intended for theta solvents, since no excluded-volume effects are included. Interestingly, the Rouse model describes many dynamic-equilibrium results for melts below the entanglement, molecular weight. It is believed that short-chained, nonentangled polymer melts behave like a Rouse model because of screening effects in the matrix.

In the next section, other improvements to the Hookean dumbbell are discussed. These other models yield nonlinear Fokker–Planck equations and require either mathematical approximations or numerical techniques. Generalizations that are not discussed below, but have been considered and found unimportant are inclusion of bead inertia (Schieber and Öttinger, 1988), and accounting for solvent inertia in the hydrodynamic force (Szu and Hermanns, 1974; Schieber, 1991).

Instead of using springs, Kramers (1944) and Kirkwood and Riseman (Kirkwood, 1967) have used models involving rigid rods as connectors. Kramers's connectors are freely jointed bead-rod chains, whereas Kirkwood and Riseman considered a chain in which each connector is constrained to a valence cone about the previous rod orientation. Brownian-dynamics simulation results for Kramers chain were found by Liu (1989), to show that the model does predict shear thinning for both the viscosity and the first normal-stress coefficient. The power-law region has slope of approximately $\frac{2}{3}$ for two beads down to about $\frac{1}{2}$ for 20 beads in the viscosity, and a second plateau region is predicted, all in reasonable agreement with experiment. However, the zero–shear-rate viscosity is predicted to scale with molecular weight squared.

3.1.2 Generalizations and Improvements It is generally believed that the above models are insufficient to describe data for several reasons:

1. neglect of hydrodynamic interaction;
2. infinite extensibility of springs; and
3. neglect of excluded volume.

It is also speculated that internal friction (or internal viscosity) may play an important role.

The motion of one bead on the chain will perturb the flow field felt by all other beads in the chain, giving rise to *hydrodynamic interaction* between the segments. The interaction can be accounted for by either the Rotne–Prager–Yamakawa or the Oseen–Burgers tensors (see p. 133 of Bird *et al.*, 1987), which yield the perturbation to the flow field at one point in the continuum given a hydrodynamic force at a second point. Since the effect is nonlinear in configuration, most of the work has involved mathematical approximations of the tensor.

The earliest work was by Zimm (see p. 94 of Bird *et al.*, 1987), who replaced the configuration-dependent tensor by an average taken over the equilibrium configurations of the chains. This approximation was sufficient to correct the prediction of the zero–shear-rate viscosity scaling dependence on molecular weight. Also, Zimm's approximation predicts that the longest relaxation time goes as $M\eta_{p,0}/4.04RT$, which agreed well with the subsequent experiments of Caroline and Jones (1980) given in Sec. 2.1.1. However, no other improvements are offered by Zimm's approximation.

Subsequent approximations include replacing the equilibrium-averaged hydrodynamic-interaction tensor with its consistently averaged (or iteratively averaged) values. These approximations led to improved viscosity and first normal-stress coefficient predictions. These latter approximations were then replaced by making a Gaussian closure approximation on the second-moment equation arising from the Fokker–Planck equation. The earlier approximations cannot account for fluctuations in the configurations of the chains, whereas the Gaussian closure can. This last approximation has subsequently been verified by exact Brownian-dynamics simulations by Zylka (1991) to be valid. The simulations predict that the viscosity and first normal-stress coefficient show shear thinning at moderate shear rates followed by shear thickening at high shear rates. The second normal stress has opposite sign to that of the first normal-stress coefficient at small and moderate shear rates, and then changes sign at high shear rates.

Finally, both hydrodynamic interaction and excluded volume were considered by Zylka and Öttinger (1991). Both the hydrodynamic-interaction and excluded-volume effects are accounted for as perturbations to the Rouse model. Since these effects scale with chain length to the one-half power, renormalization-group techniques are needed to find asymptotic, or universal, behavior for long chains. The excluded-volume effect is used to find predictions for dilute solutions in good solvents, and is switched off to find predictions for theta solvents. Zylka and Öttinger find the diffusion tensor for the chain in shear flow, and steady-state viscometric functions. The predictions are qualitatively unchanged from the Brownian-dynamics results for the theta-solvent conditions. However, the results do show that the viscosity grows without bounds with increasing shear rate.

The classic textbook by Yamakawa (1971) considers many dynamic-equilibrium properties of polymer solutions using a two-parameter model: the Kuhn step length, and a binary cluster parameter for excluded volume. The book also describes Fixman's use of boson operators to approximate excluded-volume interactions, and makes many comparisons with experimental measurements from dynamic light scattering.

Three results indicate that the models discussed so far (using Hookean springs) predict an overstretching of the polymer coil in flows: The coil size is found by light scattering to be much smaller than predicted, the coil stretches to infinite length for elongational rates above a critical value, and the hydrodynamic-interaction model of Zylka predicts unbounded shear thickening. These results suggest that a realistic model must include finitely extensible connectors.

The spring force arises from a coarse-graining of the random-walk chain. Derivation of the precise form of the potential is as follows. One begins by modeling the chain segment as a random walk of $N - 1$ Kuhn steps of length a. The probability of the end-to-end vector of the segment is found from a straightforward probability transformation. From the end-to-end vector distribution, the partition function for the segment is found from Gibbs's postulate. Once the partition function is available, all thermodynamic quantities can be found, including the Helmholtz free energy. Now, if one isothermally increases the length of the segment, the change in free energy is found from the thermodynamic relation just derived. This change in free energy must be the physical work done on the chain by pulling. From the change in length and the change in free energy, the force can be inferred. In this way, the force is found as a function of segment length:

$$\coth\left(\frac{aF^{(c)}(\mathbf{Q})}{kT}\right) - \frac{kT}{aF^{(c)}(\mathbf{Q})} = \frac{Q}{(N-1)a}. \qquad (37)$$

Such an expression is unwieldy, and so two approximations are generally used. The simplest is the linearization in small Q, which leads to the Hookean spring law $\mathbf{F}^{(c)}(\mathbf{Q}) = -H\mathbf{Q}$, for which the spring constant can now be identified as $3kT/a^2(N-1)$. A better approximation that is nonlinear in Q and prevents the spring from stretching farther than $(N-1)a$ is called the FENE (finitely extensible nonlinear elastic) spring:

$$\mathbf{F}^{(c)}(\mathbf{Q}) = -3kT(N-1)\mathbf{Q}/[(N-1)^2a^2 - Q^2]. \qquad (38)$$

The FENE law approximates Eq. (37) rather well and captures the important features. Most of the calculations for this model have involved a consistent-averaging approximation, whereby one replaces the Q^2 in the FENE expression with its flow-dependent average value. In other words, the average length of each segment is constrained to be less than a. Exact calculations (Rudisill and Cummings, 1992; Hua and Schieber, 1994) have confirmed the qualitative features of the approximation. Namely, shear thinning in viscosity and first normal-stress coefficient is predicted, and the stresses remain bounded in strong flows, such as steady elongation.

Also, finite extensibility reduces the amount of stretching of the coil, bringing the predictions in closer agreement with observation.

The above derivation for the connector law is derived from thermodynamic arguments, which assume a quasi steady-state stretching of the segment. Physically, one might expect that rapid deformations of the chain encounter an additional, rate-dependent, dissipative force. This additional *internal viscosity* was first proposed by Kuhn and Kuhn (1945). In addition to the spring force, one postulates an internal-viscosity force

$$\mathbf{F}^{(iv)}(\mathbf{Q}) = -\frac{\epsilon\zeta}{2}\frac{\mathbf{QQ}}{Q^2}\cdot\frac{d}{dt}\mathbf{Q}, \tag{39}$$

where ϵ is called the *internal-viscosity parameter,* whose value determines the strength of the internal viscous drag relative to the solvent drag.

Again, most calculations have been made using an approximation, such as perturbation for small ϵ, small strain rates, linearization of Eq. (39) in $\mathbf{Q}$, or Gaussian closure of the second-moment equation. However, Brownian-dynamics simulation (Hua and Schieber, 1994; Wedgewood, 1994) shows that these approximations break down for all but small values of ϵ, and often are valid only for small strain rates. The Gaussian closure is a good approximation for small ϵ at all flows, small strain rates for all values of ϵ, or short-time transients for large ϵ at large strain rates. For $\epsilon > 3$, the Brownian-dynamics simulations appear to be best approximated by rigid connectors, with a Gaussian distribution of lengths. The internal-viscosity effect is able to describe positive values for the second plateau region in the in-phase part of the complex viscosity, and predicts shear thinning at moderate shear rates. However, at large shear rates, shear thickening of viscosity is predicted for Hookean connectors, which is similar to hydrodynamic-interaction effects. The internal-viscosity effect also decreases the amount of predicted coil stretching in shear flow.

Addition of internal viscosity does predict one effect that is distinct from others. Namely, it predicts both an elastic and a viscous contribution to the stress during flow. The viscous stress contributes nothing when the flow field is switched off, whereas the elastic stress persists for some time, before decaying to zero. The other effects (e.g., FENE connectors, hydrodynamic interaction) lead to a purely elastic polymer contribution to the stress. Recent experiments of Liang and Mackay (1993) have shown that semidilute solutions of xanthan do have apparent elastic and viscous polymer contributions to the stress. However, these results could conceivably be explained by a change in solvent characteristics from the presence of the polymer, or polymer–polymer interactions.

Many different combinations of the above effects have been tried: multiple connectors, nonlinear springs, excluded volume, hydrodynamic interaction, and internal viscosity. Each of the effects has been able to explain some aspect of the data, and points to the importance of the effect. To incorporate all of these effects, one must specify two parameters that are not directly connected to the chemical structure of the polymer: bead size and ϵ. In principle, the other parameters follow from these and the Kuhn step length a, which can be estimated from the chemical structure of the chain. However, some workers choose to leave some of these as independent adjustable parameters.

3.2 Concentrated Solutions and Undiluted Polymers

3.2.1 Reptation Models The term *reptation* was coined by de Gennes (1979), who was the first to calculate quantitative predictions for the dynamics of polymer chains trapped in a gel. The ideas were later generalized to polymer melts by Doi and Edwards (1986), and then expanded by many other workers. One begins with a mean-field model, in which the surrounding matrix of chains in the gel (or melt) is replaced by a "tube" that constrains the motions of the probe chain. The chain is assumed to move rather easily along its contour, but cannot move very far laterally before "feeling" the constraints of the surrounding matrix. One then considers a *primitive chain,* which is meant to be a sort of coarse-graining of the real (probe) chain. The primitive chain is allowed to move in a coordinated fashion such that it can slink along its one-dimensional contour inside the tube. When the end of the chain exits either end of the tube, it takes a random orientation. The tube is defined by the presence of the chain, and so the tube segment at the receding end of the chain is destroyed. It is assumed that the reptative motion is driven by one-dimensional Brownian motion, and that the friction between the tube and the chain is proportional to the length of the chain.

These straightforward ideas were sufficient to allow de Gennes to predict scaling dependence of the diffusion coefficient and the longest relaxation time constant on chain length, or molecular weight for a chain in a gel. De Gennes found

$$D \sim M^{-2}, \quad \lambda_{\mathrm{R}} \sim M^{3}, \tag{40}$$

where λ_{R} is the longest relaxation time constant. Reptation was the first model to predict the correct diffusion-scaling exponent for many systems. The exponent describing the time constant does not agree with the value of 3.4 found experimentally, and the fact that the diffusion scaling predicted by reptation holds well below M_e also raises questions. However, these predictions were sufficient to generate a great deal of interest in reptation.

Predictions of the reptation model in flowing polymer melts require additional assumptions. First, the chain is assumed to relax by reptation and the additional mechanism of *chain retraction.* For example, in single-step strain, the following dynamics is assumed for the chain. First, during the imposition of the strain, the segments are deformed affinely. One can show that most equilibrium configurations of the chain are stretched after the strain. Then, on a rapid time scale, the chains are assumed to retract back to their equilibrium lengths; this motion is the first relaxation mechanism. The second relaxation mechanism is reptation of the chain to a new configuration. In other flow fields, it is generally assumed that the retraction mechanism can be treated as essentially instantaneous.

For tractability, additional mathematical approximations, such as *independent alignment,* or consistent averaging, are usually employed to make predictions of the dynamics of the chain. Independent alignment is the most severe of the approximations, but allows solution to a very large number of problems. This approximation assumes that the retraction of the entire chain can be replaced by a retraction of each of the segments of the chain independently. Then, the dynamics of the segments are decoupled, and the following Fokker–Planck equation is obtained:

$$\frac{\partial f(\mathbf{u},s,t)}{\partial t} = \frac{kT}{N\zeta}\frac{\partial^2 f}{\partial s^2} - \frac{\partial}{\partial \mathbf{u}}\cdot[\mathbf{u}\cdot\nabla\mathbf{v}_f - \nabla\mathbf{v}_f : \mathbf{uuu}]f, \tag{41}$$

where ζ is the effective friction factor felt by a segment in the tube, $\mathbf{u}$ is the unit orientation vector of a tube segment, s is the position of the tube segment relative to the chain end, and f is the probability density of finding a tube segment with orientation $\mathbf{u}$, and containing chain segment s along the chain contour. Note that since the chain diffuses randomly within the tube, s is treated as a stochastic variable that can take values between $\pm Na/2$. The boundary conditions associated with Eq. (41) couple the orientation $\mathbf{u}$ with position along the chain s:

$$f(\mathbf{u},s,t) = 1/4\pi, \quad \text{for } s = \pm Na/2. \tag{42}$$

Equation (41) has a general integral solution for f (Bird *et al.*, 1987, p. 330).

To be consistent with the rapid retraction mechanism, the tension in the chain is assumed to be the equilibrium value, independent of flow field. Thus, Doi and Edwards (1986) assume that the stress tensor is just

$$\boldsymbol{\tau} = \frac{G_e}{3}\boldsymbol{\delta} - \frac{G_e}{Na}\int_{-Na/2}^{Na/2}\int \mathbf{uu}f(\mathbf{u},s,t)\,d^2u\,ds, \tag{43}$$

where G_e is the plateau modulus and is a function of segment length a, number of chain segments N, chain concentration, and temperature.

Since the reptation model requires mathematical approximations to find quantitative predictions, the approximations have sometimes obscured the conclusions that can be drawn from quantitative comparisons with data. However, some results are conclusive, and many of the conclusions are compiled by Lodge *et al.* (1990) and by Skolnick and Kolinski (1990).

The model is able to capture qualitatively the features of the relaxation modulus, although the spectrum is too narrow. These discrepancies can be improved by accounting for polydispersity, but the general trend of relative weight for the time constants in the spectrum is inconsistent with experiments by Baumgärtel *et al.* (1990) discussed in Sec. 2.4.1.

The damping function, which arises from the retraction mechanism, is consistently underpredicted as a function of strain for linear chains. Reptation with a consistent-averaging approximation for the retraction mechanism predicts approximately that $a_d = 39/175$ in Eq. (22). Nonetheless, since the damping function contains no adjustable parameters, the comparison is impressive. After the relaxation modulus has been "corrected" (fitted to experiment), double-step strain predictions of the Doi–Edwards model are improved. However, if the second step strain is imposed before chain retraction is complete, current mathematical models are unable to describe the data (Venerus and Kohvand, 1994).

When independent alignment is assumed, the theory predicts shear thinning for both the viscosity and the first normal-stress coefficient, but the power-law region is predicted to have slopes that are too steep. Part of the discrepancy can be attributed to polydispersity in the sample. To date, there are few quantitative predictions for the reptation model that account for polydispersity (Schieber, 1987). Stress overshoot is predicted for the viscosity, but not for the first normal-stress coefficient. Elongational viscosity is also not well described by the model.

Many comparisons with data have indicated that relaxation processes in addition to reptation are needed to describe the data (Saab *et al.*, 1982). Subsequently, additional chain motions have been considered in a phenomenological manner, such as "tube renewal," "constraint release," or "tube dilation." Most of these additional mechanisms are incorporated to account for an important problem in the original formulation. Namely, the surrounding matrix of chains in a polymer melt is relaxing on the same time scale as the probe chain. Hence, it is not consistent to treat the tube as a stationary object when considering the dynamics of the chain. Some experimental results indicate that the diffusion coefficient of a shorter chain is independent of the molecular weight of the matrix for matrix chains sufficiently longer than the probe chain, as discussed in Sec. 2.2.

One of the more successful generalizations to the reptation idea is the so-called *double reptation* of des Cloizeaux (1990), to account for relaxation coupling between different chains in an *ad hoc* manner. He postulated that, since a chain segment can relax by two processes—namely its own reptation, or the relaxation of a surrounding chain—the relaxation modulus of the mixture should be the root mean square of the individual components. Apparently, the resulting mixing rules for the relaxation modulus of polydisperse systems are able to describe experimental results quantitatively, and are currently being used to estimate polydispersity distributions from complex viscosity data (Mead, 1994).

Additional models have been proposed that incorporate some form of reptation in the dynamics. For example, the work of Hess (1986, 1988) attempts to derive reptation dynamics from the Liouville equation using projection operators.

3.2.2 Anisotropic Mobility Models Additional mean-field models have been proposed for polymer melts that do not assume reptation. A few of these have incorporated anisotropic mobility for the chain segments in order to account for the restriction to mobility of chains in melts. The model of Curtiss and Bird (Bird *et al.*, 1987) assumes that it is easier for a segment of chain to move in the direction of the orientation of segments adjacent along the chain. They also assume an anisotropic Brownian motion of the chain, and that only chains that are mildly curved contribute to the stress tensor. With these assumptions, they arrive at the same Fokker–Planck equation (within a constant) as the Doi–Edwards model, Eq. (41), but an expression for the stress tensor that involves an additional adjustable parameter called the *link tension coefficient*. Within a constant, all of the results of the Doi–Edwards model are recovered when the link tension coefficient is set equal to zero.

Nonzero values of the link tension coefficient worsen the predictions of the relaxation modulus, but improve predictions of the viscosity, first normal-stress coefficient, and elastic recovery (Saab *et al.*, 1982). Also, many calculations have been made that account for polydispersity in the model, which generally compare quite well with experimental data (Schieber, 1987). However, the model has been criticized for failure to predict the stress-optic law. Also, the mild-curvature approximation does not appear to be consistent with other assumptions in the model.

An additional model containing the concept of anisotropic mobility is the constitutive equation of Giesekus (Bird *et al.*, 1987). This approach models the polymer coil as a dumbbell that can stretch more easily than it can rotate. To achieve mathematical closure in the second-moment equation of the orientation vector, a consistent-averaging approximation is made on the mobility tensor. For a given range of the adjustable parameters, reasonable qualitative results are obtained for many nonlinear experiments.

3.2.3 Mode–Mode Coupling Models The stochastic equations used for dilute-solution polymer modeling can be derived from Hamilton's equations of motion using Mori–Zwanzig projection operators (Berne, 1977). However, validity of the derivation relies on a separation of time scales between the motion of the polymers and the motion of the solvent particles. For polymer melts, such a separation is clearly not valid, as all polymer chains relax on approximately the same time scale. To account approximately for the coupling between the different modes relaxing on various time scales, it is possible to use projection operators to project the dynamics onto higher moments of the quantities of interest. An additional closure must be made on these higher moments, but it is hoped that capturing the couplings between different modes even roughly is sufficient to make good predictions. Such an approach is called mode–mode coupling (Berne, 1977).

Mode–mode coupling results in generalized Langevin equations to describe the stochastic equation of motion of the chains. The memory kernel in the history-dependent drag force on the chain depends, in principle, on the underlying interparticle potential. However, for mathematical tractability, approximations must usually be made. By considering Rouse chains that are not allowed to cross, Schweizer (1989) has considered perturbative approximations of the memory kernel to estimate some dynamic-equilibrium properties. With these approximations, the diffusion coefficients for linear chains and ideal rings are predicted to scale inversely with the molecular weight squared, whereas the plateau modulus and zero-shear viscosity are predicted to scale with molecular weight as M^3. Alternative approximations for the memory kernels lead to a scaling for viscosity more in line with experiment. Using the mode–mode coupling framework, Schweizer is able to predict many of the scaling results of reptation, without introducing any dominant form of chain motion. In an appendix, Schweizer also critically examines and compares the work of Hess.

3.2.4 Network Models Thermodynamic and kinetic-theory models of elastic rubbers have been generalized to describe polymer melts. Instead of chemical bonds that create permanent junctions between polymer strands, mechanical entanglements are assumed to provide temporary cross-link junctions. The lifetime of a given junction is modeled as a stochastic process, so that the existence of entangled strands can be treated as a birth–death process. In real systems, the destruction of an entanglement should result in the motion of nearby segments, as stress is relaxed. However, most network theories decouple the motion of segments, so that the time evolution of the probability function of a single segment may be written. If the network strands between entanglement points are assumed to deform affinely (as can be shown for a permanently cross-linked network), the creation rate and orientation of strands are assumed to be the same as at equilibrium, and a constant destruction rate is assumed, the Lodge rubberlike liquid model arises, with "convection equation" (Lodge, 1964)

$$\frac{\partial \Psi_{iN}}{\partial t} = -\left(\frac{\partial}{\partial \mathbf{Q}} \cdot [\mathbf{Q} \cdot \nabla \mathbf{v}_f] \Psi_{iN}\right) + L_{iN} \Psi_{iN,\mathrm{eq}}(\mathbf{Q}) - \frac{1}{\lambda_{iN}} \Psi_{iN}, \qquad (44)$$

where L_{iN} is the (constant) creation rate of strands and λ_{iN} is the (constant) destruction rate of strands. The distribution Ψ_{iN} ($\Psi_{iN,\mathrm{eq}}$) is the probability-density function (at equilibrium) for the configuration of entangled polymer strands. The subscript iN allows for the existence of different types and lengths of strands. The equilibrium distribution is assumed to be Maxwellian, since each strand is assumed to have a spring force associated with it. These distributions are normalized to the strand number density, rather than 1.

One also generally assumes that the proper form of the stress tensor is the Kramers form, Eq. (6), except that a sum over each type of strand must be made, and the number density of strands is already implicit in the distribution function.

The Lodge model assumes that the appropriate connector force is Hookean. The resulting constitutive equation is very similar to the Rouse model. However, the Lodge network model allows for the relaxation modulus to be a sum of exponentials with any desired spectrum of relaxation times by selecting the proper values for the L_{iN} and λ_{iN}. Thus, many of the shortcomings of the Rouse model in predicting nonlinear properties also apply for the Lodge model.

Many generalizations have been made to this straightforward model. Most of these involve nonlinear deformation of the strands, or time-dependent or conformation-dependent destruction or creation of strands. Since these generalizations make the time-evolution equation nonlinear in $\mathbf{Q}$, consistent-averaging approximations are often made. Stochastic simulations have been used by Biller and Petruccione (1990) to find exact numerical solutions to the above types of generalizations. Van den Brule and Hoogerbrugge (1994) have simulated networks of many connected strands using a stochastic dynamic simulation of birth–death processes. The simulations predict average affine motion of the strands, but shear thickening of viscosity and first normal-stress coefficient, in contradiction with experiment.

3.2.5 Poisson-Bracket Formulations Poisson brackets were developed to write deterministic equations of motion on a vector space utilizing a generator function, such as the Hamiltonian or energy, rather than from a mechanistic approach. In the mechanistic approach above, many degrees of freedom are not accounted for explicitly in the equations of motion, but rather their influence is felt through the addition of stochastic (Brownian force) and dissipative (Stokes drag) terms. When one works from Poisson brackets, the influence of the missing degrees of freedom is described through an additional "dissipative" bracket. Working with such generalized Poisson brackets has the advantage that consistency relations, such as fluctuation–dissipation relations, or thermodynamics, are straightforward to satisfy. However, a mechanistic approach often has an intuitive advantage in modeling.

In theory, the Poisson-bracket approach can be written on many levels of description, from Hamilton's equations of motion for all degrees of freedom to the phase-space configuration distribution function of a single chain, to the second moment of the connector vector of a chain segment (*conformation tensor*). In practice, however, nearly all predictions have been accomplished on the conformation-tensor level. At this level, much information is gleaned from the mechanistic approach, which makes the Poisson-bracket formulation complementary to kinetic theory. A detailed discussion of the method is described in the monograph by Beris and Edwards (1994), where many applications are made to liquid-crystalline systems (among others).

3.2.6 Computer Simulations A novel approach to model hydrodynamics in complex geometries and flows has recently been proposed (Hoogerbrugge and Koelman, 1992; Koelman and Hoogerbrugge, 1993). The method is based on modeling the fluid as a collection of fluid "particles," and, in principle, is capable of handling an extremely broad array of problems, including porous walls. These systems can be dynamic equilibrium or nonequilibrium. Dissipative particle dynamics (DPD) simulates a large number of interacting particles in a flow field by using crude, short-range interparticle potentials, in addition to some fluctuating random forces. The time steps are kept large, and only particles near in space interact. A particle can represent a "packet of fluid," a segment of polymer chain, a portion of solid particle, or a portion of solid wall. The algorithm is inspired by cellular automata programs, and shares some of the same features.

This novel approach has several advantages over existing methods (Kremer, 1983; Kremer *et al.*, 1988; Kremer and Grest, 1990). The time steps are much larger than the time steps of molecular dynamics, and, since far fewer particles interact, the required CPU time for each time step is much less. Since random forces are added, no thermostatting of temperature is required. Thus, macroscopic time scales are attainable with DPD.

Dissipative particle dynamics also exploits the universal characteristic of the hydrodynamics more directly. DPD utilizes simplified potentials for many interacting degrees of freedom. Since chemistry does not appear to be important for the observed universal macroscopic properties of supramolecular systems, DPD chooses the simplest possible potentials, but maintains the important geometric constraints. In this way, it is hoped that universal properties are captured by DPD.

Despite these advantages, dissipative particle dynamics has some drawbacks. For example, the method is an algorithm that guarantees the satisfaction of some general physical principles, such as conservation of momentum and Galilean invariance, but energy is not conserved (although the temperature is fixed). Also, there exists no equation describing the governing dynamics of the system—only individual dynamics are described.

Dynamic Monte Carlo simulations are reviewed by Baumgärtner (1992). For example, Kolinsky, Skolnick, and Yaris (Skolnick and Kolinsky, 1990) simulated multiple nonphantom chains on a lattice. Dynamic-equilibrium properties of the chains are followed with time. The simulations do predict proper scaling coefficients for the diffusion constant and the longest relaxation time constant, as found by autocorrelation functions. However, the systems studied need to be far from highly concentrated to prevent freezing of the motion, or else the dynamics appears to be glassy. Generalization to flow fields does not appear to be straightforward, except perhaps through dissipative-dynamics simulations.

Ideally, one would like to perform molecular dynamics on concentrated systems to find equilibrium-dynamics properties. However, the long-time-scale dynamics of real chains is far out of reach of current computational resources. Instead, Kremer and coworkers (1983, 1988, 1990) simulated a concentrated system of Rouse chains with excluded volume. Their results appear to give proper scaling laws, and the innermost segments exhibit reptationlike autocorrelation functions for their motion. Hence, they concluded that reptation provided a good description of their simulations. However, all chains do not exhibit these laws, and some controversy remains about whether or not the simulations confirm reptation. Also, although the chains have excluded volume, it is still possible that chains can pass through one another for some configurations. An additional drawback of the computations is that additional Brownian forces and frictional forces were added to the beads to keep a constant temperature of the system. Such stochastic forces change the fundamental nature of the equations integrated.

3.3 Flows and Stresses in Complex Geometries

3.3.1 Numerical Solution of Constitutive Equations Predictions of stresses in flow fields are useful from a practical point of view. Many industrial processes involve the flow of non-Newtonian fluids in complex geometries—injection-molding dies, for example. Also, prediction of viscoelastic-flow instabilities is desirable. For a given constitutive equation and geometry, one must simultaneously solve several equations for all points inside the geometry while satisfying the boundary conditions. In the simplest case, these equations would be the equation of motion, Eq. (5), the equation of continuity (conservation of mass), and the constitutive equation. In addition, for nonisothermal problems, one may need to solve the energy equation and an equation of state simultaneously as well. The constitutive equation may be of the differential type (depending upon local velocity gradients only), or of the integral type (depending upon the deformation history of a fluid element).

Addition of the constitutive equation leads to complications not found in solving the Navier–Stokes equation, and current efforts have centered around four chosen problems: a four-to-one contraction flow, extrudate swell, viscoelastic stability in flows around cylinders, and flow through tubes of sinusoidal cross section.

The outstanding problems posed by viscoelastic fluids in complex flows can be understood in terms of the Weissenberg and Deborah numbers. The Deborah number is defined as the ratio of the fluid's largest relaxation time, which may be estimated from the relaxation modulus, Eq. (20), to the residence time of a fluid particle in the flow regime of interest. When the Deborah number is very small, then elastic effects are not as important as viscous effects, and the fluid behaves effectively as Newtonian. On the other hand, flow fields for which the Deborah number is very large may appear more like an elastic solid. Most interesting flow fields lie between these two extremes. Hence, special problems arise in attempting to predict flow fields for viscoelastic fluids that are not seen for either purely viscous or purely elastic deformations.

The Weissenberg number is defined (by Tanner, 1985, for example) as

$$We := \lambda\sqrt{\mathrm{tr}[\nabla\mathbf{v}_f + (\nabla\mathbf{v}_f)\dagger]}. \tag{45}$$

In other words, the Weissenberg number is the ratio of the relaxation time of the polymer to a characteristic time of the local rate of deformation of the fluid. Many numerical methods work well at small *We* and *De*, but fail as these groups are made larger than 1.

Special variations of mixed finite-element methods have been used to tackle special numerical problems presented by the particular forms of the constitutive equations being used. Current methods of attack on the prediction of viscoelastic-flow fields (Crochet *et al.*, 1984; Crochet, 1986) are finite-element methods, finite-difference methods, spectral methods, and boundary elements. Several recent papers on current methods have recently been published in an issue of the *Journal of Rheology* (Vol. 38, No. 2, 1994), including a comparison of higher- and lower-order techniques (Khomami *et al.*, 1994). Other techniques were recently studied in a comparison of numerical stability by Brown *et al.* (1993).

Many constitutive equations being used are from continuum mechanics, but some molecular-based models have been used as well. However, the molecular-based models require some mathematical approximation to find the closed-form expression for the stress tensor, necessary for the numerical method.

3.3.2 Combined Stochastic Simulation and Finite-Element Techniques In order to avoid the shortcomings of using the approximate molecular models, Laso and Öttinger (1993) have proposed combining finite-element techniques with Brownian-dynamics simulations. To estimate the stress field, Brownian-dynamics simulations are performed at each element, using the linearized local velocity field. Although the method is computationally (and memory) intensive, spatial and temporal problems are attainable. As an example, they calculated the stress and velocity fields for the inception of steady shear flow of a dilute solution of FENE dumbbells. The results are qualitatively quite different from the analytic solution using the approximate FENE model with Peterlin's consistent-averaging approximation; for example, when the exact model shows a single overshoot, the approximate model shows multiple oscillations, and the steady state is reached at a much later time.

ACKNOWLEDGMENTS

The author would like to thank the following people for aiding in the preparation of this manuscript: Prof. Hans Christian Öttinger, Prof. R. Byron Bird, Prof. T. C. B. McLeish, Prof. David C. GLOSSARY

Constitutive Equation: An equation relating the stress in a continuum to the imposed flow field.

Cox–Merz Rule: The observation that the steady-state viscosity curve as a function of shear rate has the same form as the magnitude of the complex viscosity as a function of frequency in small-amplitude oscillatory shearing flow.

Damping Function: A function that describes the strain-dependent part of the shear stress following a shear step strain.

Dynamic Structure Factor: A time-dependent averaged quantity that describes the relative positions among different segments of the same chain.

Entanglement Concentration: A critical concentration of polymer chains in a solvent, above which the chains exhibit properties consistent with the existence of chain–chain entanglements.

Entanglement Molecular Weight: A critical molecular weight below which it is believed that concentrated chains are not substantially entangled. The onset of entanglement is indicated by the appearance of a plateau in the relaxation modulus.

Flory Interaction Parameter: A parameter that describes the relative energetic interaction between chain segments and solvent molecules.

Kinetic Theory of Polymers: The description of macroscopic behavior of polymers by the use of equilibrium or nonequilibrium statistical mechanics.

Linear Viscoelasticity Theory: The theory that relates the stress tensor in any given small-strain deformation to the stress in any other small-strain deformation.

Polydispersity: The distribution of molecular weights of a batch of polymer chains.

Polymer Fluid Dynamics: The motion of polymeric liquids as described by the equations of motion and continuity.

Polymer Rheology: The study of flows of polymeric liquids.

Power-Law Region: The intermediate region of the steady-state viscosity curve that is linear on a log–log plot as a function of shear rate.

Radius of Gyration: An averaged quantity that indicates the size of a polymer coil in solution.

Reptation: The postulation that the dominant motion of linear polymer chains in concentrated systems is a one-dimensional diffusion of the chain along its backbone.

Stress-Optic Law: The observation that, within a constant factor (called the stress-optic coefficient), the index-of-refraction tensor and the stress tensor are equal during flow for a polymer melt.

Theta Solvent: A solvent for which the energetic interaction between segments on a chain relative to solvent–segment interactions is balanced by segment–segment steric interactions, and the Flory interaction parameter is $\frac{1}{2}$.

Theta Temperature: The temperature at which a solvent is a theta solvent.

Time-Temperature Superposition: The observation that changing the temperature of an experiment does not change the functional forms of measured properties, but appears to rescale the frequency for most experiments.

Zimm Plot: A plot of light-scattering data that allows double extrapolation of chain concentration and magnitude of the scattering wave vector to obtain the molecular weight and radius of gyration of a polymer chain in solution.

INTRODUCTION

Polymers are macromolecules synthesized from small-molecule precursors or *monomers* by a process termed *polymerization.* The linkages along the polymer chain are formed by mechanisms that are generally divided into two classifications—*step growth* and *chain growth.* Reaction conditions and constituents determine the final chain structure and the number of repeating units of the macromolecule. Polymers can have relatively low molecular weights (often termed *oligomers*) or may have ultrahigh molecular weights reaching $>10^7$ g/mol.

Synthetic polymers have traditionally been divided into categories based on their respective physical properties. These include plastics, elastomers, coatings, adhesives, fibers, water-soluble resins, etc. Equally diverse in properties are *biopolymers* synthesized in biochemical processes. These include polynucleotides (deoxyribonucleic acid, DNA, and ribonucleic acid, RNA), polysaccharides, proteins, natural rubber, and naturally occurring polyesters.

In subsequent sections for organizational purposes, polymerization or polymer-forming reactions are presented in terms of step-growth and chain-growth mechanisms for major synthetic polymer types. Postpolymerization modifications or reactions are then addressed.

1. STRUCTURAL FEATURES OF POLYMERS

General structural features of polymers are illustrated in Fig. 1. Architecture of the polymer may be linear, branched, or cross linked. Additional diversity in architecture and ultimate behavior can be built in by introducing multiple monomers into the macromolecules during or subsequent to polymerization. For example, linear chains composed of two constitutive repeating units A and B can be arranged in random, alternating, block, graft, or cross-linked fashion as illustrated in Fig. 2. The behavioral characteristics are determined by the structural features of each and would be expected to differ markedly even if the compositions of A and B units were the same. In addition to the above considerations, bond type, valence-bond and conformational angles, steric, polar, and electrostatic interactions, segmental solvation, long-range interactions, molecular weight, concentration, packing, and exclusion effects are among the many variables that dictate ultimate properties. Thus, there are nearly limitless opportunities for tailoring macromolecules for specific applications by rational monomer selection and effective polymerization procedures.

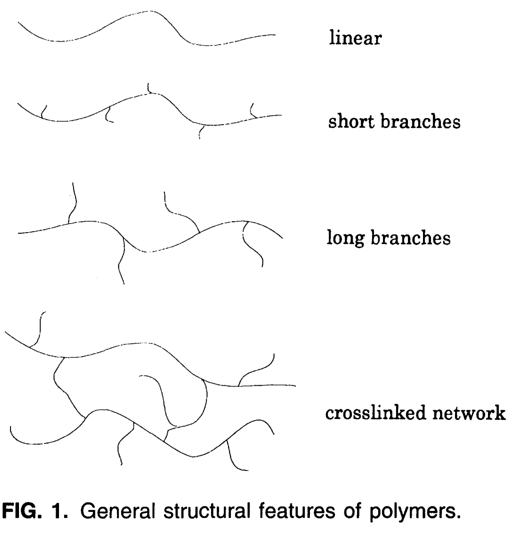

FIG. 1. General structural features of polymers.

2. MECHANISMS OF POLYMERIZATION

In early years, as the polymerization process was being studied, pioneering work by Wallace Carothers (1929) and by Paul Flory (1953) revealed that not only were structural features important, but also the mechanisms (and kinetics) of polymer-forming reactions could be separated. Carothers's classification of the two major modes, termed "condensation" reactions and "addition" reactions, was later updated to use the more precise designations of "step-growth" and "chain-growth" processes.

In step-growth polymerization reactions, functional groups on respective monomer units react in a manner to build molecular weight slowly. The linking mechanism results in formation of dimers, tetramers, pentamers, etc. In chain-growth polymerization, chain extension or propagation occurs by addition of monomer to an active chain end, which generally occurs at a rapid rate. *Initiation* and *termination* reactions (and often *chain-transfer* reactions) determine the final degree of polymerization and the distribution of molecular sizes.

Table 1 (Lenz, 1967) compares step-growth and chain-growth polymerization processes in terms of component reactions, growth, and monomer reactivity.

2.1 Step-Growth Polymerization

Step-growth polymerizations require reactive functional groups that combine to form a new linking unit between reactant pairs. In order to obtain linear polymers with high molecular weights, the reactants must be difunctional. Monofunctional reactants serve as chain stoppers, and multifunctional monomers lead to branching and/or cross linking.

2.1.1 The Carothers Equation Wallace Carothers, often called the father of step-growth polymerization, developed an equation that relates the degree of polymerization ($\bar{D}p$) to the extent of reactions, ρ, for linear

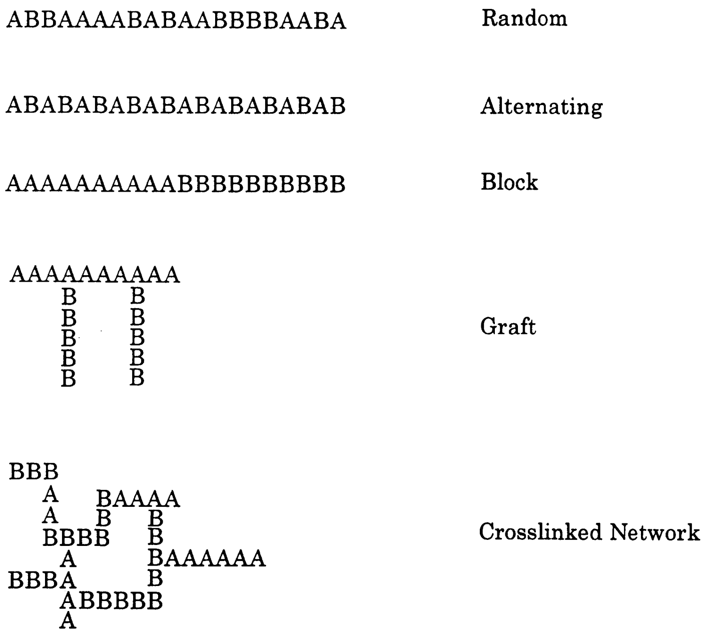

FIG. 2. Possible copolymer structures formed from respective monomers *A* and *B*.

polymers prepared by self-condensation of a monomer (*A–B*),

$$N_0A\text{–}B \rightarrow A\text{–}B\left[A\text{–}B\right]_{N_0-2}A\text{–}B, \tag{1}$$

or by reaction of monomer pairs (*A–A* plus *B–B*).

$$N_0A\text{–}A + N_0B\text{–}B \rightarrow A\text{–}A\left[B\text{–}B\text{–}A\text{–}A\right]_{N_0-2}B\text{–}B. \tag{2}$$

In these cases *A* and *B* possess reactive functional groups. At a given time, the conversion ρ is defined by

$$\rho = (N_0 - N)/N_0, \tag{3}$$

in which N represents the total number of molecules present. The term N_0 is the number of molecules originally present. Since the degree of polymerization is given by

$$\bar{D}p = N_0/N, \tag{4}$$

Table 1. Characteristics of step-growth and chain-polymerization growth.

Characteristic	Step-growth polymerization	Chain-growth polymerization
Component	Initiation, propagation, and termination reactions essentially identical in rate and mechanism	Initiation, propagation, and termination reactions significantly different in rate and mechanism
Polymer growth	Slow, random growth of polymer with high reaction conversion required for a high degree of polymerization	Rapid, preferential growth of each polymer chain, once initiated, with high degrees of polymerization attained at the start of the reaction
Reactivity of monomer	Monomer capable of combining with itself or with any other species present with equal facility, resulting in rapid disappearance of monomer at early stages of the polymerization reaction	Monomer capable of reaction only with an active end group on a polymer chain, resulting in steadily decreasing but significant concentrations of monomer throughout the polymerization reaction

then substitution yields the Carothers equation,

$$\bar{D}p = 1/(1 - \rho). \tag{5}$$

Here $\bar{D}p$ represents the number-average degree of polymerization or the average number of structural repeating units per polymer chain. The number-average molecular weight $\bar{M}_n$ is then obtained by multiplying $\bar{D}p$ by M_0, the repeating-unit molecular weight, and adding the molecular weight of the end groups.

In order for step-growth polymerization to yield a high–molecular-weight, linear polymer, high conversion must be attained. This requires nearly exact equivalency of reacting functional groups of the monomers and the absence of side reactions.

The Carothers equation can be modified for the presence of molecules N_1 with only single functionality (A or B):

$$\bar{D}p = \frac{1 + N_1/N_0}{1 + \rho + N_1/N_0}. \tag{6}$$

In A–A plus B–B polymerization, for molar ratios r of the reactant monomers less than 1, the degree of polymerization is given by

$$\bar{D}p = \frac{1 + \rho}{1 + \rho - 2r\rho}. \tag{7}$$

The extent of reaction or conversion is represented by ρ.

Equations (6) and (7) may be used to show the importance of stoichiometric balance and monomer purity in attaining high molecular weight. Organic reactions that can be utilized for step-growth polymers must proceed to virtually 100% yield of the desired linkages. It should be noted that controlled addition of monofunctional monomers or excess difunctional monomers is an effective method of controlling molecular weight. Often prepolymers for subsequent polymerization or cross linking are prepared in this manner.

The Carothers equation is also useful for predicting conversion at which gelation occurs for multifunctional monomers containing equivalent numbers of A and B groups:

$$\rho = 2/f_{\text{avg}} - 2/\bar{D}pf_{\text{avg}}. \tag{8}$$

The value of f_{avg} is calculated from

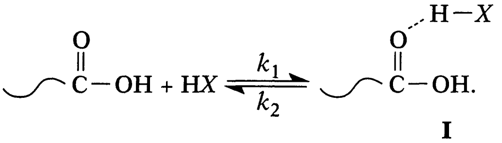
$$f_{\text{avg}} = \Sigma N_i f_i (\Sigma N_i)^{-1}, \tag{9}$$

where N_i is the number of molecules with reactive functionality. At the gel point, $\bar{D}p \rightarrow \infty$; Eq. (8) can be rewritten as

$$\rho_c = 2/f_{\text{avg}} \tag{10}$$

at the critical conversion ρ_c. Similar expressions have been derived for nonstoichiometric mixtures containing more than two monomers.

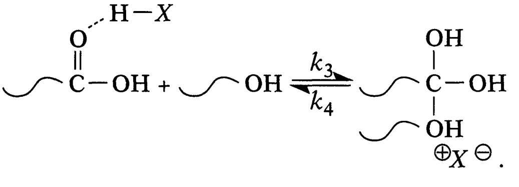
2.1.2 Kinetic Expressions Kinetic expressions for step-growth polymerization have been detailed in several reviews (Odian, 1991, Chap. 2; Manaresi and Munari, 1989; Elias, 1977, vol. 2, Chap. 17). Rates of step-growth polymerization can be easily followed by monitoring the concentrations of reacting functional groups. An example of the polycondensation of the A–A + B–B type involving a dicarboxylic acid and a diol is given below. For polymerization catalyzed by an added protic acid, HX, the reaction scheme involves first the equilibrium formation of complex I between one carboxylic acid of an A–A monomer with protic acid:



I

(11)

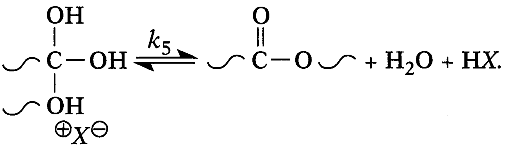
Complex I subsequently reacts with one of the alcohol functional groups on a B–B monomer via addition to the carboxyl carbon yielding II:



I II

(12)

In the final step, elimination of water with recovery of HX catalyst yields the ester:



$$\sim\overset{\displaystyle OH}{\underset{\underset{\displaystyle \oplus X\ominus}{\sim OH}}{C}}-OH \underset{}{\overset{k_5}{\rightleftharpoons}} \sim\overset{\displaystyle O}{\overset{\|}{C}}-O\sim + H_2O + HX.$$

II

(13)

The successive esterifications are equilibrium reactions. In order to obtain conversions necessary for high molecular weight, the equilibrium is shifted to the right by removal of water. Under these conditions, reactions (12) and (13) are considered to be irreversible. Generally formation of II is the rate-limiting step. Since k_1, k_2, and k_5 are large compared with k_3, an expression for the rate of polymerization, R_{po}, in terms of the rate of disappearance of the carboxylic acid groups is given by

$$R_{po} = \frac{-d[\sim COOH]}{dt} = k_3[I][\sim OH]. \tag{14}$$

Because the determination of the concentration of I experimentally is not easy, the usual approach is to express I in terms of the equilibrium expression

$$K = \frac{k_1}{k_2} = \frac{[I]}{[\sim COOH][HX]}; \tag{15}$$

rearrangement and substitution into Eq. (14) yields

$$\begin{aligned} R_{po} &= \frac{-d[\sim COOH]}{dt} \\ &= k_3K[\sim COOH][\sim OH][HX]. \end{aligned} \tag{16}$$

The value of K is dependent on the strength of the external acid under the solvation and temperature conditions of the polymerization. In polymerization starting with equimolar concentrations of [~COOH] and [~OH], the molar concentration of carboxylic acid groups at time t can be related to the original concentration, $[COOH]_0$, by the conversion; Eq. (16) after integration yields an expression for the degree of polymerization,

$$\bar{D}p = \frac{1}{1+\rho} = 1 + k_3[K][\sim COOH]_0 t. \tag{17}$$

In polymerization self-catalyzed by the carboxylic acid groups on the monomers, the rate of polymerization can be shown to yield

$$\begin{aligned} R_{po} &= \frac{-d[\sim COOH]}{dt} \\ &= k_3[\sim COOH]^2[\sim OH]. \end{aligned} \tag{18}$$

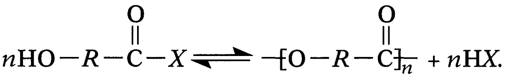
For equimolar concentrations of monomers, the degree of polymerization at time t is given by

$$\bar{D}p^2 = \frac{1}{(1+\rho)^2} = 1 + 2k_3[\sim COOH]_0^2 t. \tag{19}$$

Experimental observations of the kinetics of step-growth polymerization often deviate from those predicted by Eqs. (17) and (19). The nonlinearity has been attributed to changes in the polarity of the reaction medium. Early in the reaction, small molecular species account for the solvent conditions. As the reaction proceeds the number of functional (usually polar) groups decreases, resulting in a medium of lower dielectric constant. The solvent conditions would be expected to affect the potential energy of both the ground state and transition state, thus changing the activation energy. Other kinetic factors affecting the rate constant include collision frequency and orientation. These may change with conversion for particular step-polymerization reaction types.

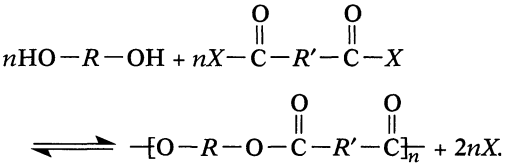
2.1.3 Examples of Linear Step-Growth Polymers In order for step-growth polymerizations to yield molecular weights >20 000, conversion must be high and stoichiometry must be maintained (Sec. 2.1.1). Despite an abundance of potential polymer-forming organic reactions, relatively few meet the criteria demanded by the Carothers relationship. Selected successful commercial routes are discussed below.

2.1.4 Polyesters Linear *polyesters* may be prepared by reactions of *A–B* monomers of the type HO–*R*–*X* in self-condensation reactions



$$n HO-R-\overset{\displaystyle O}{\overset{\|}{C}}-X \rightleftharpoons -\!\!\!\!\left[O-R-\overset{\displaystyle O}{\overset{\|}{C}}\right]_n\!\!\!\!- + nHX. \tag{20}$$

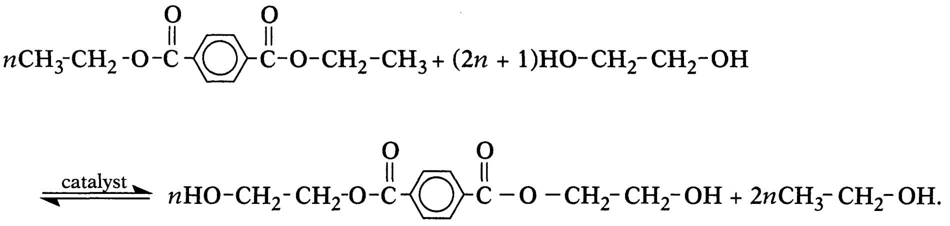
Likewise difunctional alcohols (*A–A* type monomers) may be reacted with difunctional diacyl monomers (*B–B* type) as shown in



$$n\mathrm{HO}-R-\mathrm{OH}+nX-\overset{\overset{\mathrm{O}}{\|}}{\mathrm{C}}-R'-\overset{\overset{\mathrm{O}}{\|}}{\mathrm{C}}-X \rightleftharpoons -\!\!\!\left[\mathrm{O}-R-\mathrm{O}-\overset{\overset{\mathrm{O}}{\|}}{\mathrm{C}}-R'-\overset{\overset{\mathrm{O}}{\|}}{\mathrm{C}}\right]_n + 2nX. \qquad (21)$$

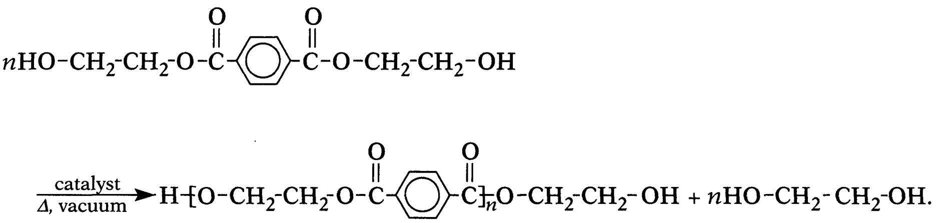
In both of the above examples, $-\overset{\overset{\mathrm{O}}{\|}}{\mathrm{C}}-X$ may be a carboxylic acid, anhydride, acid chloride, amide, ester, or other derivative in which *X* is a good leaving group. The terms *R* and *R'* are general representations of alkyl or aromatic groups.

A widely used method for preparation of polyesters is an *interchange reaction. Ester interchange* is shown below for the preparation of poly(ethyleneterephthalate). The preformed diethylester of terephthalic acid is reacted with diethylene glycol to yield the ester:



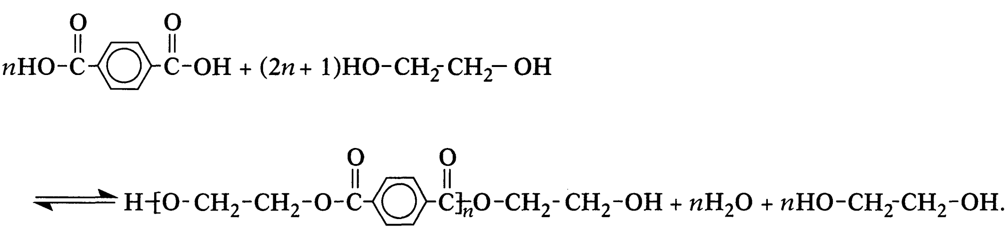
(22)

A transesterification catalyst (usually a proton donor, metallic ion, or weak base) is utilized and the equilibrium is shifted to the right by removal of ethanol. The ester-interchange intermediate is then polymerized to poly(ethyleneterephthalate) utilizing a catalyst (often a transition-metal complex) under reduced pressure:



(23)

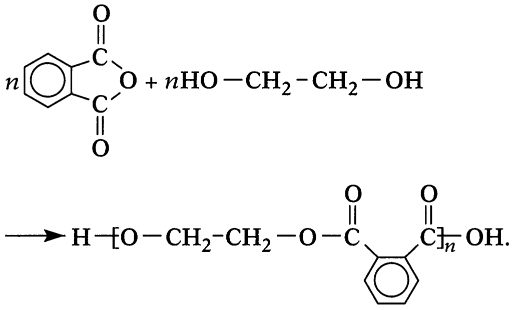
Alternatively, *direct esterification* of terephthalic acid with ethylene glycol can be accomplished to yield the polyester:



(24)

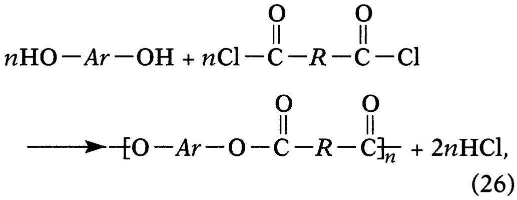
Often an excess of ethylene glycol is used to increase the rate of the initial esterification of the diacid. The excess ethylene glycol also allows conversion of any carboxyl end groups to esters, which are less likely to catalyze unwanted side reactions during processing. Unreacted ethylene glycol is removed during the final stages of polymerization under reduced pressure.

Phthalic anhydride may be reacted with ethylene glycol to produce poly(ethylene-orthophthalate):



(25)

A final example of esterification is that of a diol reacting with a diacid chloride via the Schotten–Baumann reaction,

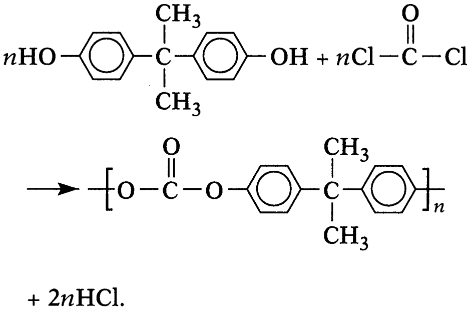


$$n\mathrm{HO}-Ar-\mathrm{OH}+n\mathrm{Cl}-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-R-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-\mathrm{Cl} \longrightarrow -[\mathrm{O}-Ar-\mathrm{O}-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-R-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}]_n- + 2n\mathrm{HCl},$$

(26)

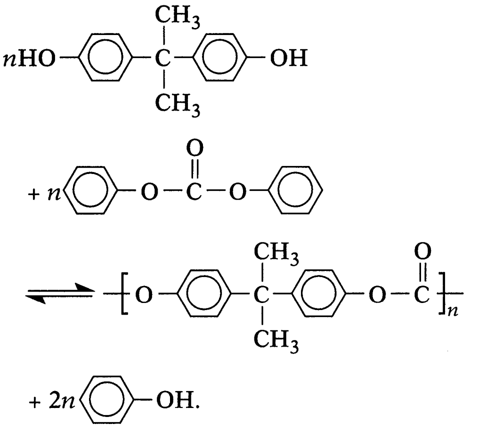
where *Ar* denotes an aromatic group. This interfacial polymerization procedure is often used with aromatic diols and is particularly facile at an interface between an aqueous alkaline solution of the aromatic diol and an immiscible organic solution of the diacid chloride. Alternatively, an amine is added as an acid receptor.

2.1.5 Polycarbonates Interfacial polymerization is also used to produce *polycarbonates* such as bisphenol A polycarbonate:



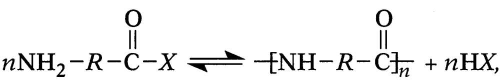
(27)

An alternative method to the above polycarbonate preparation involves the interchange reaction of the aromatic diol with diphenylcarbonate:



(28)

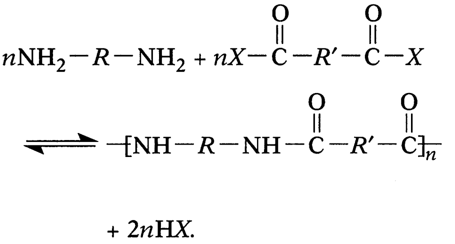
2.1.6 Polyamides *Polyamides* can be prepared by reactions of *A–B* monomers,



$$n\mathrm{NH}_2-R-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-X \rightleftharpoons -[\mathrm{NH}-R-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}]_n- + n\mathrm{H}X,$$

(29)

or *A–A* + *B–B* monomer pairs,

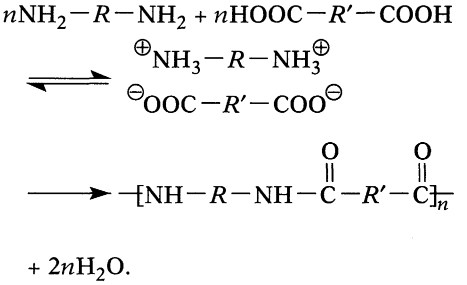


$$n\mathrm{NH}_2-R-\mathrm{NH}_2+nX-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-R'-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-X \rightleftharpoons -[\mathrm{NH}-R-\mathrm{NH}-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-R'-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}]_n- + 2n\mathrm{H}X.$$

(30)

The nature of *R* and *R′* can be varied and, as with polyesterification reactions, *X* should be a good leaving group.

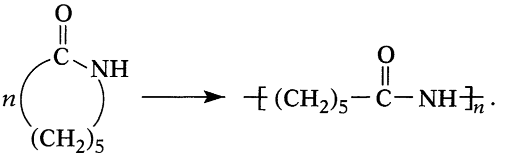
Direct amidation is often useful in preparing polyamides. An advantage of this method is that reaction of a diabasic acid and a diamine allows isolation of a diammonium salt prior to polymerization. The exact stoichiometry and high yields on subsequent heating under reduced pressure meet the requirement of the Carothers equations for obtaining reasonable molecular weights. Nylon 6,6 is prepared in this manner by reacting hexamethylene diamine with adipic acid:



$$nNH_2-R-NH_2 + nHOOC-R'-COOH \rightleftharpoons \begin{matrix} {}^{\oplus}NH_3-R-NH_3^{\oplus} \\ {}^{\ominus}OOC-R'-COO^{\ominus} \end{matrix} \longrightarrow -\!\!\left[NH-R-NH-\overset{\overset{O}{\|}}{C}-R'-\overset{\overset{O}{\|}}{C}\right]_n + 2nH_2O.$$

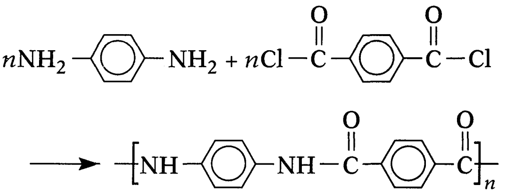
(31)

Nylon-6, polyamide, is commercially prepared by the combination of *ring opening/transamidation* reaction of the cyclic lactam monomer, caprolactam:



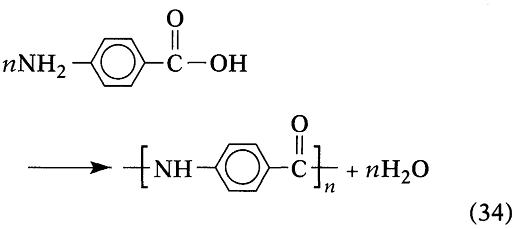
(32)

Aramids or aromatic polyamides are prepared by reacting aromatic diamines with aromatic diacids or diacid chlorides (*A–A* + *B–B* type). Alternatively an *A–B* type monomer can be polymerized. The respective reactions are



(33)

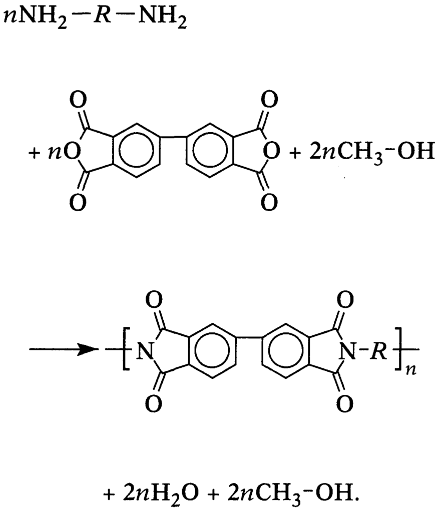
and



(34)

for synthesis of poly(imino-1,4-phenyleneiminoterephthaloyl) and poly(iminocarbonyl-1,4-phenylene)—both sold under the trade name Kevlar® (Odian, 1991, p. 105).

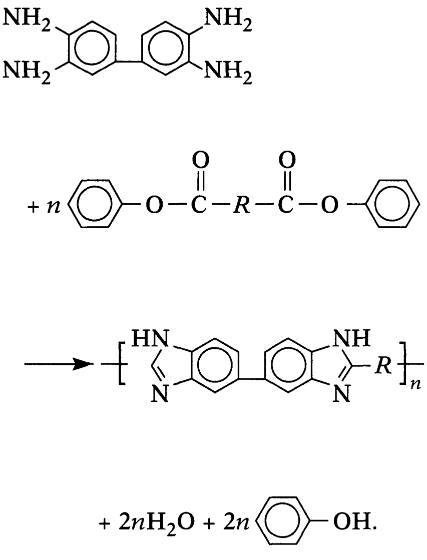
2.1.7 Polyimides and Polybenzimidazoles *Polyimides* are formed by the reaction of aliphatic or aromatic diamines with a dianhydride,



(35)

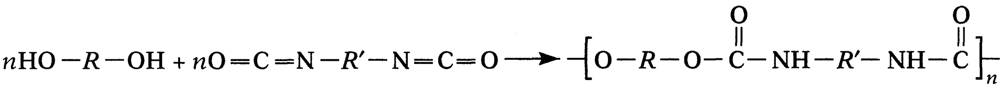
The reaction is usually carried out in a stepwise fashion to produce a polyamic acid intermediate prior to imidization.

Polybenzimidazoles are also heterocyclic polymers with high temperature stability. These are found by reactions of tetramines with diacyl monomers:



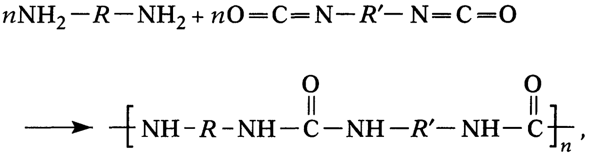
(36)

2.1.8 Polyurethanes and Polyurea *Polyurethanes* and *polyureas* are prepared from *A–A* and *B–B* monomer pairs in which a diisocyanate is added to a diol,



$$n\mathrm{HO{-}}R\mathrm{{-}OH} + n\mathrm{O{=}C{=}N{-}}R'\mathrm{{-}N{=}C{=}O} \longrightarrow \left[\mathrm{O{-}}R\mathrm{{-}O{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{{-}NH{-}}R'\mathrm{{-}NH{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\right]_n, \tag{37}$$

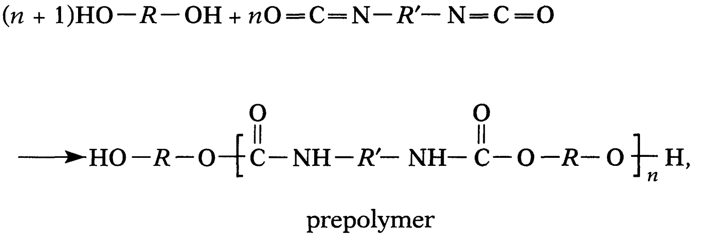
or diamine



$$n\mathrm{NH_2{-}}R\mathrm{{-}NH_2} + n\mathrm{O{=}C{=}N{-}}R'\mathrm{{-}N{=}C{=}O} \longrightarrow \left[\mathrm{NH{-}}R\mathrm{{-}NH{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{{-}NH{-}}R'\mathrm{{-}NH{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\right]_n, \tag{38}$$

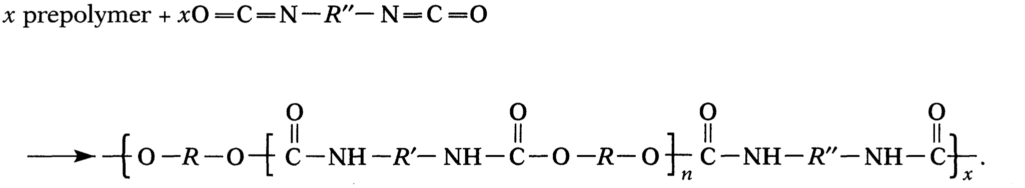
respectively. Linear high-molecular-weight polymers are formed readily by maintaining a stoichiometric balance with the reacting monomers. The reactivity of the diisocyanate groups allows the reactions to proceed at moderate temperatures.

Polyurethane and polyurea prepolymers are often prepared for subsequent chain extensions in which *multiblock* copolymers are desired. The Carothers equation can be used to predict stoichiometry necessary to form a prepolymer, with end groups,



$$(n+1)\mathrm{HO{-}}R\mathrm{{-}OH} + n\mathrm{O{=}C{=}N{-}}R'\mathrm{{-}N{=}C{=}O} \longrightarrow \underset{\text{prepolymer}}{\mathrm{HO{-}}R\mathrm{{-}O}\left[\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{{-}NH{-}}R'\mathrm{{-}NH{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{{-}O{-}}R\mathrm{{-}O}\right]_n\mathrm{H}}, \tag{39}$$

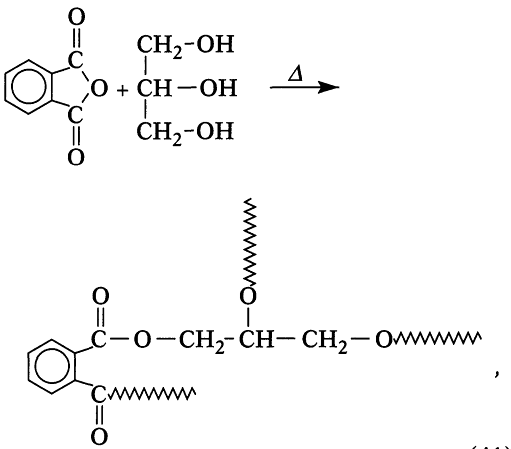
which can subsequently be reacted with a second diisocyanate to form the copolymer,



$$x\ \text{prepolymer} + x\mathrm{O{=}C{=}N{-}}R''\mathrm{{-}N{=}C{=}O} \longrightarrow \left[\mathrm{O{-}}R\mathrm{{-}O}\left[\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{{-}NH{-}}R'\mathrm{{-}NH{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{{-}O{-}}R\mathrm{{-}O}\right]_n\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{{-}NH{-}}R''\mathrm{{-}NH{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\right]_x. \tag{40}$$

2.1.9 Network Polymers As discussed previously, introduction of multiple functional groups (>2) onto reactive monomers can result in network formation. The Carothers equation can be utilized to estimate the conversion necessary for this to occur; thus somewhat controlled network formation is possible with many of the step-growth reactions discussed previously. For example, polyurethane and polyurea networks can be easily formed by reacting multifunctional diols or diamines with diisocyanates. Alternatively, excess diisocyanate may be added to the linear polymers, which can react at elevated temperature with the active hydrogen atoms of the urethane or urea groups to form cross links.

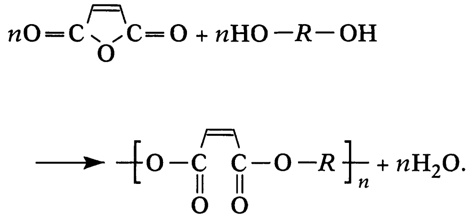
Another convenient way to control network formation is to introduce functional groups that are less reactive than those participating in the initial polymer-forming reaction. Subsequent reaction (for example, heating with additional comonomer to a higher temperature) results in network formation. Reactions of this type, illustrated by



(41)

are important in technologies (plastics, coatings, elastomers) in which liquid prepolymers are converted to cross-linked materials with outstanding physical properties.

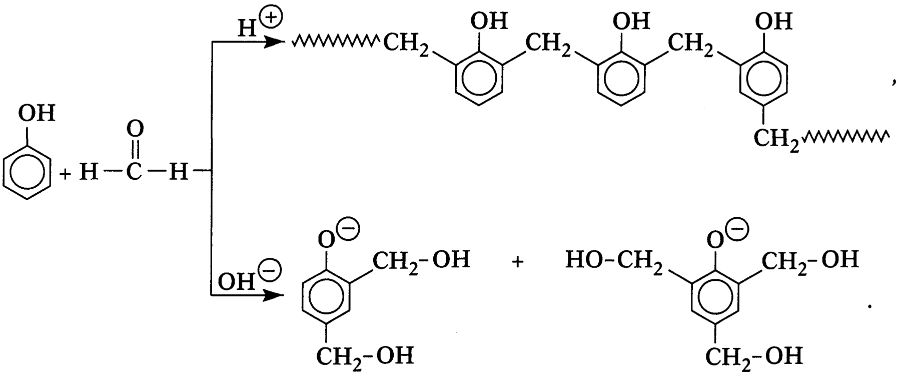
Unsaturated polyesters, polyamides, polyurethanes, etc., can be prepared by incorporating monomers containing double bonds:



(42)

The double bonds can then serve as reactive sites for ionic or free-radical addition resulting in network formation.

Some of the earliest network polymers were prepared in the early 1900s by Leo Baekeland. The Bakelite® polymers were condensation products of the reactions of phenol with formaldehyde:

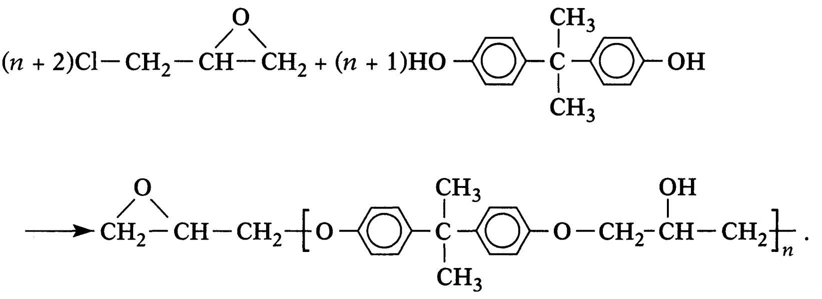


(43a)

(43b)

Under acidic conditions, (43a), "novolak" resins are formed by electrophilic aromatic substitution of methyloyl groups onto phenol; under basic conditions (43b), "resoles" are formed by nucleophilic attack of the ortho phenolate carboanion onto formaldehyde. The novolak resins have no residual $-CH_2-OH$ groups and cannot cross link without additional reagents. However, the resoles can undergo facile cross linking on heating. Cross-linked resins are also obtained by reactions of formaldehyde with urea or melamine through a series of methyloyl condensation reactions.

A final example of a cross-linkable resin formed by step-growth polymerization is that of an *epoxy* resin. An excess of the epoxide, epichlorohydrin, is reacted with bisphenol A,



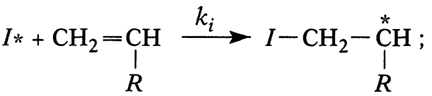
(44)

Multifunctional acyl compounds may be used to cross link the residual -OH groups in the repeating sequence. Alternatively, the epoxide end groups can be reacted with difunctional amines or alcohols. The properties of epoxy cross-linked materials vary over a wide range depending on copolymer composition and cross-link density. Current uses include adhesives, coatings, and matrix resins for high-performance composites.

2.2 Chain-Growth Polymerization

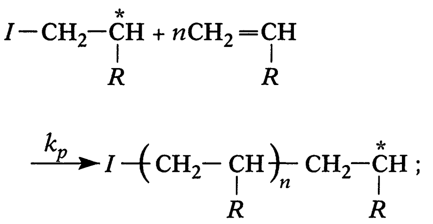
In contrast to step-growth polymerization, chain-growth polymerization proceeds in a rapid manner in which the *initiated* species continues to add monomer or *propagate* until *termination* occurs. Thus control of three essential steps—initiation, termination, and propagation—as well as possible competing reactions is vital for chain growth to proceed to high molecular weight. In the sections to follow, major types of chain-growth polymerization initiated by free-radical, anionic, cationic, and coordinated species will be examined. The general scheme for an alkene with a functional group R is given by initiation,

$$I \xrightarrow{k_d} I*, \tag{45}$$



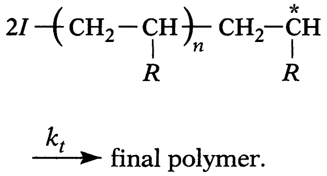
$$I* + CH_2{=}\underset{R}{CH} \xrightarrow{k_i} I{-}CH_2{-}\overset{*}{\underset{R}{CH}}\,; \tag{46}$$

propagation,



$$I{-}CH_2{-}\overset{*}{\underset{R}{CH}} + nCH_2{=}\underset{R}{CH} \xrightarrow{k_p} I\left(CH_2{-}\underset{R}{CH}\right)_n CH_2{-}\overset{*}{\underset{R}{CH}}\,; \tag{47}$$

and termination,



$$2I\left(CH_2{-}\underset{R}{CH}\right)_n CH_2{-}\overset{*}{\underset{R}{CH}} \xrightarrow{k_t} \text{final polymer.} \tag{48}$$

An initiator species (anionic, cationic, free radical, or coordinated) is formed in the first step with rate constant k_d. The second step of the initiation involves addition (in this case to a double bond) of the monomer. Subsequent monomer additions to the propagating chain continue with addition of n molecules of monomer until termination occurs. The respective rate constants for the second and third steps are k_p and k_t.

Successful polymerization by the pathway shown by Eqs. (45)–(48) requires careful consideration of initiator, monomer, and reaction variables.

The nature of the R group is important in selecting the proper type of initiator for the monomer. For the propagation step, the rate is given by

$$R_p = k_p[M*][M], \tag{49}$$

in which $M*$ represents the propagating species and M the monomer. The rate is therefore dependent upon the concentrations of the propagating species and the monomers as well as the magnitude of k_p. From the Arrhenius equation

$$k_p = A_p \exp(-E_p/R_gT), \qquad (50)$$

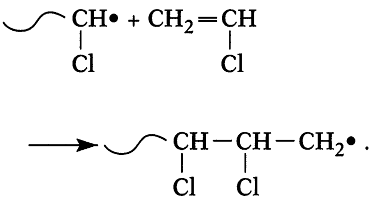
it is evident that k_p will be dependent upon the activation energy E_p for propagation, the reaction temperature T, and the pre-exponential term A_p, which includes collision frequency and orientation effects. Activation-energy values are largely determined by the nature of the R group on the unsaturated monomer, $\mathrm{CH_2{=}}\underset{R}{\mathrm{CH}}$, and reactivity of the propagating species, $\sim\mathrm{CH_2{-}}\underset{R}{\overset{*}{\mathrm{CH}}}$. Electronic and steric effects on the relative potential energy of the ground state and activated complex in transition state dictate the magnitude of the activation energy. Those factors increasing reactivity of the ground-state reagents and lowering the potential energy of the transition state lower E_p and increase the rate of the reaction.

For the above reasons, monomers with electron-donating R groups generally polymerize by cationic or coordinated cationic mechanisms. Monomers with electron-withdrawing substituents polymerize by anionic or coordinated anionic mechanisms. In the above cases, the transition states develop late in the reaction and predictions are easy. Those groups that stabilize the developing carbocation or carbanion lower ΔE_p. However, in free-radical reactions, radical character can be developed early or late along the reaction pathway. Both the potential energy of the ground-state reactants and that of the activated complex in the transition state must be assessed in order to predict reactivity.

In anionic or cationic polymerization, the concentration of the propagating species is on the order of 10^{-3} to 10^{-5} molar as compared with 10^{-7} to 10^{-9} for free-radical polymerization. The reactions are exothermic and are often carried out at low temperatures. The advantages of enhanced rates and stereocontrol inherent with ionic polymerizations are often negated by the strict requirements of avoiding termination by contaminants such as water or other acids and bases.

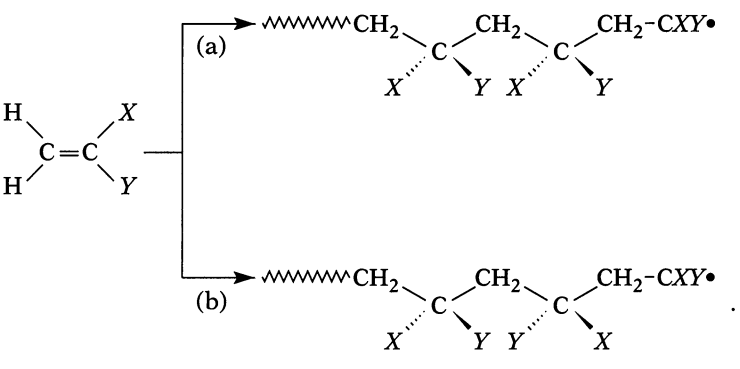
2.2.1 Structural Features A virtually limitless number of monomers are available for chain-growth polymerization. A number of important commercial polymers and some typical properties are given in Table 2.

In addition to repeating structures that normally arrange in a head-to-tail fashion, mono-substituted alkenes may add in a head-to-head fashion:



$$\sim\underset{\mathrm{Cl}}{\mathrm{CH}\bullet} + \mathrm{CH_2{=}}\underset{\mathrm{Cl}}{\mathrm{CH}} \longrightarrow \sim\underset{\mathrm{Cl}}{\mathrm{CH}}{-}\underset{\mathrm{Cl}}{\mathrm{CH}}{-}\mathrm{CH_2\bullet}. \qquad (51)$$

Steric factors in the transition state or complexation of chain ends with monomer and counterions in ionic polymerizations can yield stereoregular isotactic, (52a), or syndiotactic, (52b), segments as differentiated by the configurations along the polymer backbone:



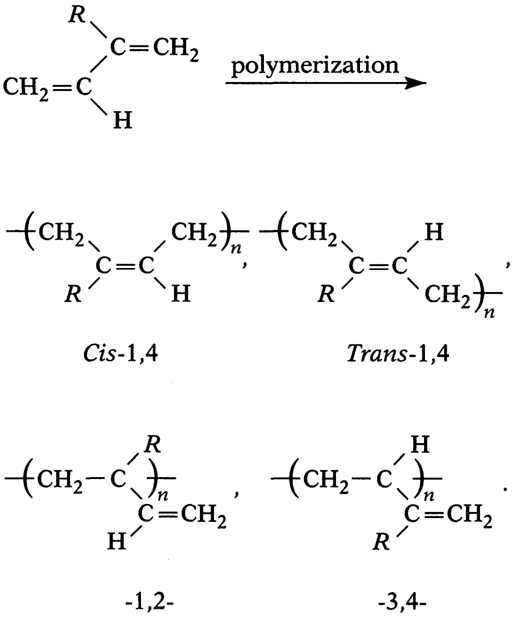
(52a)

(52b)

Table 2. Representative chain-growth polymers.

Name	Repeating unit	Properties
Poly(acrylamide)	 $-\!\left(CH_2-\underset{\underset{NH_2}{\overset{\vert}{C=O}}}{\overset{}{\underset{\vert}{CH}}}\right)_{n}\!-$	Water soluble, viscosifier
Poly(acrylonitrile)	 $-\!\left(CH_2-\underset{C\equiv N}{\underset{\vert}{CH}}\right)_{n}\!-$	High strength, tough, chemical resistant
Poly(vinyl acetate)	 $-\!\left(CH_2-\underset{\underset{\underset{CH_3}{\overset{\vert}{C=O}}}{\overset{\vert}{O}}}{\underset{\vert}{CH}}\right)_{n}\!-$	Film former, adhesive
Poly(vinyl chloride)	 $-\!\left(CH_2-\underset{Cl}{\underset{\vert}{CH}}\right)_{n}\!-$	Chemical, moisture resistant, UV unstable
Poly(tetrafluoroethylene)	$-\!\left(CF_2-CF_2\right)_{n}\!-$	Chemically inert, low friction properties, low surface energy
Poly(ethylene)	$-\!\left(CH_2-CH_2\right)_{n}\!-$	Transparent, flexible, film former, good electrical properties
Poly(propylene)	 $-\!\left(CH_2-\underset{CH_3}{\underset{\vert}{CH}}\right)_{n}\!-$	High strength, hard, high softening point, chemical, moisture resistant
Poly(isoprene)		Elastomeric, properties of natural rubber
Poly(styrene)		Clear, moderate glass transition temperature
Poly(methyl methacrylate)	 $-\!\left(CH_2-\overset{CH_3}{\overset{\vert}{\underset{\underset{\underset{CH_3}{\overset{\vert}{O}}}{\overset{\vert}{C=O}}}{\underset{\vert}{C}}}}\right)_{n}\!-$	Clear, good impact strength, mechanical properties

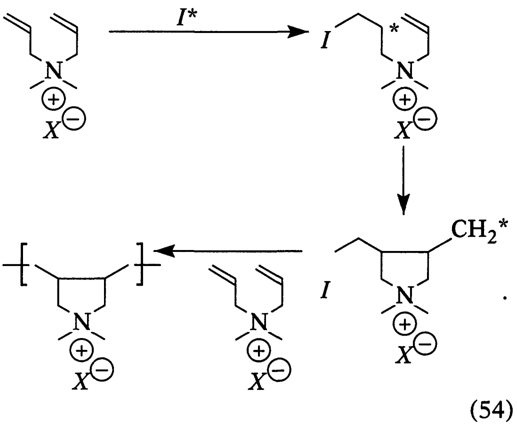
Atactic polymers are those with randomly placed units of both along the backbone. Dienes can polymerize through the 1,2 or 1,4 positions to yield polymers with isomeric repeating units,



(53)

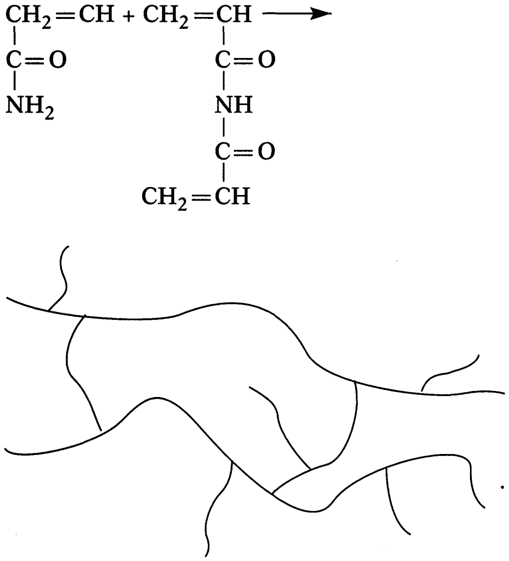
Not only can *cis* and *trans* isomers be prepared; tactic structures can result by changing appropriate polymerization conditions.

In the late 1950s, Butler first reported cyclopolymerization of nonconjugated dienes to give non–cross-linked polymer structures. The mechanism has been shown subsequently (Butler, 1989) to occur by an alternating intra-intermolecular propagation,



(54)

Cross-linked or network polymers can be formed by chain-growth polymerization of nonconjugated monomers provided the reactivity of the double bonds is sufficient. For example, hydrogel polymers are prepared by action of acrylamide with varying amounts of bisacrylamide,



(55)

2.2.2 Kinetics of Radical Chain Polymerization Initiation in free-radical polymerization takes place in two steps. In the first, an initiating radical $I\bullet$ is formed (usually from thermal or photochemical decomposition). The initiator choice (Table 3) is extremely important for rate of reaction and molecular-weight distribution.

The rate constants for propagation for free-radical chain-growth polymerizations can be easily determined knowing the rate of disappearance of monomer, $-d[M]/dt$, the original concentration of monomer, M, and the concentration of radicals $[M\bullet]$, utilizing

$$\frac{-d[M]}{dt} = k_p[M\bullet][M]. \tag{56}$$

Unfortunately the concentration of radicals, $[M\bullet]$, is not easily obtained since it is usually 10^{-7} to 10^{-9} mol/L. An alternative approach utilizes the *steady-state* assumption discussed subsequently in this section.

In most polymerizations, the second step of the initiation is much faster than the first,

Table 3. Initiators and reaction parameters for free-radical polymerization (data from Brandrup and Immergut, 1975).

Initiator	Solvent	Temp. (°C)	K_d (s^{-1})	E ($kcal \cdot mol^{-1}$)
2,2′-azo-bis-isobutyronitrile (AIBN)	Benzene	40	5.4×10^{-7}	30.7
Phenyl-azo-triphenylmethane	Benzene	80	4.3×10^{-6}	26.8
tert-butyl-peroxide (TBP)	Benzene	80	7.8×10^{-8}	34.0
Cumyl peroxide	Benzene	115	1.6×10^{-5}	40.7
Acetyl peroxide	Benzene	35	9.5×10^{-5}	32.3
Benzoyl peroxide	Benzene	30	2.6×10^{-8}	30.4
Lauroyl peroxide	Benzene	30	2.6×10^{-7}	30.4
tert-butyl hydroperoxide	Benzene	154	4.3×10^{-6}	40.8
tert-butyl perbenzoate	Benzene	100	1.1×10^{-5}	34.7

and since two initiator fragments are formed, the rate of initiation is given by

$$R_i = 2fk_d[I_2], \tag{57}$$

in which $[I_2]$ represents the initiator concentration. The factor f is included to indicate the efficiency of initiation. It should be noted that the larger the number of chains initiated, the lower the molecular weight; the closer in time all chains start, the narrower the molecular-weight distribution.

In the propagation step, the free radical generated in the second step of the initiation reacts with monomer. During propagation, chain length grows as monomer is added. The reactivity of the growing radical chain is related to those factors previously discussed. For example, if monomer M is represented by $CH_2{=}CHR$, the nature of the substituent in regard to steric, polar, and resonance effects in both the ground state and the transition state is important. In the simplest case, the length of the growing chain is usually assumed to be unimportant for each successive step,

$$M\bullet + nM \xrightarrow{k_p} M(M)_{n-1}M\bullet \tag{58}$$

Under such conditions, the rate expression is given by

$$R_p = \frac{-d[M]}{dt} = k_p[M\bullet][M]. \tag{59}$$

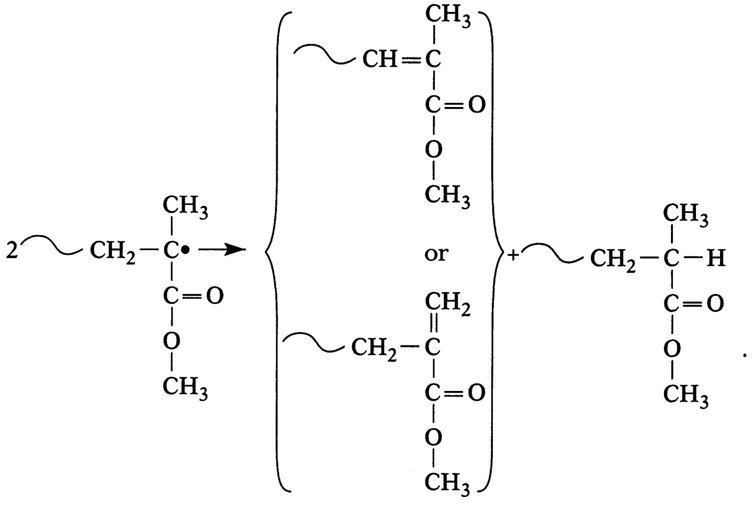
Two common ways that free radicals terminate are by *combination,*

$$M_n\bullet + M_m\bullet \xrightarrow{k_{tc}} M_n - M_m, \tag{60}$$

and *disproportionation,*

$$M_n\bullet + M_m \xrightarrow{k_{td}} M_n(\mathrm{H}) + M_m(-\mathrm{H}). \tag{61}$$

The rate constants for those processes are k_{tc} and k_{td} respectively. Those monomers possessing abstractable hydrogens on carbons located in the β position relative to the propagating radical are prone to disproportionation during polymerization. This process is illustrated for termination of methyl methacrylate, which possesses five abstractable hydrogens:



(62)

The mechanism for termination for many polymers may be a combination of both reactions (60) and (61); therefore a rate expression may be written as

$$R_t = k_{tc}[M_n\bullet][M_m\bullet] + k_{td}[M_n\bullet][M_m\bullet]. \tag{63}$$

Since $[M\bullet]$ is often difficult to measure, a simple assumption is made based on the production, after an initial induction period, of a constant concentration or "steady state" of radicals. In such cases, the rate of change of radical with time is given by

$$\frac{-d[M\bullet]}{dt} = 0. \tag{64}$$

The rate of termination should be equal to the rate of initiation,

$$R_i = R_t. \tag{65}$$

Therefore, rearrangement of

$$R_i = 2k_t[M\bullet]^2 \tag{66}$$

and solving for $[M\bullet]$ yields

$$[M\bullet] = (R_i/2k_t)^{1/2}. \tag{67}$$

Substituting into the propagation expression

$$R_p = k_p[M\bullet][M] \tag{68}$$

yields

$$R_p = k_p(R_i/2k_t)^{1/2}[M]. \tag{69}$$

Substitution of Eq. (57) for R_i yields

$$R_p = k_p[M](k_d f[I_2]/k_t)^{1/2}, \tag{70}$$

in which the constants can be combined,

$$k' = (k_p^2 k_d f/k_t)^{1/2}, \tag{71}$$

to yield the final expression for the rate of polymerization,

$$R_p = k'[M][I_2]^{1/2}. \tag{72}$$

2.2.3 Kinetic Chain Length and Degree of Polymerization The kinetic chain length, ν, in a free-radical polymerization is the number of monomers consumed per effective initiator radical and is equal to R_p/R_i as given by

$$\nu = \frac{k_p[M]}{2(k_d k_t f[I_2])^{1/2}}. \tag{73}$$

Combining constants,

$$k'' = \frac{k_p}{2(k_d k_t f[I_2])^{1/2}}, \tag{74}$$

and substituting into Eq. (73) yields the simple expression

$$\nu = k''[M]/[I_2]^{1/2}. \tag{75}$$

The degree of polymerization is then equal to 2ν for combination and ν for disproportionation.

Chain-transfer reactions involve abstraction of a labile hydrogen or halogen atom by the propagating radical:

$$\sim\!\bullet + R{-}H \longrightarrow \sim\!H + R\bullet. \tag{76}$$

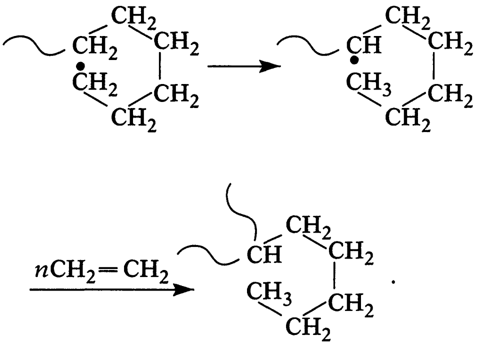
The abstraction may occur on initiator, solvent, monomer, or polymer. Hydrogens or halogens with low bond-dissociation energies (i.e., those on benzylic or allylic carbons) are most likely candidates for abstraction.

Since chain transfer competes with propagation, the considerations discussed previously are also important here. For example if the activation energy for addition is similar to that of chain transfer to monomer, the degree of polymerization should be low and the molecular-weight distribution wide. The expression for the degree of polymerization is given, in terms of transfer to monomer, solvent, initiator, and polymer, by

$$\bar{D}p = R_p\{(R_t/2) + k_{\mathrm{tr},M}[M\bullet][M] + k_{\mathrm{tr},S}[M\bullet][S] + k_{\mathrm{tr},I}[M\bullet][I_2] + k_{\mathrm{tr},P}[M\bullet][P]\}^{-1}. \tag{77}$$

After chain transfer, the new radical formed may then add monomer. When the rate of propagation does not change, this is termed "effective" chain transfer. If the rate is slowed, the term "degradative" chain transfer is used. In some cases, the reaction is stopped. In fact, retarders or inhibitors are often added to control chain length or to stabilize monomers during shipment and storage. Inhibitors include quinones, nitro aromatics, phenols, and aromatic amines. Note that these compounds provide stable radicals upon addition or abstraction that are of too low potential energy to add to monomer.

Intramolecular chain transfer along the polymer chain may occur especially at latter stages of the reaction. Such transfer results in branches:



(78)

Equation (77) can be simplified by substituting expressions for R_p and R_t and combining constants. The reciprocal expression

$$\frac{1}{\bar{D}p} = \frac{1}{\bar{D}p_0} + C_m + C_s\frac{[S]}{[M]} + C_I\frac{[I]}{[M]} + C_p\frac{[P]}{[M]} \tag{79}$$

is convenient for expressing the extent of transfer in terms of chain-transfer constants to solvent, monomer, initiator, and polymer. The expression $1/\bar{D}p_0$ represents polymerization in the absence of transfer reactions and is the same as R_p/R_i. In theory, the above expression can be used to determine the magnitudes of the transfer constants

$$C_m = k_{\mathrm{tr},m}, \quad C_s = k_{\mathrm{tr},S}/k_p, \quad C_I = k_{\mathrm{tr},I}/k_p, \quad C_p = k_{\mathrm{tr},p}/k_p. \tag{80}$$

Values of chain-transfer constants for a number of polymerization reactions are compiled in Brandrup and Immergut (1975).

2.2.4 Free-Radical Polymerization Techniques Polymerization techniques for free radicals are varied and can range from those conducted under homogeneous conditions to specialized microheterogeneous polymerization. Major techniques are briefly discussed below.

In *bulk* polymerization, the monomer serves as the solvent and initiator is added. While simpler than solution polymerization in that regard, heat-transfer problems may occur or polymer solubility may diminish at a high conversion. Gel-like structures often give processing problems. In *solution* polymerization, the monomer and initiator are dissolved in a common solvent. The solvent serves as a heat sink, but isolation of polymer requires solvent removal. The techniques for *suspension* polymerization require dispersion of the monomer in an organic or water medium. Polymerization occurs in suspended droplets. An advantage of this method is that heat is dissipated and polymer is easily isolated. Suspension stability during reaction is sometimes difficult for certain monomers.

In a classical *emulsion* system, a hydrophobic monomer, a water-soluble initiator, an emulsifier, water, and stabilizers are added. Polymerization occurs in micelles. Under optimum conditions, high molecular weights may be obtained at high rates with relative ease of handling. The kinetics of the polymerization are quite different from bulk or solution polymerization. *Inverse-emulsion* techniques can be utilized with water-soluble monomers, a hydrocarbon or nonpolar solvent, and appropriate initiators. Although some systems behave as emulsion polymerizations, often the mechanism is actually that of an inverse-suspension polymerization. Both techniques have the advantage of producing water-soluble polymers, which can be easily handled.

Special cases of polymerization not discussed here are gas-phase polymerization and polymerization of monomers trapped in a continuous phase to yield compositelike structures.

2.2.5 Free-Radical Copolymerization

At the beginning of Sec. 2.2, the factors affecting the rate of homopolymerization were discussed. In copolymerization, these factors are important in determining the rates as well as microstructural compositions of the resulting copolymers. A useful approach to copolymerization is to consider two monomers M_1 and M_2 whose propagating chain ends are represented by M_1* and M_2* respectively. If reactivity of the propagating species is assumed to be dependent only on the chain end, four propagation reactions with their respective rates can be represented by

$$M_1* + M_1 \xrightarrow{k_{11}} M_1*, \tag{81}$$

$$M_1* + M_2 \xrightarrow{k_{12}} M_2*, \tag{82}$$

$$M_2* + M_1 \xrightarrow{k_{21}} M_1*, \tag{83}$$

$$M_2* + M_2 \xrightarrow{k_{22}} M_2*. \tag{84}$$

The rates of disappearance of the two monomers are given by

$$\frac{-d[M_1]}{dt} = k_{11}[M_1*][M_1] + k_{21}[M_2*][M_1] \tag{85}$$

and

$$\frac{-d[M_2]}{dt} = k_{12}[M_1*][M_2] + k_{22}[M_2*][M_2]. \tag{86}$$

The ratio of the rates of incorporation of the two monomers in the chain is obtained by dividing Eq. (85) by Eq. (86) to yield

$$\frac{d[M_1]}{d[M_2]} = \frac{k_{11}[M_1*][M_1] + k_{21}[M_2*][M_1]}{k_{12}[M_1*][M_2] + k_{22}[M_2*][M_2]}. \tag{87}$$

By assuming a steady-state concentration for each reactive species,

$$k_{21}[M_2*][M_1] = k_{12}[M_1*][M_2], \tag{88}$$

appropriate rearrangement and substitution into Eq. (87), and defining *reactivity ratios* $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$, one can obtain the *copolymerization equation*

$$\frac{d[M_1]}{d[M_2]} = \frac{1 + r_1([M_1]/[M_2])}{1 + r_2([M_2]/[M_1])}. \tag{89}$$

The relative values of r_1 and r_2 are exceptionally important since they represent the propensity of the respective monomers for self addition vs cross addition.

Although there are many cases where the assumptions used to derive Eq. (89) are inappropriate, the copolymerization equation for chain-growth processes is a useful tool for predicting *instantaneous* copolymer compositions. Reactivity ratios for common comonomer pairs are given in Table 4 as compiled in Brandrup and Immergut (1975). Detailed kinetic expressions for co- and terpolymerization are reviewed elsewhere (Odian, 1991, Chap. 6).

Most copolymerizations proceed in a manner in which the relative concentrations of the reacting monomers change with the reaction time. Only at specified azeotropic compositions is composition constant with time.

Table 4. Reactivity ratios for common monomer pairs (adapted by Seymour and Carraher, 1981, from Brandrup and Immergut, 1975).

M_1	M_2	r_1	r_2	r_1r_2
Acrylamide	Acrylic acid	1.38	0.36	0.5

N-Vinylpyrrolidone	Styrene (50 °C)	0.045	15.7	0.71

Values of r_1 and r_2 yield insight into the nature of the copolymer formed. When r_1 and r_2 are both equal to 1, the propagating radical has no preference for either monomer. A totally random copolymer is formed. Little compositional drift occurs with conversion. When the product r_1r_2 equals 1 but r_1 and r_2 differ, a random copolymer is formed. Drift worsens with divergence of the values of r_1 and r_2. When r_1r_2 is equal to zero, an alternating copolymer results. True alternation occurs when monomers copolymerize in pairs due to ground-state or transition-state complexes. When $r_1 > 1$ and $r_2 \ll 1$, monomer one is consumed almost exclusively, and thus a homopolymer is formed. When both r_1 and r_2 are $\gg 1$, two homopolymers would form.

Alfrey and Price (see Alfrey *et al.*, 1952) proposed and later refined what is known as a *Q*,*e* scheme to predict reactivity ratios from electronic considerations. In the scheme, reactivities (polar and resonance effects) of the monomers and propagating radicals are evaluated empirically and given values *Q* and *P* respectively. The polar properties of both monomers and radicals are given *e* values based on ground-state interactions. The terms Q_1 and Q_2 are related to reactivity, and e_1 and e_2 are related to polarity of M_1 and M_2, respectively. Styrene was given standard values of $Q = 1.0$ and $e = -0.80$. Experimental reactivity ratios were then used to determine Q and e values for the other monomers. The reactivity ratios are related to Q and e according to

$$k_{11} = P_1 Q_1 \exp(-e_1^2), \tag{90}$$

$$k_{12} = P_1 Q_2 \exp(-e_1 e_2), \tag{91}$$

$$k_{22} = P_2 Q_2 \exp(-e_2^2), \tag{92}$$

$$k_{21} = P_2 Q_1 \exp(-e_1 e_2), \tag{93}$$

$$r_1 = \frac{k_{11}}{k_{12}} = \frac{Q_1}{Q_2} \exp[-e_1(e_1 - e_2)], \tag{94}$$

$$r_2 = \frac{k_{22}}{k_{21}} = \frac{Q_2}{Q_1} \exp[-e_2(e_2 - e_1)]. \tag{95}$$

Tabulated values of Q and e (Table 5) can be used to predict copolymer composition at given feed ratios. Values of r_1 and r_2 are first calculated according to Eqs. (94) and (95). These values are then substituted into the copolymerization equation [Eq. (89)].

Table 5. *Q,e* values for selected monomers (adapted from Seymour and Carraher, 1981).

Monomers	*Q*	*e*
Benzyl methacrylate	3.64	0.36
Methacrylic acid	2.34	0.65
2-Fluoro-1,3-butadiene	2.08	−0.43
p-Cyanostyrene	1.86	−0.21

Vinylidene chloride	0.23	0.36
Vinyl chloride	0.044	0.20
Vinyl acetate	0.026	−0.22

The *Q,e* scheme sometimes fails despite its overwhelming success for predicting reactivity of several monomer pairs. The assignment of *e* values for both the monomer and its radical is not adequate and in fact not consistent with transition-state theory. Additionally, values of *Q* and *e* are actually determined from reactivity ratios that vary greatly with experimental conditions (solvent, *p*H, concentration, and temperature). The assumptions of a steady-state concentration of each type of radical and reactivity considerations for only the end unit on a propagating radical are often violated. Finally, solvation and chain effects have been ignored in the derivation.

A number of techniques have been used to predict *copolymer microstructure,* in other words, the statistical distribution of *A* and *B* monomers along the backbone from reactivity ratios. Although beyond the scope of this monograph, statistical methods have been developed to predict sequence-length distribution of dyads, triads, pentads, and longer sequences.

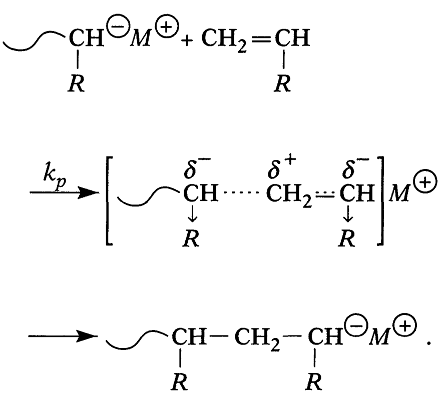
Most random and alternating copolymers are prepared in free-radical reactions. Controlled graft copolymers can be formed by including sites along or pendent to a polymer backbone that can be converted to free-radical species for further monomer addition.

Commercial examples of random copolymers are poly(vinylchloride–co-vinylacetate), poly(vinylchloride–co-acrylonitrile), and poly(styrene–co-butadiene). Block copolymers are generally prepared by ionic techniques. However, block copolymers with segments or domains of random length can be produced by thermal, mechanical, or ultrasonic degradation and recombination of mixtures of the respective homopolymers. Examples are block copolymers prepared from polyethylene and polypropylene.

2.2.6 Anionic Polymerization Anionic polymerization follows the general scheme shown in reactions (45)–(48) in Sec. 2.2. However, several features distinguish the method from free-radical polymerization. First of all, a nucleophilic species is involved in all steps rather than a free radical. Since anions have little tendency to couple, concentrations of the initiating and propagating ends are much higher, 10^{-3} as compared with 10^{-8} for free radicals. Kinetics of the reaction are easily followed by monitoring the propagation step [reaction (47)]. In cases in which addition of the nucleophile to monomer is fast compared with propagation, the propagating chains start at approximately the same time. Under conditions where termination and chain-transfer reactions are slow or negligible, narrow molecular-weight distributions are obtained.

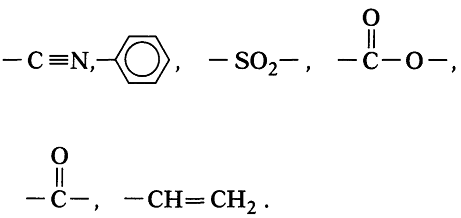
In anionic polymerization, the propagating center has an unshared pair of electrons with a charge of −1. Associated with the anion is a cation called the *counterion* or *gegenion.* The reactivity of this ion pair is determined by the nature of the functional groups to which it is attached and solvation. These factors along with temperature determine propagation rates and stereochemical control of addition.

Monomers that propagate anionically have transition states stabilized by electron-withdrawing or delocalizing groups,

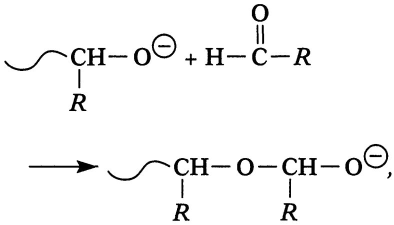


$$\sim\underset{R}{\underset{|}{CH}}^{\ominus}M^{\oplus} + CH_2{=}\underset{R}{\underset{|}{CH}} \xrightarrow{k_p} \left[\sim\underset{R}{\underset{\downarrow}{\overset{\delta^-}{CH}}}\cdots\overset{\delta^+}{CH_2}{=}\underset{R}{\underset{\downarrow}{\overset{\delta^-}{CH}}}\right]M^{\oplus} \longrightarrow \sim\underset{R}{\underset{|}{CH}}-CH_2-\underset{R}{\underset{|}{CH}}^{\ominus}M^{\oplus}. \quad (96)$$

R groups with appropriate electronic characteristics include

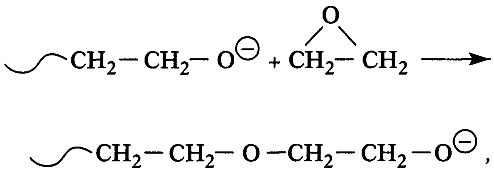


A number of anionic polymerizations involve additions to carbonyl carbons,



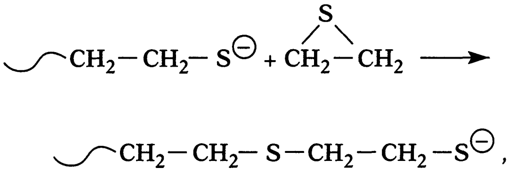
$$\sim\underset{R}{\underset{|}{CH}}-O^{\ominus} + H-\overset{O}{\overset{\|}{C}}-R \longrightarrow \sim\underset{R}{\underset{|}{CH}}-O-\underset{R}{\underset{|}{CH}}-O^{\ominus}, \quad (97)$$

or ring opening of epoxides,



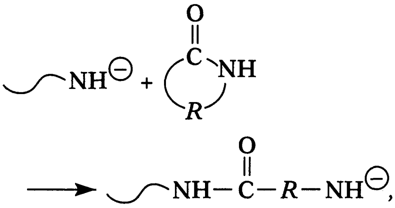
(98)

sulfides,



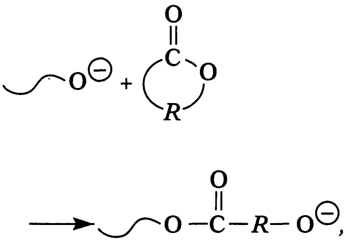
(99)

lactams,



(100)

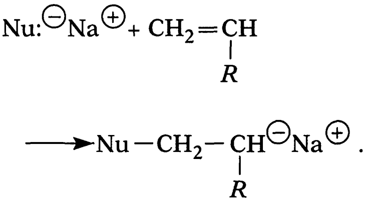
and lactones,



(101)

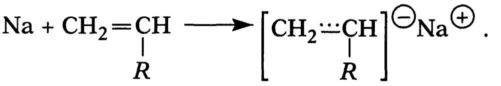
in the propagation step.

Two general mechanisms for initiation of unsaturated monomers are illustrated for substituted alkenes. The first involves nucleophilic addition to the double bond to yield a carboanion and its associated cation:



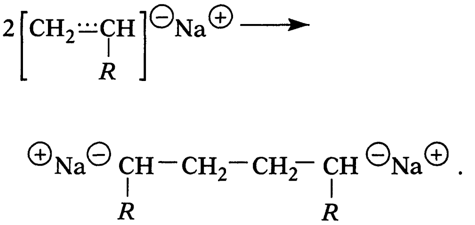
$$\mathrm{Nu{:}^{\ominus}Na^{\oplus} + CH_2{=}\underset{R}{CH}} \longrightarrow \mathrm{Nu{-}CH_2{-}\underset{R}{CH}{}^{\ominus}Na^{\oplus}}\,. \tag{102}$$

The second general mechanism involves an electron-transfer reaction to create a radical anion,



$$\mathrm{Na + CH_2{=}\underset{R}{CH}} \longrightarrow \left[\mathrm{CH_2{\overset{\cdot}{-}}\underset{R}{CH}}\right]^{\ominus}\mathrm{Na^{\oplus}}\,. \tag{103}$$

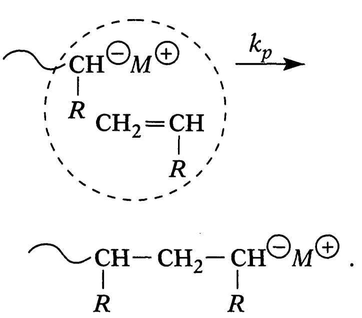
Dimerization through radical coupling yields the dianion for subsequent addition of monomer to both ends:



$$2\left[\mathrm{CH_2{\overset{\cdot}{-}}\underset{R}{CH}}\right]^{\ominus}\mathrm{Na^{\oplus}} \longrightarrow {}^{\oplus}\mathrm{Na}^{\ominus}\,\mathrm{\underset{R}{CH}{-}CH_2{-}CH_2{-}\underset{R}{CH}}\,{}^{\ominus}\mathrm{Na^{\oplus}}\,. \tag{104}$$

Initiators commonly used include organometallics, metal amides, Grignard reagents, metal alkoxides or cyanides, and alkali metals.

The dielectric constant of the solvent, counterion nature, and temperature are often manipulated to control reaction rate and stereochemistry (tacticity) during propagation of a given monomer:



$$\sim\!\mathrm{\underset{R}{CH}{}^{\ominus}}M^{\oplus}\ \ \mathrm{CH_2{=}\underset{R}{CH}} \xrightarrow{k_p} \sim\!\mathrm{\underset{R}{CH}{-}CH_2{-}\underset{R}{CH}{}^{\ominus}}M^{\oplus}\,. \tag{105}$$

The degree of dissociation of the propagating ion pair will determine the rate of the reaction as well as the tendency for complexation of the adding monomer. For solvent-dissociated ion pairs, the counterion is not intimately involved and the approach of monomer is usually dictated by the bulkiness of the R groups on the propagating chains. Syndiotactic placements (Sec. 2.2.1) are favored by their lower activation-energy requirements. Complexation mechanisms occur at low solvent polarity, often resulting in isotactic placements. The counterion is usually involved in direct chelation with the approaching monomer. Solvents commonly utilized for anionic polymerization range from nonpolar alkenes and aromatics to the more polar ethers, dioxane, and tetrahydrofuran. Perhaps one of the most attractive attributes of anionic polymerization in nonterminating conditions is the ability to control the chain length and reaction rate by considering only the propagation step

$$R_p = k_p[M^-][M] \tag{106}$$

where M^- represents the growing anion. This condition, called *living polymerization,* is usually met in polar solvents in which the counterion is dissociated at 100% conversion; the degree of polymerization is obtained by simply dividing the total monomer concentration by the initiator concentration. More complex expressions for ion-pair equilibria in moderately polar solvents have been derived (Szwarc, 1974). Since the propagating site is not destroyed during living polymerization by transfer or termination reactions, sequential addition of monomers is possible and controlled values of M_n and narrow molecular-weight distributions are attainable.

For an extensive review of various aspects of anionic polymerization and copolymerization, the reader is referred to Eastmond *et al.* (1989a), Chaps. 25–38.

2.2.7 Star and Telechelic Polymers by Anionic Polymerization Living-polymerization techniques are most useful for sequential addition to yield block copolymers,

$$R-M \xrightarrow{nA} R-A-A-A-A-A-A-A^{\ominus}M^{\oplus}$$

$$\xrightarrow{nB} R-A-A-A-A-A-A-A-B-B-B-B-B-B-B, \qquad (107)$$

or star polymers,

n
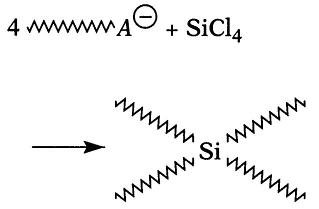
CH₂–CH–C–OH.
O

(109)

Likewise hydroxylated polymer can be formed by adding ethylene oxide. Terminal double bonds can be obtained by adding allylhaides.

Star polymers can be obtained by coupling living end groups with multifunctional reagents such as $SiCl_4$:

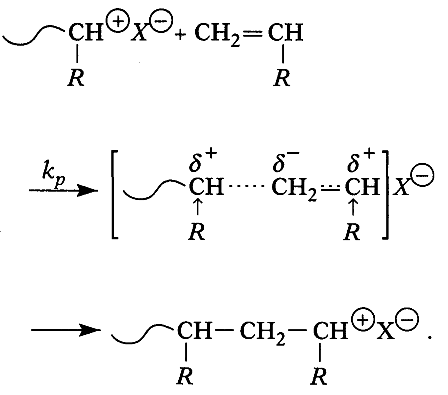


(110)

Specialty polymers with interesting morphological structures have been made by anionic techniques. For example, block copolymers of styrene with butadiene or isoprene form thermoplastic elastomers. Telechelic polymers have found application as membranes or as potential chelating sites in ionomer resins.

2.2.8 Cationic Polymerization Cationic polymerization follows the general scheme outlined in Sec. 2.2. The propagating species is generally a carbocation with its associated gegenion. The reaction is initiated by addition of a cationic species to monomer. Table 6 gives examples of representative initiators used.

The propagation step is favored by monomers that can stabilize the developing carbocation in the transition state:



(111)

Therefore, electron-donating *R* groups, those with unshared pairs of electrons, or aromatic rings, which can delocalize the positive center in the transition state, increase the rate of addition. The rate of addition depends also upon the counterion type, solvent, and reaction temperature. Narrow molecular-weight distributions can only be obtained if the rate of initiation is faster than that of propagation, allowing the chains to start at the same time. Also chain-transfer reactions must be avoided.

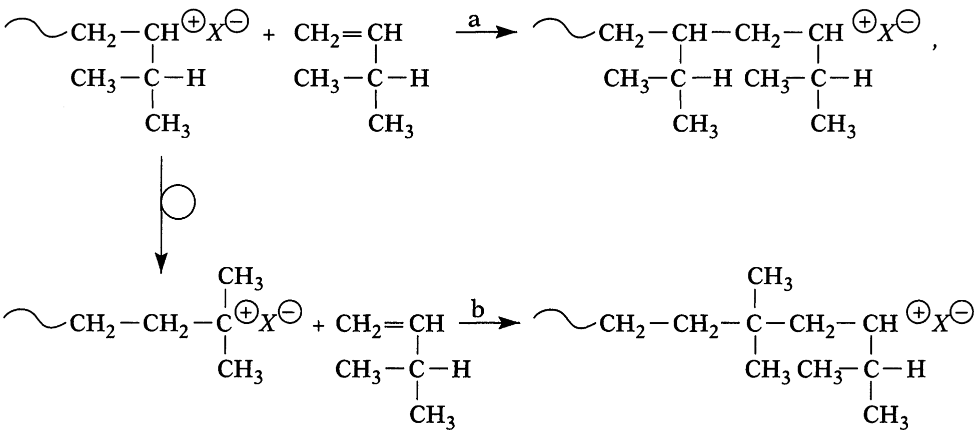
Catonic polymerization can be "living" if termination reactions are not facile. As with anionic polymerization, polar solvents favor propagation by the "free" ion while nonpolar solvents would favor ion-pair propagation. Stereoregular polymers are possible under both conditions. In the former, steric factors along the chain would dictate tacticity, while complexation of incoming monomer can control direction of attack and tacticity in the latter.

Rearrangement during polymerization is a

Table 6. Cationic initiators.

Type	Examples	Initiating species	Counterion
Protic acids	H_2SO_4	$H^{\oplus}$	$HSO_4^{\ominus}$
	$HOCOCF_3$	$H^{\oplus}$	$OCOF_3^{\ominus}$
Lewis-acid conjugates	$H_2O/ALCl_3$	$H^{\oplus}$	$ALCl_3OH^{\ominus}$
	H_2O/BF_3	$H^{\oplus}$	$BF_3OH^{\ominus}$
	$(CH_3)_3CCl/Et_2AlCl$	$(CH_3)_3C^{\oplus}$	$Et_2AlCl_2^{\ominus}$1018
Other	CH_3COClO_4	$CH_3CO^{\oplus}$	$ClO_4^{\ominus}$
	$(C_6H_5)_3C^{\oplus}\ SbCl_6^{\ominus}$	$(C_6H_5)_3C^{\oplus}$	$SbCl_6^{\ominus}$

common occurrence in cationic polymerization. The carbocation first formed upon addition during propagation can rearrange by a hydride shift to the more stable carbocation that is still capable of further addition to monomer. If the rearrangement is faster than addition, pathway (112b) rather than (112a) is followed:



(112a)

(112b)

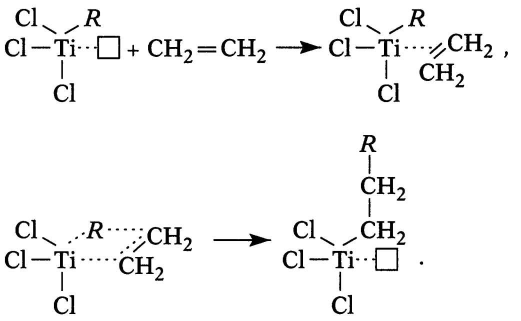
The major cationic polymerization with present technological importance is that of low-temperature polymerization of isobutylene to give butyl rubber. For detailed reviews of carbocationic polymerization and copolymerization, the reader is referred to Eastmond *et al.* (1989a), Vol. 3, Chaps. 39–53.

2.2.9 Cationic Copolymerization The number of monomer pairs that undergo random copolymerization by cationic initiation is much smaller than the number that undergo random radical copolymerization. There is also little tendency for alternation; usually block polymers or simply two homopolymers are formed in mixed-monomer systems.

The most useful cationic copolymers are formed by block polymerization, usually by sequential addition of monomers starting with the most reactive. Although the procedures can yield well-defined blocks with interesting morphologies, and can, like anionic polymerization, be used to prepare telechelic copolymers, rigorous purity and reaction conditions must be maintained. This currently limits commercial utility to specialty materials.

2.2.10 Coordination Polymerization *Coordination polymerization* or *polyinsertion* reactions involve a coordination of the monomer with the active sites on transition-metal complexes. The propagation proceeds via monomer insertion into the kinetic chain, leaving a vacant coordination site for complexation of the next monomer and repetition of this cycle.

Coordination polymerization is the commercial method by which most polyolefins including cyclic polyolefins are prepared. This represents almost half of the total industrial production of polymers. Typical of the initiation systems (often termed polymerization "catalysts") are the Ziegler catalysts derived from transition metals of groups IV–VIII with alkyl, aryl, or hydride metal compounds of groups I–III. A typical catalyst of this type is that prepared from $Al(C_2H_5)_3$ and $TiCl_3$. Equilibria reactions occur in which the chloride and ethyl groups can exchange on the metals. The metal complex active in polymerization may involve either the titanium only (monometallic complex) or both the titanium and aluminum (bimetallic complex). For simplicity, the monometallic complex mechanism with a single ethyl group is shown in



(113)

An empty *d* orbital on the transition metal (represented by □) is involved in overlap with the π system of the monomer.

When α olefins such as propylene are used, the insertion reaction can be stereoselective. With the titanium catalyst, the product is highly isotactic and the mechanism appears to be one of *catalyst site control* rather than *chain control* discussed earlier for radical and ionic polymerization. In the bimetallic mechanism, a similar pathway is followed; however, the Ti and Al are believed to "share" the alkyl chain at a coordination boundary.

The specificity of the addition is brought about by ligand coordination—in this case by the overlap of the empty *d* orbitals of the transition metal with the π orbitals of the alkene. The polyalkenes prepared in this manner have more linear structures and, therefore, can crystallize in more dense packing arrangements than the branched, low-density polyolefins prepared by free-radical polymerization. In the latter, chain transfer via a "back-biting" mechanism competes with propagation and leads to significant branching.

Both radical and ionic coordination mechanisms have been proposed for Ziegler–Natta-type polymerization (Odian, 1991, Chap. 8). Most experimental evidence gathered for polymerization of ethylene, propylene, styrene, and 1,3-dienes seems to indicate a coordinated anionic insertion (Boor, 1979). The degree of stereoregularity and the microstructure (syndiotactic vs isotactic) is dependent upon the type of the metal complex, the nature of the α olefin, the reaction temperature, and whether the catalyst is soluble or dispersed. For example, the catalyst $TiCl_4/Et_3Al$ yields largely isotactic polypropylene whereas VCl_4/Et_2AlCl yields highly syndiotactic polypropylene.

Ziegler–Natta polymerizations have some of the characteristics of "living" polymerization in that the active sites may continue to produce polymer for long periods of time. However, several individual chains may be produced during that time. The propagating chains may terminate by a β-hydride transfer to the transition metal or chain transfer to monomer. The chain may also be terminated by impurities or intentionally added reagents to "poison" the catalyst sites.

Coordination complexes formed by transition metals and alkylmetal or Lewis acids, termed metathesis catalysts, have been used for ring-opening polymerizations of cycloalkenes and bicycloalkenes and for polymerization of alkynes. The most widely used transition-metal components of the catalysts are tungsten, molybdenum, and ruthenium. Metathesis polymerization chemistry and applications are detailed in reports by Amass (1989) and Feast (1989).

Coordinated anionic polymerization termed group-transfer polymerization has been utilized successfully to prepare acrylic polymers such as methyl methacrylate (Sogah *et al.*, 1987).

3. REACTIONS OF FUNCTIONAL POLYMERS

For extensive treatments, the reader is referred to Eastmond *et al.* (1989), Seymour and Carraher (1981), Stevens (1975), and Elias (1977).

3.1 Functional-Group Reactivity

In theory, polymers with functional groups along or pendent to the macromolecular backbone should undergo reactions analogous to those of small molecules. In practice, the reaction efficiency may be much lower because of kinetic effects or thermodynamic problems related to conformational entropy changes on transformation. Major factors affecting orientation and collision frequency in polymer transformation involving isolated functional groups are solubility, chain mobility, steric and electronic effects, and neighboring-group effects. In many cases, "spacers" between the polymer backbone and the reactive functionality are required for reasonable reaction rates and conversions. On occasion, however, the polymer and its associated solvent can provide "domains" for enhanced reactions. These generally involve favorable environments in which neighboring-group assistance or local dielectric-constant changes aid in reaction kinetics. Often transformation reactions on polymers can effectively create catalytic sites in which phase-transfer reactions may be conducted on molecules held temporarily at the reaction sites.

Transformation reactions on polymers can result in systems with commercial utility. For example, cellulose, the most abundant polymer from renewable resources, can be transformed into a wide range of materials varying from membranes to water-soluble thickeners.

As with small organic molecules, chemical transformation reactions often yield by-products. These competing reactions often result in substituents permanently attached to the macromolecular backbone that can be detrimental to desired properties. Some reactions can only proceed to low conversion before precipitation occurs, and functional groups are no longer accessible. Finally, undesirable reactions may occur on polymers over a period of time such as degradation by light, oxygen, ozone, heat, or moisture.

In the sections to follow, classes of reactions representative of the myriad of polymer transformation will be presented.

3.2 Cross-Linking Reactions

Chemical cross linking through covalent, ionic, polar, or hydrophobic interactions is technologically important in developing networks that significantly alter macroscopic properties of polymers. Examples of networks are photo- or thermally cured coatings, thermoset plastics, elastomers, ionomers, and hydrogels. Since covalent network formation limits chain mobility, and thus processability, polymers of this type are formed either in one step or by preparation of linear prepolymers and subsequent cross linking. (See Sec. 2.1.8.)

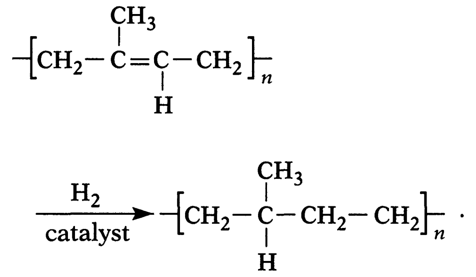
Polymers capable of noncovalent network formation are usually processed from the melt or solution. Network formation occurs in response to the cooling or solvent removal. Elastomers, such as polystyrene–polyisoprene block copolymers (Sec. 2.2.7), multiblock polyurethane elastomers (Sec. 2.1.7), and telechelic polymers (Sec. 2.2.7), are example systems forming thermally reversible domains. A classical example of the cross linking of elastomers or *vulcanization* is the formation of networks from residual double bonds in polyisoprene utilizing sulfur.

3.3 Reactions of Saturated Polyolefins

In the strictest sense, polymers such as polyethylene are functional polymers in that the pendent hydrogen atoms can be substituted for. Polyethylene and other saturated polyolefins can be reacted with the halides fluorine, chlorine, or bromine in the presence of light and heat to afford partial halogenation. Competing reactions of dehydrohalogenation and chain scission must be minimized.

3.4 Reactions of Unsaturated Polyolefins

Reactions of the double bonds in alkenes along or pendent to the polymer backbone can be useful in covalent cross linking (Sec. 2.1.8), in forming graft copolymers (Sec. 1), or for changing macroscopic properties of the polymer. The simplest transformation reaction of polyisoprene is hydrogenation,

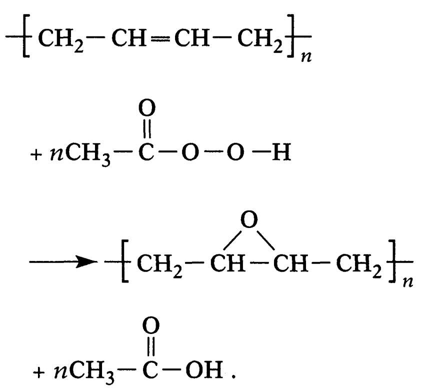


$$-\!\left[CH_2-\overset{CH_3}{\overset{|}{C}}=\underset{H}{\underset{|}{C}}-CH_2\right]_n\!- \xrightarrow[\text{catalyst}]{H_2} -\!\left[CH_2-\overset{CH_3}{\underset{H}{\overset{|}{\underset{|}{C}}}}-CH_2-CH_2\right]_n\!- \ .$$

(114)

The commercially important block copolymer Kraton® is produced by hydrogenation of the ABA triblock styrene–butadene–styrene. The double bonds of polyisoprene in linear or block copolymers can also be chlorinated.

Epoxides are easily formed by the reaction of peracetic acid or hydrogen peroxide with residual double bonds:



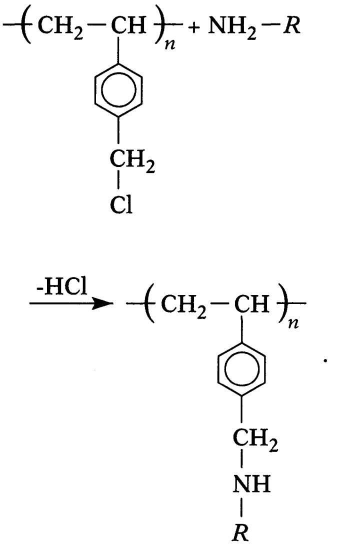
(115)

The epoxidized intermediates are easily transformed by the action of nucleophiles such as water, amines, or alcohols to functional derivatives.

Some polymers are susceptible to a number of adverse reactions, especially those with easily abstractable allylic hydrogen atoms and double bonds. Degradation reactions at moderate temperatures such as oxidation and ozonolysis rapidly break down the polymer backbone.

3.5 Reactions of Halogenated Polymers

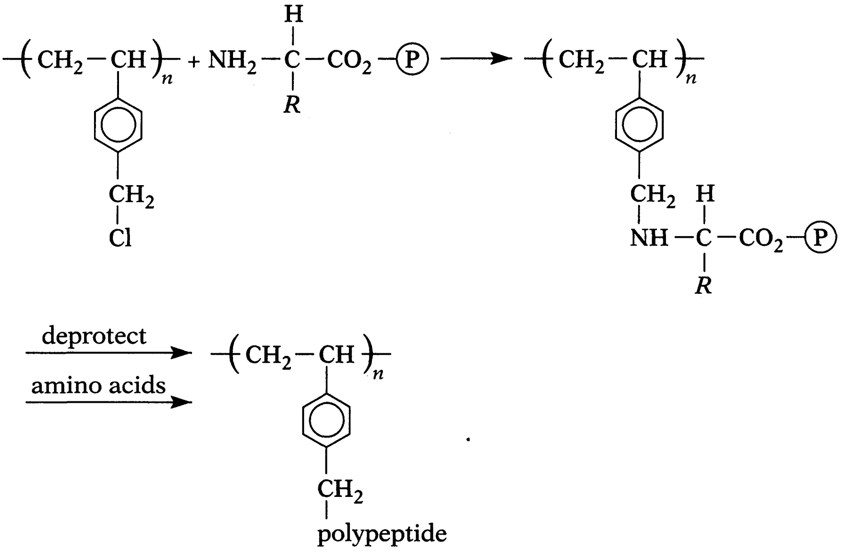
Substitution reactions of halogens directly on the polymer backbone are generally not successful because of steric requirements and/or competing dehydrohalogenation and degradation reactions. However, halides positioned farther from the backbone, and especially those attached to benzylic or allylic carbon atoms, are easily substituted for. An example is



(116)

for amination of the polymerized para-substituted benzylchloride derivative of styrene.

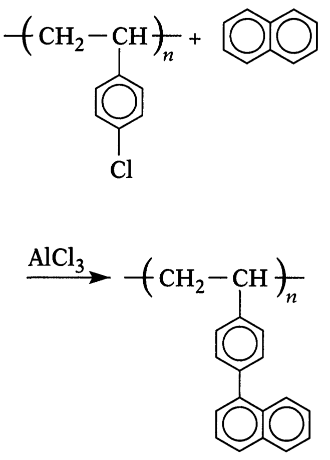
Halogenated benzylic styrene derivatives are utilized to prepare supports upon which stepwise synthesis of peptides, nucleic acids, and polysaccharides can be conducted. In the Merrifield synthesis of polypeptides, for example, a carboxyl-protected amino acid is introduced onto a cross-linked chloromethylated polystyrene resin. The protective group is removed and another carboxy-protected amino acid is added. In this way, amino acids can be sequentially added:



(117)

The polymer support allows facile synthesis, separation, and purification. The peptide is isolated in the last step by release from the solid support. Synthesis on solid supports has recently become important for production of polynucleotides, RNA, and DNA, utilized in recombinant biotechnology.

Halogenated aromatic polymers with aryl or benzyl substitution are also useful in electrophilic aromatic substitution:

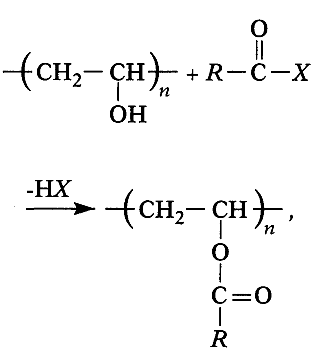


(118)

Friedel–Craft-type reactions occur readily with Lewis-acid catalysts. Competitive ring formation and intermolecular self-substitution reactions may occur along or between polymer chains.

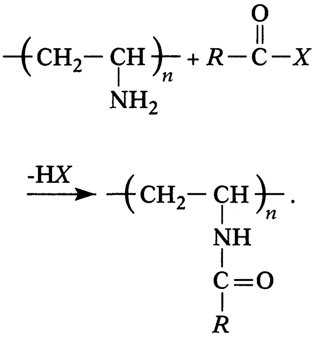
3.6 Reactions of Hydroxy- or Amine-Containing Polymers

Polyesters or polyamides can be obtained by reacting hydroxy- or amine-functional polymers through addition-elimination reactions involving acyl acids, halides, or anhydrides as shown in



$$\left(\mathrm{CH_2}-\underset{\mathrm{OH}}{\mathrm{CH}}\right)_n + R-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-X \xrightarrow{\mathrm{-H}X} \left(\mathrm{CH_2}-\underset{\substack{|\\ \mathrm{O}\\ |\\ \mathrm{C=O}\\ |\\ R}}{\mathrm{CH}}\right)_n ,$$

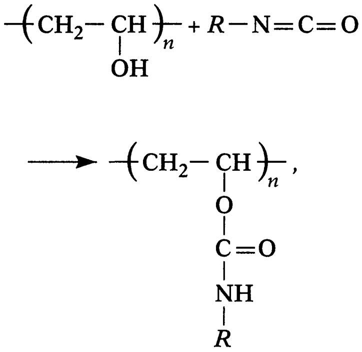
(119)



$$\left(\mathrm{CH_2}-\underset{\mathrm{NH_2}}{\mathrm{CH}}\right)_n + R-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-X \xrightarrow{\mathrm{-H}X} \left(\mathrm{CH_2}-\underset{\substack{|\\ \mathrm{NH}\\ |\\ \mathrm{C=O}\\ |\\ R}}{\mathrm{CH}}\right)_n .$$

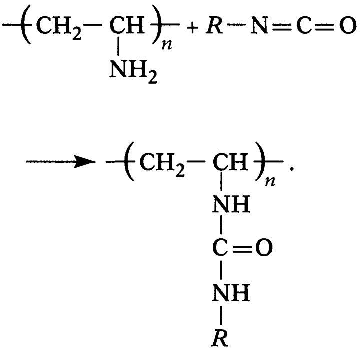
(120)

Carbonate and urea derivatives can be prepared by reactions with isocyanates:



$$\left(\mathrm{CH_2}-\underset{\mathrm{OH}}{\mathrm{CH}}\right)_n + R-\mathrm{N=C=O} \longrightarrow \left(\mathrm{CH_2}-\underset{\substack{|\\ \mathrm{O}\\ |\\ \mathrm{C=O}\\ |\\ \mathrm{NH}\\ |\\ R}}{\mathrm{CH}}\right)_n ,$$

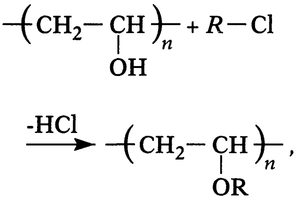
(121)



$$\left(\mathrm{CH_2}-\underset{\mathrm{NH_2}}{\mathrm{CH}}\right)_n + R-\mathrm{N=C=O} \longrightarrow \left(\mathrm{CH_2}-\underset{\substack{|\\ \mathrm{NH}\\ |\\ \mathrm{C=O}\\ |\\ \mathrm{NH}\\ |\\ R}}{\mathrm{CH}}\right)_n .$$

(122)

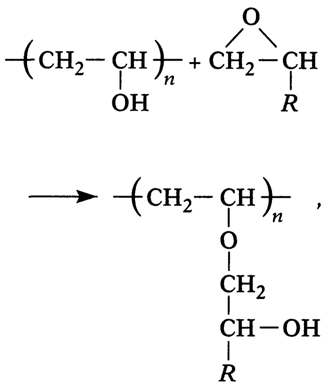
Polymers with side-chain ethers are prepared by reacting alkyl halides,



$$\left(\mathrm{CH_2}-\underset{\mathrm{OH}}{\mathrm{CH}}\right)_n + R-\mathrm{Cl} \xrightarrow{\mathrm{-HCl}} \left(\mathrm{CH_2}-\underset{\mathrm{O}R}{\mathrm{CH}}\right)_n ,$$

(123)

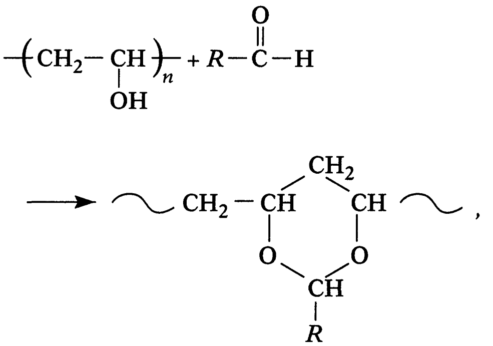
or epoxides with hydroxy functionality,



(124)

and by nucleophilic substitution reactions.

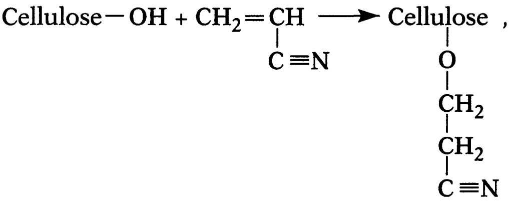
Hydroxy-containing polymers can undergo addition reactions with aldehydes to form methylol groups. Cyclization can occur, as shown in



(125)

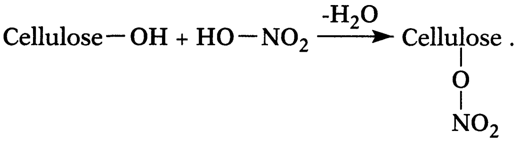
for the reaction of poly(vinyl alcohol) with aldehydes, especially when six-membered rings are possible. The product formed by the reaction of butyraldehyde, $R = C_3H_7$, which contains over 80% cyclized repeating units, is used commercially as lamination in safety glass.

Other reactions of hydroxy functionality on polymers are illustrated by alkene addition (Michael addition) of acrylonitrile,



$$\text{Cellulose}-OH + CH_2=CH(C{\equiv}N) \longrightarrow \text{Cellulose}-O-CH_2-CH_2-C{\equiv}N \quad (126)$$

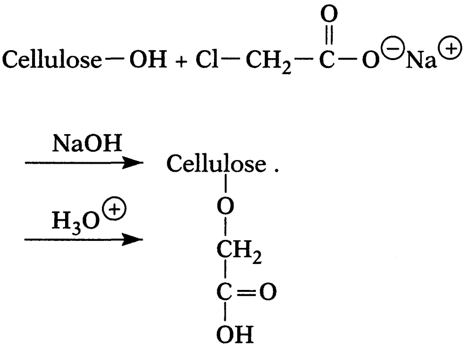
and nitration of cellulose,



$$\text{Cellulose}-OH + HO-NO_2 \xrightarrow{-H_2O} \text{Cellulose}-O-NO_2 \quad (127)$$

The nitrile derivative can be hydrolyzed to yield water-absorbent cellulose, while nitrocellulose is used in coatings.

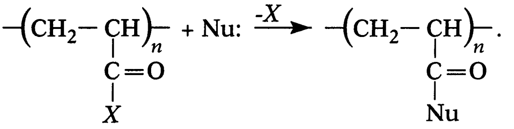
Carboxylated celluloses such as carboxymethyl cellulose may be prepared by reacting cellulose in caustic solution with sodium chloroactetate followed by neutralization:



$$\text{Cellulose}-OH + Cl-CH_2-\overset{O}{\overset{\|}{C}}-O^{\ominus}Na^{\oplus} \xrightarrow{NaOH} \xrightarrow{H_3O^{\oplus}} \text{Cellulose}-O-CH_2-C(=O)-OH \quad (128)$$

3.7 Reaction of Acyl Groups

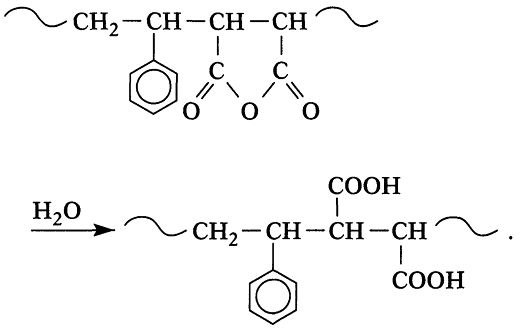
Polymers with pendent esters, acids, anhydrides, or acyl halides can undergo facile addition-elimination reactions with added nucleophiles:



$$-\!\!\left(CH_2-\underset{\underset{X}{|}}{\underset{C=O}{|}}{CH}\right)_{\!n}\!\!- + \text{Nu:} \xrightarrow{-X} -\!\!\left(CH_2-\underset{\underset{\text{Nu}}{|}}{\underset{C=O}{|}}{CH}\right)_{\!n}\!\!- . \quad (129)$$

Common nucleophiles include water, alcohols, amines, or acids to yield polymeric acids, esters, amides, or anhydrides, respectively.

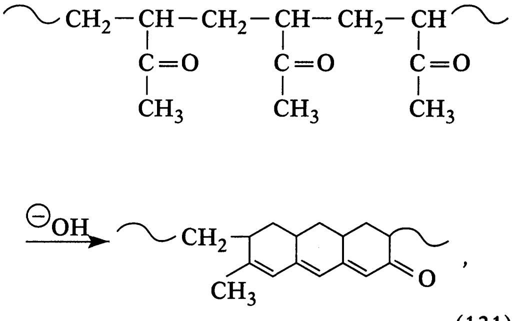
Representative of a common reaction is that of hydrolysis of the alternating copolymer prepared by chain-growth polymerization of maleic anhydride and styrene with water rendering the copolymer soluble in water:



(130)

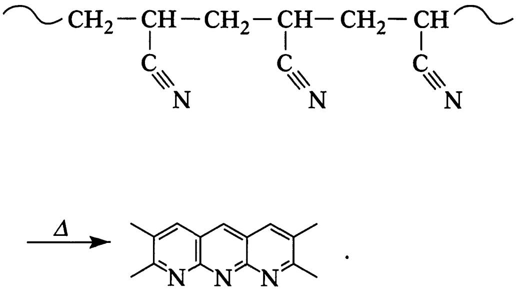
3.8 Controlled Cyclization Reactions

In addition to cyclopolymerization (Sec. 2.2.1) and polyacetal cyclization reactions [Eq. (125)], ring formation has been attempted for polymers with pendent functional groups to yield polymers with "ladder"-type structures. True "ladders" are rarely obtained, however, since isolated pendent groups are statistically predicted. Examples of ladder structures are given for the intramolecular alcohol condensation of poly(methylvinylketone),



(131)

and for the controlled heating of polyacrylonitrile,



(132)

3.9 Functionalization for Specific Activity

The wide variety of functionalized polymers formed from step-growth or chain-growth processes allows synthesis of a virtually unlimited array of materials capable of serving as reagents, catalysts, sequestrants, phase-transfer sites, stabilizers, or substrates for delivery of bioactive agents. For example, polymeric reagents have been used for hydrogenation of alkenes, epoxidation reactions, stereoselective reduction of aldehydes, and oxidation/reduction reactions. Polymeric catalysts have been used for hydrogenation, hydrolysis, esterification, amidation, and photoconversion reactions. Transition metals have been chelated to functional polymers through phosphenation reactions to serve as catalysts in hydrosilation, hydroformylation, and hydrogenation reactions. Photosensitizers have been bound to polymeric centers to assist in photochemical reactions. Bioactive agents including drugs and pesticides have been bound by covalent and ionic bonds to form controlled-activity polymers. Phase-transfer catalysts have been utilized to enhance the reaction between water-soluble and water-insoluble reactants. Finally, enzymes have been immobilized onto polymer supports for carrying out biochemical and organic syntheses.

GLOSSARY

***A–A* Monomers:** Difunctional monomers in which *A* represents the reactive functional groups.

Biopolymers: Polymers synthesized in biological systems.

***B–B* Monomers:** Difunctional monomers in which *B* represents the reactive functional groups.

Cage Recombination: Coupling of radical following formation in a confined environment.

Chain Growth: Mechanism of polymerization based on initiation, propagation, and termination.

Chain Transfer: The process by which a propagating chain is terminated by transfer of an active group from another molecular species.

Coupling: Radical chain termination by combination.

Direct Amidation: Method of formation of a polyamide by reaction of a diamine with a diacid.

Direct Esterification: Method of formation of polyesters—for example, the reaction of a difunctional alcohol with a difunctional acid.

Disproportionation: Chain termination by an abstraction elimination mechanism.

Ester Interchange: Condensation reaction in which exchange of functional groups results in ester formation.

Gegenion: Associated counterion.

Initiation: The start of a chain reaction.

Interchange Reaction: Condensation reaction characterized by exchange of functional groups.

Oligomers: Polymers with low degrees of polymerization.

Polymerization: The process of preparing polymers.

Polymers: Macromolecules composed of multiple repeating units derived from reactions of small-molecule precursors.

Propagation: Chain-extension step in chain-growth polymerization.

Ring-Opening Polymerization: Mechanism of polymerization of a cyclic monomer.

Steady State: Constant concentration of reactive species.

Step Growth: Mechanism of polymerization involving stepwise coupling reactions.

Termination: End of a chain process.

Transamidation: Amide interchange reaction common in polyamide polymerization.

Vulcanization: Controlled cross linking of unsaturated elastomers utilizing sulfur.

INTRODUCTION

Polymer molecules are chains containing a large number of one or more repeat units linked together by covalent bonds. These molecules make up important materials that have been put to use in a variety of ways that take advantage of their unique physical, mechanical, electrical, and optical properties. Crystal structure determination, using x-ray diffraction; morphological investigation, employing optical and electron microscopy; and the viewing of individual molecules, using scanning probe microscopy, are characterization techniques currently in use by polymer scientists. These and other methods have allowed the investigation and characterization of a large number of new polymeric substances and compositions.

The form and structure, the morphology, of a polymeric material depends on the molecular structure and mass, the chain confor-

mation, the thermal history, and the mechanical stress history. A polymer sample can be

1. an isotropic glass or rubber,
2. partially crystalline with glassy or rubbery interlayers,
3. completely crystalline,
4. in the form of a liquid-crystalline mesophase, or
5. part of a phase-separated or composite system.

Before use, polymeric materials undergo fabrication processes such as molding, extrusion, casting, and uniaxial or biaxial extension; these processes can lead to new or mixed morphologies and have a direct effect on the properties and performance. Therefore, a detailed understanding of the morphology and structure of polymeric substances and mixtures thereof is an important goal.

In the sections to follow, the requirements for polymer crystallization, chain regularity, conformation, orientation, packing, and folding are discussed, the various polymer morphologies known to date are explained and illustrated, the methods of crystallization, crystal structure determination, and morphological investigation are reviewed, and the effects of thermal changes, mechanical stress, solvents, and irradiation on the morphology are presented.

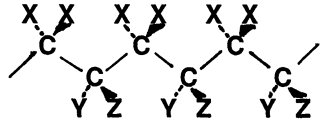
1. POLYMER CRYSTAL STRUCTURE

1.1 Chain Regularity

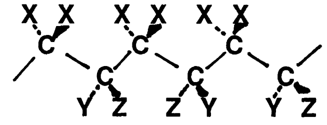
The ability of a polymer to form a three-dimensional repeating structure is largely, but not totally, dependent on the regularity of the atomic placement in the chain. Homopolymers that crystallize can be obtained by polymerization of unsaturated monomers, by condensation-type reactions of bifunctional monomers, and by polymerization of certain ring monomers.

Some of the repeat units obtained by polymerization of unsaturated monomers to form singly bonded carbon-atom chains are symmetrical, having the same substituents attached to each carbon atom in the chain, e.g., the repeat unit in polyethylene, —CH_2CH_2—, and some have different types of substituents on alternate carbon atoms but have a head-to-tail, isoregic, linking of the repeat units, as shown in Fig. 1. The substituents on a given carbon atom can be the same, as for poly(vinylidene chloride), —CH_2CCl_2— or they can be different, e.g., polypropylene, —$CH_2CH(CH_3)$—, with the latter referred to as asymmetric. The three arrangements, *configurations*, of three successive asymmetric repeat units, shown in Fig. 1 are possible; in this figure X, Y, and Z denote substituent groups attached covalently to carbon atoms in the chain. In some cases X and Y (or Z) are the same. Since the substituents on singly bonded carbon approximate a tetrahedral arrangement, the Y and Z groups project out in front or behind the zigzag carbon chain drawn in the plane of the paper. An isotactic placement has all Y groups projected out on one side and all Z groups projecting out the other side.

The polymers with asymmetric repeat units that crystallize usually have a regular configuration, isotactic or syndiotactic; some examples of isotactic polymers that have been prepared are polypropylene, Y = H, Z



ISOTACTIC



SYNDIOTACTIC

FIG. 1. Types of isoregic configurations in chains containing asymmetric repeat units. X, Y, and Z are different chemical substituents. Three repeat units are shown.

= CH_3; poly(butene-1), Y = H, Z = CH_2CH_3; polystyrene, Y = H, Z = phenyl; poly(methyl ether), Y = H, Z = OCH_3; and poly(methyl methacrylate), Y = CH_3, Z = $C(O)OCH_3$. Syndiotactic polymers include polypropylene and poly(methyl methacrylate). Polymers with asymmetric repeat units in an atactic configuration that crystallize are those with small highly polar substituents such as the CN group in polyacrylonitrile, Y = H, Z = CN, and the OH group in poly(vinyl alcohol), Y = H, Z = OH. Polymers with large Y and/or Z substituents, such as poly(methyl methacrylate) and polystyrene, do not crystallize, if the configuration is atactic. An example of a polymer with an asymmetric repeat unit, shown to contain nonisoregic as well as atactic linkages, is free-radical–initiated poly(vinyl fluoride); despite these irregularities, this polymer crystallizes. Polymers synthesized from diene monomers are crystallizable if the linkage is 1,4, and if the substitution is predominately *cis* or *trans* or if an isotactic or syndiotactic arrangement occurs in the 1,2 or 3,4 substituted isomers. Representative polydiene repeat units are given in Fig. 2. In these structures R = H for polybutadiene and R = CH_3 for polyisoprene.

Polymers containing a symmetrical repeat unit and *small* amounts of a second unit, statistically placed, such as polyethylene with some propylene repeat units, are crystallizable; the repeat unit present in small amount may be excluded from the crystal stems and appear at the crystallite surface. Polymers containing two different repeat units are called copolymers. Statistical copolymers with both repeat units asymmetric usually do not crystallize.

The chains formed from unsaturated monomers are generally flexible because of the presence of many singly bonded carbon atoms. The effects of this flexibility on the morphology will be discussed below.

Many polymers are synthesized from monomers with reactive end or side groups, such as alcohols, acids, or amines. Homopolymers formed from monomers containing two reactive groups are usually crystallizable since only one isomeric choice exists and ordered arrangements can be formed. Condensation-type repeat units can be incorporated in flexible chains, e.g.: poly(6-amino hexanoic acid) and poly(ethylene terephthalate); semiflexible chains, e.g: polycarbonate; semirigid chains, e.g.: polybenzamide; and rigid chains, e.g.: polybenzimidazole. The repeat units for these are given in Fig. 3. These dif-

ferent types of polymers show different characteristics, particularly in their ease of crystallization and, to some extent, in their morphologies. Many of these polymers contain unsubstituted aromatic rings with para linkages—linkages on diametrically opposite atoms. The introduction of ortho (on adjacent atoms) and meta (on next-nearest neighbor atoms) linkages will cause disorder in the crystal lattice and thereby lower the crystallization ability. Substituents on the rings will have a similar effect on the crystal lattice.

The presence of trifunctional or tetrafunctional monomers in a condensation-type reaction mixture leads to highly branched or to network polymers, which usually do not crystallize. Epoxy resins are an example of this type of system. Also, the presence of a three-dimensional covalent network precludes any further molding, extrusion, or drawing.

Various small molecules with ring configurations can be polymerized to form crystalline linear-chain products. Included in this group are polymers containing silicon and phosphorus atoms in the chain. Polymers formed from ring monomers generally have flexible chains.

1.2 Chain Conformation, Orientation, and Packing

In the tacticity structures given above, when the carbon atoms are in the same plane, one of the two atoms or groups of atoms on each projects out and the other projects in. The spatial placement of each CX_2 and CYZ group and the remainder of the chain attached to it can be changed by rotation about the C—C bond between the two carbon atoms preceding the group in question. Each allowed change of the rotation angles yields another conformation for the chain. The chemical makeup and configuration of the polymer repeat units present dictate which conformations are energetically feasible as well as the relative energies of each. Rotation angles of 0, ±60, ±120, and 180 are labeled as *trans* (t), *skew*± ($s^{\pm}$), *gauche*± ($g^{\pm}$); and *cis* (c). For a polymer molecule any combination of bond conformations that results in close approach or overlap of nonbonded atoms will be of high energy and therefore will not be preferred. For polyethylene a succession of *trans* conformations (ttt), which gives a chain with the lowest energy and highest extension, is the arrangement present in the crystal. However, many other combinations of *trans, gauche*+, and *gauche*− occur for this polymer in the liquid state and in solution. For isotactic polypropylene and polystyrene a tg^+tg^+ conformation, resulting in a helix with three monomer units per turn, has the lowest energy for an isolated chain. For the polydienes, with repeat units —CH_2—CR=CH—CH_2—, *skew* and *cis* states are energetically preferred to the *trans* and *gauche* states for the single bond following the double bond in the repeat unit. Two chain conformations have low energy for *trans*-1,4-polyisoprene: s^+ts^- and cts^+cts^-. [The first (and fourth) symbol in these groups refers to rotation about the CH—CH_2 bond, the second (and fifth) symbol to rotation about the adjoining CH_2—CH_2 bond, and the third (and sixth) symbol to rotation about the subsequent CH_2—CR bond.] A polymer chain can contain relatively inflexible groups such as —C=C— units, aromatic rings, and amide groups. The all-aromatic polyamides, e.g., polybenzamide (see Fig. 3 for repeat unit structure), and polyesters are semirigid with limited conformational choices per repeat unit available. Rotation about the C(O)—NH bond takes considerable energy, resulting in a fixed conformation for that group. A rodlike polymer, such as polybenzimidazole, has only one conformation available to it and is fully extended.

During crystallization the chains adopt a particular low-energy conformation and pack together in a three-dimensional repeating array, usually with the conformed chains parallel. The unit cell usually contains only a small part of any particular chain, depending on the conformation adopted (see CRYSTALLOGRAPHY). The orthorhombic unit cell in polyethylene contains two —CH_2—CH_2— units side by side with one chain turned with respect to the other; the unit cell for the triclinic form of polytetrafluoroethylene is a helix containing 13 —CF_2—CF_2— units on the same chain having six turns. These and other unit cells are described by Wunderlich (1973).

1.3 Chain Folding

Crystallites formed from flexible-chain polymers can vary in size depending on the crystallization conditions; the dimension of the crystallite in the chain direction, referred to as the crystal stem length, can be considerably less than the total length of the chain having the particular bond conformations found in the unit cell. One very important parameter determining the crystal stem length is the degree of supercooling, given by $T_m^0 - T_c$, where T_m^0 is the equilibrium melting point and T_c is the crystallization temperature. Crystallization conditions leading to large stem lengths include high pressure, small degrees of supercooling, and long crystallization time. The remainder of the chain not incorporated in a particular crystal stem can be partially incorporated as one or more crystal stems in the same or a different crystallite or it can project from the crystallite surface. If the remainder of the chain is to be incorporated into the same crystallite, it must turn back, or fold, resulting in the appearance of bond conformations other than those in the unit cell. Chain folding, protrusion, or incorporation in two different crystallites would lead to a noncrystalline component. Folded-chain crystallites melt at temperatures below T_m^0 with the melting temperature decreasing with lamellar thickness and crystallization temperature. If the heating rate is low, reorganization with longer stem lengths can occur.

1.4 Crystallization Methods

1.4.1 Crystallization from Solution Most crystallizable flexible-chain polymers form solutions with one or more solvents at elevated temperatures. With prolonged heating crystal nuclei present due to previous crystallization are lessened in number or destroyed completely. Cooling this solution to a temperature sufficiently below that for dissolution can lead to crystallization, once nucleation occurs. Crystallization can be carried out isothermally or upon slow cooling. The crystal growth rate increases with the degree of supercooling. A seeding technique can be used to regulate the nucleation process. An essentially nucleus-free solution is subjected to a high degree of supercooling, causing rapid nucleation and crystallization; this suspension is then heated to a temperature below the minimum dissolution temperature and crystallization carried out isothermally. Crystallization can also be brought about by solvent evaporation at a temperature above that for dissolution.

1.4.2 Crystallization from the Melt Most crystallizable flexible-chain polymers form isotropic liquids at sufficiently elevated temperatures. Crystallization is usually brought about by sufficient cooling of this liquid below the equilibrium melting temperature under quiescent conditions. This process can be carried out at atmospheric or elevated pressures. Crystallizable polymers containing bulky groups in the main chain or as substituents, when cooled from the melt, can be easily quenched to a glass. Crystallization of these can be afforded by heating to a temperature above the glass transition temperature but below the melting temperature.

1.4.3 Crystallization under Mechanical Stress The application of a tensile stress to a crystallizable polymer in the rubbery liquid state can lead to chain extension and crystallization. Imposition of a tensile or a shear stress on a supercooled melt undergoing crystallization brings about changes in the morphology of the material. Vigorous stirring of a supercooled solution at temperatures above those at which crystallization occurs quiescently can bring about crystallization and a different morphology.

1.5 Crystal Structure Determination

The determination of the crystal structures of many synthetic polymers by x-ray diffraction has been carried out using quiescently crystallized samples subsequently subjected to a tensile stress that acts to orient the chains in a known direction. The resulting fiber is rotated about the orientation direction and the diffraction pattern obtained on film using the Laue or Weissenberg methods (see CRYSTALLOGRAPHY). The pattern resulting consists of lines, arcs, spots, or a combination thereof, depending on the amount of chain orientation. The periodicity and the unit cell distance along the chain can be obtained from the distances between lines or layers of arcs or spots appearing perpendicular to the direction of orientation. Unit cell distances in the two other directions are found from spacing of spots or arcs within the layers. Diffraction patterns obtained on unstretched quiescently crystallized films consist of rings or ellipses, due to random orientation of the crystallites, superimposed on a broadened diffraction background, due to the noncrystalline portions present.

Single-crystal diagrams have been obtained by selected-area electron diffraction on single platelets of polymers precipitated from dilute solution. In these samples the chain direction is usually parallel to the beam direction, affording a pattern of $h,k,0$ diffraction spots (see CRYSTALLOGRAPHY).

2. POLYMER MORPHOLOGY

2.1 Methods of Investigation

2.1.1 Optical Microscopy Solids and solid–liquid mixtures can be examined using optical microscopy at magnifications up to about 2000. Viewing of images formed with transmitted plane polarized light is done through an analyzer, a polaroid lens with its axis usually oriented at right angles to that of the polarizer. Light can be transmitted through the analyzer if parts of or if all of the sample is birefringent—that is, with a refractive index for light with electric vibrations parallel to the optic axis different from that for light perpendicular to this axis. Light will not be transmitted for the following reasons:

1. the thickness of the birefringent area is less than one wavelength,
2. the optic axis is parallel to the polarizer or analyzer direction,
3. the direction of the light is parallel, and therefore the electric vector is perpendicular, to the optic axis.

Phase contrast uses a 90° change of phase of the light diffracted from various regions of the sample; this shows up differences in refractive index within the specimen when this light is recombined with the transmitted beam.

In interference contrast one portion of the beam passes through the sample and the other part is changed in phase by a variable amount to give optimum contrast upon recombination of the two beams, showing up steps and surface tilts present and giving a three-dimensional view.

2.1.2 Electron Microscopy Electron microscopy is carried out in transmission, TEM, on relatively thin polymer specimens at magnifications up to about 2×10^6. Bright-field conditions, in which the transmitted electrons form the image, are usually used. It is possible to reverse the contrast by forming the image in dark field with one or more diffracted beams. If the sample is crystalline, a selected-area electron-diffraction pattern can also be obtained. Phase contrast is obtained by defocusing the objective lens, which produces a phase shift. By using a high-resolution electron microscope, HREM, at low dosages and moderate magnifications, followed by photographic enlargement and computer-controlled image enhancement, a crystalline or liquid-crystalline lattice can be imaged. Restrictions on sample thickness necessitate microtoming or surface replication of samples. Prior to replication or following microtoming, various treatments, such as reaction with OsO_4 or RuO_4 or etching with acids, bases, organic liquids, ions, or electrons, have been employed to highlight or reveal certain parts of the total solid sample. Shadowing with a heavy metal is carried out in order to provide contrast between the sample and substrate.

Scanning electron microscopy, SEM, uses a focused electron beam to scan the sample surface. Magnifications up to about 100 000 are possible although most work is carried out below 10 000×. In addition to having a higher resolution than optical microscopy, SEM has a much larger depth of field. Samples are thinly coated with a metal to provide a conductive layer.

2.1.3 Scanning Probe Microscopy This involves moving a probe with a finely ground tip, from one to a few atoms across, over the surface of the specimen (Wickramasinghe, 1989). The specimen surface can be imaged on an atomic scale with a small electrical current, as used in the scanning tunneling microscope, STM, or by application of a mechanical force, employed in the atomic force microscope, AFM. STM requires a conducting surface; AFM can be used to investigate insulating surfaces including polymers. In both the STM and the AFM the electron cloud at the tip of the probe is in contact with that at the specimen surface.

2.2 Morphologies of Crystallized Polymers

2.2.1 Single Lamellas Single platelets can be formed, by isothermal crystallization in a quiescent supercooled melt or solution, from a large variety of polymers with a wide range of chain flexibility (Geil, 1963; Woodward, 1988; Wunderlich, 1973). Single-polymer lamellas can have a highly regular geometry, appearing to be single crystals. Faceted lamellar geometries reported include diamond, hexagonal, pyramidal, square, and lathe shapes. Some atactic polymers form irregularly shaped nonfaceted lamellas. The observed geometries depend on the crystal lattice type adopted and the crystallization solvent.

A schematic representation of the center part of a single-polymer lamella, based on the chain folding model, is shown in Fig. 4. Each straight line represents a section of a polymer chain incorporated in the crystal lattice and contains a number of repeat units; the loops shown depict the folds, represented as

1. tight adjacent reentrant,
2. loose adjacent reentrant, and
3. nonadjacent reentrant.

The dimension along the chain direction in the crystallized portion of a single lamellar platelet from solution is usually of the order of 5–20 nm, while the lateral dimensions are in the range of 1–20 μm (1000–20 000 nm). Diamond- and square-shaped lamellas have four sectors and hexagonally shaped ones have six, corresponding to different crystallographic growth planes. Polymer lamellas can be nonplanar and therefore collapse features, such as creasing and splitting, can be evident in samples deposited from solution, as shown in Fig. 5 (Anandakumaran *et al.*, 1983). Twinning, growth of two lamellas from a common face, can occur. Growth-face splitting, leading to lamellar branching and to the formation of spiral growths, can take place.

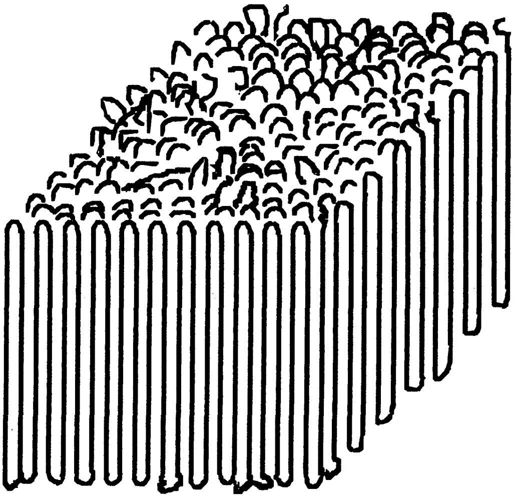

FIG. 4. Polymer single lamella with folded chains.

2.2.2 Dendrites, Hedrites, and Spherulites Under many conditions, particularly during crystallization from concentrated solution or the melt, branched and/or multilayered lamellar structures appear.

Dendrites are branched lamellas with the branches related in a definite crystallographic way to each other. Dendritic structures are found for solution-crystallized polyethylene with branches along the crystallographic *a* and *b* axes, perpendicular to the chain direction in the lamellas, and can have lengths of hundreds of micrometers (Wunderlich, 1973). At high concentrations thick multilayered dendrites are formed. Interpenetrating crosshatched dendritic structures, called quadrites, of one polymer, isotactic polypropylene, have been crystallized from solution and from the melt.

Hedrites (axialites) are stacks of centrally connected lamellas that grow from solution or the melt (Geil, 1963). A SEM micrograph of two hedrites is given in Fig. 6. During

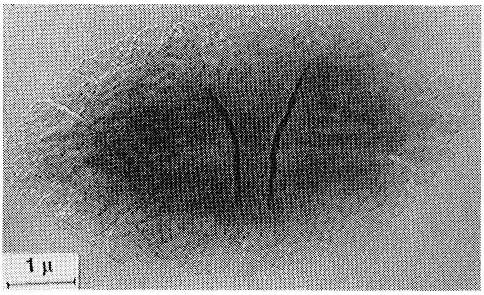

FIG. 5. Transmission electron micrograph of a *trans*-1,4-polyisoprene lamella grown from dilute amyl acetate solution at 20 °C showing wrinkling and splitting. [Reprinted from Anandakumaran *et al.* (1983). Copyright 1983, American Chemical Society.]

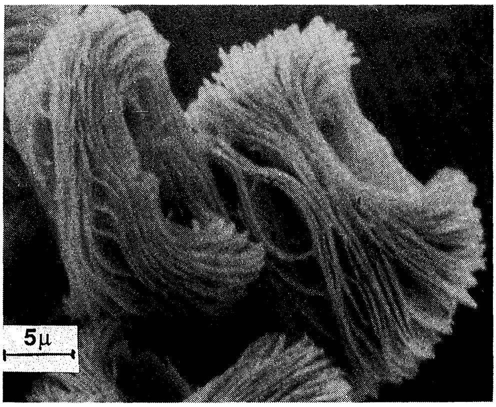

FIG. 6. Scanning electron micrograph of *trans*-1,4-polyisoprene hedrites grown from 1% amyl acetate solution at 20°C. [As in Xu and Woodward (1986). Copyright 1986, American Chemical Society.]

growth from solution, the lamellas can develop further connections as a result of the incorporation of a single chain or a group of chains in neighboring lamellas. One consequence is that two lamellas can be closely connected to each other at more than one place in the stack; repeated events of this sort give the hedrite a cellular appearance. A lamellar stack can exhibit considerable curvature, and separation or splaying of the lamellar ribbons can occur.

Spherulites are composed of lamellar ribbons that usually grow outward, radially

1. from a single (heterogeneous) nucleus,
2. from a group of lamellas similar to that in a hedrite, or
3. from a quadrite, a crosshatched lamellar array.

After sufficient supercooling of a relatively concentrated solution or of a melt, spherulites can be grown at constant or slowly decreasing temperature. The growing spherulite is filled in by lamellar branching, particularly at high degrees of supercooling. Branches can be created by nucleation of new lamellas at the surface of a parent lamella, as occurs in hedrites, or by dendritic branching, branching at the growth face, which occurs at high degrees of supercooling. When the crystallization temperature is raised, the degree of supercooling is decreased, branching diminishes, the primary lamellas increase in average thickness, and additional lamellas fill in the spherulite structures at a later time. Curvature and twisting of the lamellas in spherulites occur during growth. A common birefringence pattern for melt-crystallized spherulites is four bright quadrants separated by a dark cross, with the arms of the cross in the directions of the polarizer and analyzer. In addition, sometimes alternating bright and dark (extinction) rings are observed. Multilamellar crystallization from the melt usually yields a coherent sample made up of individual structures impinging on and linked to one another by common lamellas. An interference contrast optical micrograph of spherulitic growth from the melt is shown in Fig. 7 (Woodward, 1983). Individual spherulites can be grown from solution; two examples are shown in Fig. 8 (Xu and Woodward,

1986). Both quasicircular and scrolled lamellar spherulites have been reported (Lovinger, 1980; Vaughan, 1993).

Crystallization at high pressure (4 to 5 kbar) and increased temperature yields spherulites with highly, if not completely, extended chains. Crystallization from a liquid crystalline mesophase of semistiff chains (see Sec. 2.3) can give lamellar stacks linked together by extended chains (Hudson and Lovinger, 1993).

Hedrites and spherulities have crystallinities significantly smaller than those for solution grown lamellas, mainly because of a larger degree of supercooling that results in a smaller crystal stem length. In multilamellar structures, not all of the noncrystalline component resides in chain folds and chain ends, particularly when the nucleation rate is large. Under that condition a given chain can be incorporated in more than one lamella leading to the presence of an interlamellar traverse.

2.2.3 Fibers Fibers are long, narrow, ribbonlike structures, having a different chain orientation from that present in lamellas. In these structures the chain (*c* crystallographic axis) orientation is mainly along the ribbon direction; it is not perpendicular to it, as found in lamellas. Fibers are usually composed of smaller units, fibrils, microfibrils, and nanofibrils, oriented in the same direction. Fibrillar structures can be formed naturally, during synthesis, from solution, from the melt, from a gel, or from quiescently melt-crystallized material with the chains being placed in extended conformations during the crystallization or recrystallization process. Fibers can be prepared from crystallizable polymers with flexible chains, as well as from those with completely stiff or semistiff chains. Depending on the method of preparation, fibers from flexible-chain polymers can contain extended noncrystalline portions of chains and chain folds, or they can have perfect or nearly perfect order, as shown schematically in Figs. 9(a) and 9(b), respectively.

2.2.4 Epitaxial Growths Epitaxial or oriented overgrowth of flexible-chain polymer crystals on crystalline substrates can occur from solution or the melt.

Epitaxial crystallization of a polymer on the surface of a highly oriented crystalline film of another polymer has been carried out by pressing thin films of the two polymers together and applying a tensile stress during the melt crystallization process (Gross and Petermann, 1984).

The nucleation of folded-chain lamellar growth on a small group of extended chains of the same or a different polymer is another form of epitaxial growth. In this type of crystallization the *c* crystallographic axis, usually the chain axis, in the lamellas and in the fiber are parallel. A schematic representation of folded-chain growth on extended chains is shown in Fig. 10.

2.2.5 Dislocations and Defects Microscopic defects in crystallized polymers include

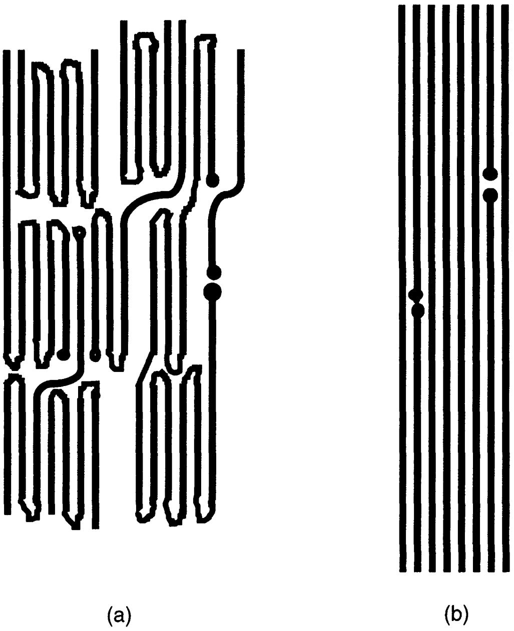

FIG. 9. Fibrillar crystallization. (a) Cold-drawn melt crystallized, (b) ultradrawn solution crystallized.

1. localized deviations from a periodic arrangement within the crystal lattice caused by screw and edge dislocations,
2. the changes in overall order occurring at lamellar surfaces and between lamellas, and
3. chain disorder within a crystal lattice.

Edge and screw dislocations in a crystal lattice are generated by line translations (see CRYSTALLINE STATE). The existence of a screw dislocation in polymer lamellas with a size of about 10 nm is readily observed by electron microscopy, because the dislocation causes the appearance of a lamellar growth spiral (Keller, 1958). Dislocations of the order of one repeat unit and dislocation networks are observed on polymer lamellas using moiré patterns generated in dark-field TEM by two superposed but misaligned lamellas.

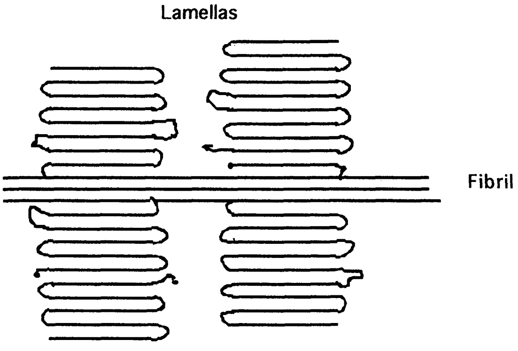

FIG. 10. Epitaxial lamellar growth on an extended chain fibril.

Chain folds and chain ends at lamellar surfaces and interlamellar chain traverses between neighboring lamellas, as discussed in Secs. 2.2.1 and 2.2.2, can be considered to be surface defects. Folds on single lamellas have been imaged using decoration techniques, employing evaporated metal atoms or evaporated and degraded polymer molecules (Wittmann and Lotz, 1985). Lamellar sectors and fold direction are delineated by those methods.

Chain disorder within the crystal lattice includes kinks, jogs, and twists in a crystal stem or stems as well as chain ends and folds. Kinks have been observed on fracture surfaces of extended chain lamellas prepared under pressure. Kinks can also be introduced into single lamellas by stress application (see Sec. 4.2).

2.3 Liquid-Crystalline Mesophases

Some polymer fluids exhibit one- or two-dimensional order involving all of the chain, parts of the main chain, parts of side chains, or parts of both the main and side chains.

2.3.1 Types of Mesogens Flexible-chain polymers can exhibit mesophases in which there is side-by-side chain alignment with disorder and movement along the chain direction. One such is the pseudohexagonal or hexatic liquid crystalline state (Kojima and Magill, 1986). Adequate cooling of this mesophase leads to crystallization and the attainment of three-dimensional order.

Polymers with chains composed of

1. alternating rigid rodlike and flexible main-chain sections,
2. rigid rodlike side-chain units and flexible main-chain sections, or
3. disk-shaped moities

can form heat-sensitive (thermotropic) liquid-crystalline mesophases. Polymers having completely inflexible chains form mesophases only in solution (lyotropic). The order in a liquid-crystalline mesophase of a polymer with rodlike mesogens can be one dimensional, nematic, with the rigid rodlike parts of the polymer molecules possessing an average molecular orientation called the director. A two-dimensional arrangement, smectic, with the rigid sections in straight or oblique rows can occur. A third arrangement of the rodlike sections is cholesteric and involves nematic layers arranged with a helical twist relative to each other. The cholesteric phase is only observed for optically active polymers or inactive polymers mixed with optically active small molecules. Molecules with rigid disk-shaped sections can form discotic liquid-crystalline mesophases in which the disk-shaped parts are stacked in columns. Some liquid-crystalline arrangements involving polymer chains are illustrated in Fig. 11.

Amphiphilic polymers in which alternate carbon atoms in the main chain have acidic and basic substituents form thermotropic liquid-crystalline mesophases, as a consequence of ion–dipole interaction between side-chain substituents on different chains. Block copolymers (see Sec. 2.4) can form lyotropic mesophases containing a close-packed array of spheres, a hexagonal array of cylinders, or a planar array of polymer layers.

2.3.2 Mesophase Textures A domain of rodlike mesogens oriented in the same direction and placed between crossed polaroids can transmit light. However, orientation of the rodlike parts of the chains along the polarizer or analyzer directions or perpendicular to the analyzer and polarizer will lead to extinction of the light and the field will appear dark. The complete disorientation of the rodlike parts in the isotropic liquid also causes extinction. Other orientations of the rods can bring about light transmition. Interaction of the light waves with the oriented mesogenic units induces a wavelength-dependent change in polarization causing the light transmitted through the analyzer to have one or more colors, when white light is used for the source.

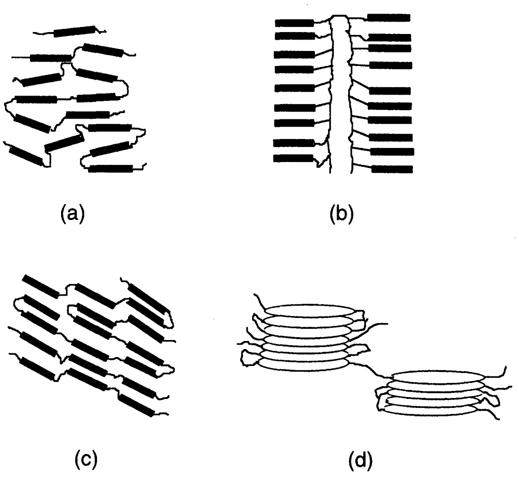

FIG. 11. Liquid crystalline mesophases: (a) main-chain nematic, (b) side-chain smectic, (c) main-chain smectic, (d) main-chain discotic.

When a nematic liquid-crystalline mesophase is first formed by melting a thin microcrystalline film sample, many domains are present and many entangled dark lines, disclinations (line rotational defects), appear in the microscopic pattern (Noel *et al.*, 1984). Usually the number and tortuosity of these lines decrease with time as a result of disclination coalescence and mesogen alignment; an example of this texture at an early time is given in Fig. 12(a). Alignment can be accelerated by shearing at low rates or by the application of a high-strength electrical or magnetic field. However, disorder will occur on cessation of shearing or field application. As the temperature is increased closed loops are formed, which eventually disappear. Thinner films of a nematic mesophase can exhibit a schlieren texture [Fig. 12(b)]. This texture contains singular points (marked by arrows in figure), connected by two or four intersecting black wavy stripes or brushes. The points are disclinations viewed end-on. The dark brushes occur where the orientation of the director is parallel to the analyzer or polarizer directions; regions transmitting light contain domains for which the director orientation is not parallel to these directions.

Smectic mesophases can display a schlieren texture with four brushes, a focal conic, or a fan-shaped texture. Cholesteric mesophases can have a fingerprint and a ribboned texture and in reflected white light show iridescent colors. Dendritic and fan-shaped textures have been reported for polymers with disk-shaped mesogens (Percec *et al.*, 1992).

2.3.3 Disclination Imaging The director field in the vicinity of a line rotational defect, or disclination, in a thin sample of a

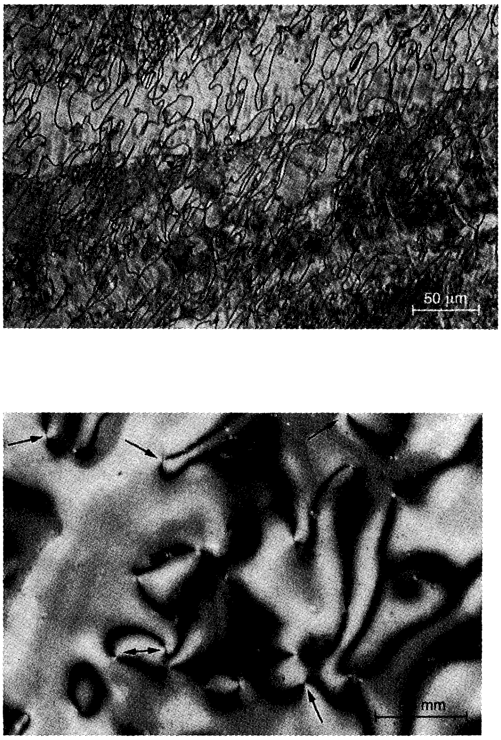

FIG. 12. Optical micrographs using polarized light for copolyesters in a nematic mesophase, showing (a) threaded and (b) schlieren textures. Courtesy of C. Noel. [(a) reprinted with permission from Noel *et al.*, (1984).]

polymeric liquid-crystalline mesophase can be imaged using TEM. The mobile mesophase is quenched to form a nematic glass; then the temperature is raised to about 20° below the crystalline melting point and the glass annealed, leading to the formation of many lamellar crystals with sizes smaller than the disclination size (Wood and Thomas, 1986). The lamellas are viewed edge-on and the director is normal to them.

Disclinations can occur in dipolar or in quadrupolar (Lehman) clusters. Nematic polymer mesophases aligned in a magnetic field of intermediate field strength display both dipolar and quadrupolar clusters, and extensional flow of oriented nematic liquid crystals brings about the appearance of many Lehman clusters (Hudson and Thomas, 1991a, 1991b). Inversion walls, where the director inverts by 180° from one side to the other, have been observed in nematic liquid-crystalline mesophases under the same conditions producing Lehman clusters.

2.4 Phase-Separated Block Copolymers

Block copolymers are polymers containing sequences of two or more repeat units. Various types of block copolymers that have been prepared are described below. Many polymers are incompatible to some degree and mixtures of them will undergo phase separation, if in solution or melt. This process also occurs in block-copolymer samples, if the blocks are long enough and if the constituent polymers are incompatible. For noncrystallizable flexible polymers the chains in phase-separated domains will be randomly coiled. If one or more of the polymers present crystallize then additional phases are formed.

2.4.1 *AB*, *ABA*, and Star-Block Types

In an *AB* block copolymer a sequence of one type of repeat unit is covalently linked to a sequence of another type; in an *ABA*-type block copolymer the *B* sequence is linked at both ends to *A* sequences; and in a star-block copolymer sequences of one type of repeat unit are attached to a multifunctional nucleus at one end and to sequences of a second type of repeat unit at the other end, as shown schematically in Fig. 13. The attachments between the *A* and *B* portions cause them to stay in close proximity to each other, greatly limiting the size of the separated phases and also affecting the morphol-

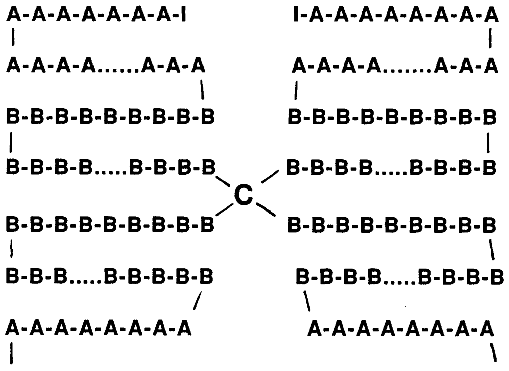

FIG. 13. Star-block copolymer structure with four arms. *A* and *B* denote different types of repeat units, *I* an end unit, and *C* a multifunctional linking agent.

ogy of the phase-separated system. The four phase-separated morphologies observed for two-component noncrystallizable block-copolymer systems (*AB*, *ABA*, and star block) are illustrated in Fig. 14 and include

1. spheres of *A* embedded in a continuous *B* phase,
2. cylinders of *A* in a continuous *B* phase,
3. the ordered bicontinuous double-diamond type, and
4. layers of *A* separated by layers of *B*.

These are listed in order of increasing volume fraction of the *A* component. The precise morphology adopted by a phase-separating *AB*-type block copolymer depends on the composition and the molecular weight. Inclusions or layers of 20–30 μm are observed. Changes in morphology can occur for *ABA* block-copolymer systems, if the components are interchanged.

Flexible-chain block copolymers containing a crystallizable component do not show the morphologies discussed above. For quiescently crystallized flexible-chain *AB* or *ABA* block copolymers, single lamellas are expected during prenucleated crystallization from dilute solution and multilamellar structures would appear from .moderately concentrated solution without seeding. If the two components are incompatible, the chains of the noncrystallizing component will separate from the folds of the crystallizing component.

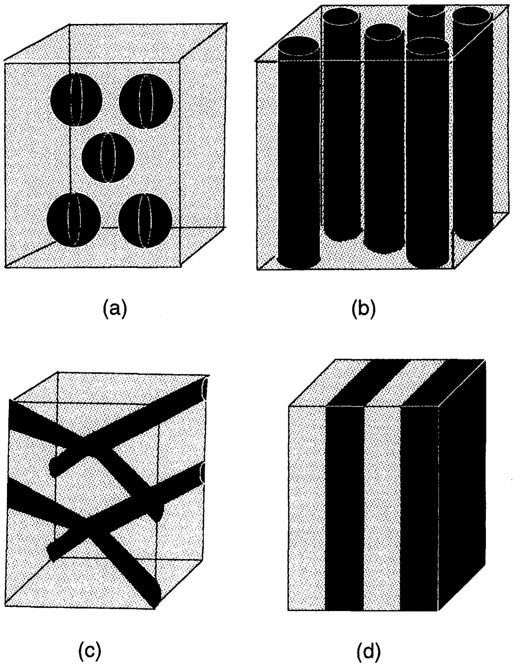

FIG. 14. Microphase separation in *AB* and star-block copolymers. (a) Spherical inclusions, (b) cylindrical inclusions, (c) ordered bicontinuous double-diamond inclusions, and (d) layers.

2.4.2 ABC Type Ten different phase-separated morphologies have been reported to date for three-component block-copolymer systems (*ABC* type with *B* the middle block). Eight of these are shown schematically in Fig. 15 and involve spheres, spheres with shells, cylinders, cylinders with shells, and layers (Woodward, 1995). Also, mutually interpenetrating double-diamond frameworks

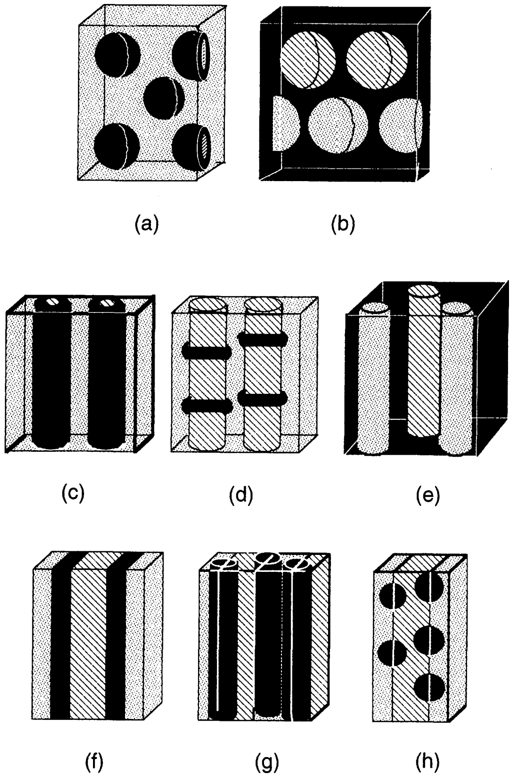

FIG. 15. Microphase separation in *ABC* block copolymers (the *B* portion is black): (a) spherical inclusions with spherical shells, (b) separate spherical inclusions of *A* and *C* in *B*, (c) cylindrical inclusions with cylindrical shells, (d) cylindrical inclusions with rings, (e) separate cylinders of *A* and *C* in *B*, (f) four layers, (g) cylindrical inclusions at layer interfaces, (h) spheres at layer interfaces.

and spheres with hexagonal shells have been found.

2.4.3 Segmented Type In this type of block, copolymer sections of one repeat unit alternate with sections of another many times per chain. These copolymers form lamellar structures on crystallization (Woodward, 1988).

2.5 Phase-Separated Blends

Mixing of two incompatible amorphous homopolymers sufficiently, prior to obtaining a rigid or semirigid mass, can lead to microphase separation in which particles of the constituent present in the smaller quantity are dispersed in the other, more prevalent, constituent. Cooling of the mixture to form a glass of one or both components gives a metastable system; at equilibrium, two separated phases would be present, one rich in one component and the other rich in the other component. Subinclusions of the dominant constituent within the dispersed particles of the lesser can form in the cooling process as a result of a decrease in miscibility with decreasing temperature. The size of the dispersed particles depends on the polymers chosen, the temperature, and the mixing speed, as well as other processing variables. The dispersed particles in an unstressed blend are expected to be approximately a spherical collection of randomly coiled chains. A spherical inclusion would minimize the surface area present and the interfacial energy. The application of mechanical stress during mixing can lead to elongated dispersed particles.

Various morphologies have been reported for binary homopolymer/block-copolymer blends, including

1. rounded particles of the microphase-separated block copolymer in a continuous homopolymer matrix,
2. small interspersed regions of each constituent,
3. a double-diamond structure, and
4. lamellar channels connected by periodic columns, which is a "mesh" or "lamellar cantenoid" structure.

When one of the constituents in a binary blend of two flexible homopolymers is crystallizable, spherulites or hedrites can appear either from the melt or from a cast film. If the two polymers are miscible, extinction rings, attributed to lamellar twisting (see Sec. 2.2.2), are evident on the spherulites where none exist for the pure polymer. If both homopolymers in a binary blend are crystallizable but do not cocrystallize, spherulites of both with large reductions in spherulite size, changes in the amount of crystallization, or elongated growths can be observed.

2.6 Composites and Laminates

Composites, heterogeneous mixtures of two or more components, can be prepared with a linear-chain polymer or a rigid network as the continuous phase and short fibers or particles of another material, not necessarily polymeric, making up the dispersed phase. Both crystallizable and noncrystallizable linear-chain polymers are used to form composites. Glass fibers, glass beads, carbon fibers, carbon black, kaolin, and mica are some of the particulate materials used. More than one type of filler can be used in the same composition.

The particle size of the dispersed material is usually many times larger than that found in blends. The shape of the dispersed particles will depend on the material used and can be spherical, rodlike, or flat. The degree of orientation of fibrous components will depend on the composition and the sample preparation method; in thick samples fiber orientation varies with sample depth. Various fiber reinforcement patterns can be used, including uniaxially oriented, biaxially oriented, and random. If a composite contains particulates, the degree of dispersion will depend on the materials and the mixing technique.

The components of a composite are incompatible and form separate phases. The dispersed component in a composite will have the same form before and after formation of the composite, although the particle size or fiber length, depending on the material, can be reduced during processing. The morphology of the continuous polymer phase in a composite containing particulates can differ from that for the polymer alone. Particulates can act as nucleating agents for crystallization and lead to a loss of spherulite texture. When certain fibers are present in a supercooled crystallizable polymer melt, transcrystallization occurs (Chatterjee *et al.*, 1975). Cylindrical columns of crystallized material, with diameters the same as those for the free spherulites present, form around the fiber. As a result of crowding on the fiber caused by the nucleation of many potential spherulitic structures, development in the long direction of the fiber is impeded, while radial growth occurs in a normal fashion.

Laminates usually contain alternating layers of two or more materials. Laminates can be formed using pieces of a woven fabric as one component and a liquid prepolymer that polymerizes to give a rigid-network polymer as the other component. Laminates can be prepared containing alternating layers of two linear-chain materials or of layers of a continuous-fiber/rigid-network composite with a change in the fiber orientation from layer to layer.

3. EFFECTS OF PROCESSING ON POLYMER MORPHOLOGY

3.1 Uniaxial Orientation during Crystallization

Application of a uniaxial tensile stress during bulk crystallization of a thin film can give lamellas with the crystallographic *c* axis along the deformation direction (Gohil and Petermann, 1982). TEM investigation of uniaxially melt-drawn polyethylene films, following annealing, shows that adjacent lamellas have many chains in common.

Extrusion of a flexible-chain polymer through a small orifice, such as present in a capillary rheometer, yields tapered interlocking lamellas epitaxially crystallized on extended chains (Bashir *et al.*, 1986). The lamellas are arranged perpendicular to the extrusion direction, while the extended chains and the crystal stems in the lamellas are oriented along the extrusion direction. The lamellar tapering taking place during crystallization is attributed to a temperature gradient existing in the extruder.

3.2 Skin/Core Morphology

Injection of a polymer melt into a mold by the application of pressure causes chains to assume elongated conformations in the direction of the applied stress. A higher degree of orientation is usually achieved with injection molding than by extrusion, because of the forces involved. If the surface of the mold is cold and the sample is thin, solidification will occur quickly, freezing in some or all of the chain orientation throughout the sample. If the surface of the mold is cold, but the sample is thick, cooling of the polymer in the interior is slower than near the surface and morphological differences will be observed due to a return to less elongated conformations of the chains in the interior prior to solidification. For some crystallizable polymers the center portion of thick samples (the core) will contain undeformed spherulites and the surface (the skin) will consist of highly oriented chains. For other polymers the spherulites in a region between the skin and the core have conical shapes due to extended lamellar growth caused by the temperature gradient present. Crystallizable polymers having high glass-transition temperatures exhibit an unoriented noncrystalline skin and a spherulitic core (Sawyer and Grubb, 1987).

3.3 Blend Morphologies

The morphology that results on the extrusion of a blend depends on the relative viscosities of the polymers present, the composition, the processing parameters, such as the flow rate and the temperature, and the sample thickness. At high flow rates the extrudate can contain fibers of the less viscous component; both irregularly shaped rods and spheres have been observed in the same sample. Injection molding of blends can lead to polymer degradation, thereby yielding unexpected morphologies.

3.4 Biaxial Orientation during Molding

If biaxial orientation occurs during molding, lamellas stacked normal to the extrusion direction and adjacent piles connected by fibrils in the extrusion direction are observed, as a result of sequential extension in two perpendicular directions.

4. MORPHOLOGICAL TRANSFORMATIONS OF POLYMERS

4.1 Thermal Effects

A temperature increase can bring about the following:

1. a change from an isotropic or liquid-crystalline glass to an isotropic or liquid-crystalline liquid, respectively,
2. transformation of a microcrystalline material with glassy interlayers to a microcrystalline material with rubbery interlayers,
3. a transition from a microcrystalline state to a liquid-crystalline or isotropic liquid state at the equilibrium melting temperature,
4. a change from one crystal form to another, or
5. a first-order transition of a mobile liquid-crystalline fluid from one type of order to another type or to a disordered isotropic liquid.

These five processes can usually be reversed. A crystal form change occurring via melting and recrystallization is not reversible and two crystal forms can exist together without spontaneous conversion to one form. Crystallizable polymers supercooled to a glass can be crystallized by heating to a temperature where the polymer is below T_m but above T_g for a time that allows adoption of the appropriate conformation of each repeat unit involved.

The morphologies before and after a cyclic thermal process may not be the same. Heating amorphous block copolymers cast from solution to a temperature above T_g for all of the components present, followed by cooling, can lead to morphological changes. When polymer crystal lamellas are annealed at temperatures above the crystallization temperature but below the equilibrium melting temperature, the lamellar thickness increases; upon cooling a change back to the original lamellar thickness does not take place.

4.2 Mechanical Stress Effects

Lyotropic liquid-crystalline mesophases subjected to shear exhibit banding that is perpendicular to the flow direction. This band formation is caused by mesogen disorientation with a periodic variation in the director, and it occurs upon removal of the field and evaporation of the solvent, if present. If the system remains in a mobile state after the bands are formed, a very slow process involving transition from banding to a polydomain situation takes place. For some fibers obtained from liquid-crystalline mesophases, banding disappears upon annealing.

Upon tensile stress application isotropic rubbers will easily deform, giving elongated chain conformations; a rubber specimen will recover its original dimensions and conformational distribution on stress release, if the system is a crosslinked one. Triblock copolymers containing a rubbery component present as spherical shells and two glassy components can be elastically deformed and returned to their original dimensions upon stress release. Cylindrical inclusions of a rubbery component in a glass matrix, subjected to a shear stress applied at a right angle to the direction of the cylinders, rotate by 90° into the shear direction.

Glassy homopolymers and blends undergo localized plastic deformation and form crazes, networks of voids, and fibrillar elements oriented in the stress direction (Kausch, 1983). Compressive stress can cause the formation of shear bands, due to the lateral movement of sections of the material without voiding. Shear banding and crazing can occur together in ductile glassy polymers under oscillatory stress.

Microcrystalline polymers will yield and undergo relatively large amounts of plastic deformation, which remains after stress release; this process is known as cold drawing. Tensile stress applied to single lamellas that have been deposited on a polymer film which is subsequently drawn causes

1. lamellar thinning in the stress direction and the appearance of a void network in the thinned regions at low stress amounts,
2. the appearance of fibrils in the deformation direction at higher deformations, and
3. shear bands at various angles and buckling more or less at right angles to the shear direction.

For lathe-shaped lamellas deformation also yields kinks and twin bands at lower deformations. For spherulites both localized yielding (inhomogeneous) and elongation and yielding of all parts (homogeneous) have been observed, with the two types usually occurring together. Both interlamellar and intralamellar yielding occur when the deformation is primarily inhomogeneous.

Ultradrawn fibers, tapes, and films, in

which there are few, if any, chain folds, have been prepared from flexible-chain polymers starting with as-polymerized and solution-cast gel samples. Biaxial drawing of dried films of ultrahigh–molecular-weight flexible-chain polymer, obtained by extrusion of a concentrated solution, can give a porous product.

Application of compressive stress to crystallized polymer samples creates shear bands at angles of ±45° with respect to the flow direction, tilting of shear bands, lamellar kinking, orientation and fragmentation, or crystal slip depending on the type and amount of compression and the sample morphology.

4.3 Effects of Solvents and Other Chemicals

Solvents, as vapor or liquid, can cause changes in morphology of a crystallized polymer by a dissolution and recrystallization process, induce crystallization in glassy crystallizable polymers, or induce crazes in glassy polymer blocks under compression. Acids and bases attack both the amorphous and crystalline portions of crystallized polymer samples, causing degradation and chemical modification.

4.4 Environmental Effects

Oxidative degradation at the surface can take place when a predominantly hydrocarbon polymer is heated in air. Environmental stress cracking can occur on polymer samples under constant load.

4.5 Irradiation Effects

Ultraviolet irradiation in air can cause surface embrittlement, raised regions on the surface, and development of spiral defect tracks along which fracture occurs.

Ion etching in air or argon gas strips away parts of polymer surfaces. The electron beam used in scanning electron microscopy can cause the appearance of grooves, cracks, and craters.

GLOSSARY

Blend: A compatible, partially compatible, or incompatible mixture of two or more polymers.

Block Copolymer: A polymer containing sequences of two or more repeat units joined covalently.

Compressive Stress: A compressive force per unit area of surface. Compression can be carried out uniaxially, where pressure is applied to the exposed end of a sample enclosed in a rigid chamber or die, or under plain strain conditions, where pressure is applied at opposite ends of an unenclosed sample.

Configuration: The way in which the atoms in a molecule are bonded to each other. Many isomers, molecules with the same chemical formula but with different atomic arrangements, are possible when the number of atoms is large as it is in polymer molecules.

Conformation: The spatial projection of a molecule due to allowed rotation about covalent bonds. For example, in the butane molecule, $CH_3CH_2CH_2CH_3$, rotation about the CH_2—CH_2 bond can occur at 25 °C, giving different spatial arrangements of the two CH_3 groups with respect to one another. The potential energy for the molecule varies with the rotation angle, and is lowest when the nonbonded atoms are farthest apart.

Crystallinity: The relative amount of crystalline regions in a sample. This is usually expressed as a fraction or a percentage of a two-phase or three-phase system. In a two-phase system the other phase is amorphous or noncrystalline; in a three-phase system a phase with intermediate order exists.

Crystallite: A collection of portions of chains in a three-dimensional repeating array. These portions are usually attached to other portions that are noncrystalline.

Degree of Supercooling: The number of degrees Celsius a crystallizable system is cooled below T_m^0 prior to the onset of crystallization. Crystallization occurs isothermally if its onset follows cooling to a constant crystallization temperature.

Equilibrium Melting Temperature, T_m^0: The melting temperature observed for a homopolymer with an infinitely large crystal stem length. The melting temperature of polymer lamellas containing folded chains is dependent on the crystal stem length and is lower than T_m^0.

Extrusion: A process in which a mobile but viscous material is forced through an orifice, giving the extruded sample a particular shape. If the sample is cooled during extrusion, crystallization or glass formation can occur, causing the sample to retain this shape although the dimensions may undergo a change.

Glass: A liquid state in which the chain segment motion is confined to oscillation about energy minima.

Glass Transition Temperature, T_g: A temperature separating the thermal region in which all or portions of the chains are confined to a particular conformation from the thermal region where the chains have conformational mobility.

Graft Copolymer: A polymer containing sequences of one repeat-unit type attached as branches on a chain of another repeat-unit type.

Homopolymer: A chain containing one type of chemical unit repeated many times with successive units held together by covalent bonds; because of valency requirements the end units are different from the ones in the body. Examples of repeat units are given in the text.

Injection Molding: A process in which a viscous fluid is pushed into a closed area having a particular shape. Following solidification, the mold is opened and the sample removed.

Liquid Crystalline Mesophase: A liquid phase with one-dimensional or two-dimensional order.

Monomer: A small molecule precursor of a synthetic polymer; these can be unsaturated, e.g., propylene, $CH_3{-}CH{=}CH_2$, or butadiene, $CH_2{=}CH{-}CH{=}CH_2$; occur as rings, e.g., ethylene oxide; or contain functional groups, e.g., caproic acid, $NH_2{-}(CH_2)_5{-}COOH$.

Nucleation: The initiation of crystallization by small ordered regions of atoms, molecules, parts of polymer chains, or foreign bodies.

Plastic Deformation: A change in dimensions caused by the application of a stress that leads to a permanent deformation in the sample after removal of the stress.

Rubber: A polymer liquid phase in which the chain segments can undergo conformational changes in the absence of an applied stress.

Shear Stress: A force per unit area applied at right angles to two opposite faces of the sample and in opposite directions.

Statistical Copolymer: A polymer with one type of repeat unit mixed statistically with another in the chain.

Strain: Change in dimensions of a body due to stress application.

Tensile Stress: A tensile force per unit area. Tension is brought about by application of forces in opposite directions at opposite surfaces of a sample.

Yielding: See **Plastic Deformation**.

INTRODUCTION

Polymers in an electric field exhibit a redistribution of charges that are mobile enough to respond in the time scale of the applied field. No polymers are completely free of charges. However, in most polymeric materials, the number of free charge carriers is very small, and their mobility is very low,

so that polymers are essentially insulating materials. Low dc conductivity σ may often be attributed to impurities (ions) and a small concentration of electrons or holes that may be injected from electrodes, particularly at high fields. At very high fields, the injected carriers will lead to a variety of breakdown phenomena.

If the concentration of intrinsic thermally generated or photogenerated mobile carriers and their mobility is higher, polymeric materials exhibit semiconducting properties. Usually the conductivity of polymeric insulators and semiconductors varies exponentially with temperature. Because the mobility and concentration of charge carries are thermally activated, the properties of polymeric semiconductors cannot be described using classical models elaborated for covalent semiconductors.

If the diffusion of mobile charges is spatially limited, the dc conductance is absent, but ac conductivity can be observed. If the limitation of carrier mobility is important, e.g., at the phase boundary, interfacial polarization occurs. The polarization may also be induced by the redistribution or partial orientation of dipoles bound to the polymer chains in the direction of electrical field. The polarization effects are related to dielectric properties characterized by the dielectric permittivity, which is frequency dependent. Low concentrations of charges and dipoles in polymeric materials are responsible for their good dielectric properties, which can be modified by the chemical constitution and structure of the polymeric system.

Polymeric materials can exhibit high conductivity when the chemical structure of the polymer chain is such that a large number of delocalized charge carriers can be thermally generated (low ionization potential of the macromolecular chain) or enhanced by molecular doping using donor or acceptor molecules. These systems are polymeric conductors; however, the charge transport mechanism differs from that of metals.

1. BASIC CONCEPTS OF ELECTRONIC STRUCTURE OF INSULATING, SEMICONDUCTING, AND CONDUCTING POLYMERS

All materials when subjected to an electrical field show electronic and atomic polarizations. They depend on the frequency and are active at $\omega = 10^{-12}$ to 10^{-15} s^{-1}. These phenomena are responsible for optical properties. The most important for polymeric dielectrics is the polarization connected with the presence of dipoles bound to the backbone or with the pendant groups. Under an electric field, they undergo orientation that is frequency and temperature dependent. When the electric field is removed, this polarization disappears with time and with temperature increase, and it is called relaxation polarization. It defines the dielectric permittivity ϵ_r, the value of which is in consequence frequency and temperature dependent. For a good insulating material, the concentration of mobile dipoles must be low, and ϵ_r values are low. Usually, nonpolar saturated polymers are oxidized to some extent, and the presence of C=O groups is responsible for an increase of ϵ_r values. High values of ϵ_r are suitable for capacitor materials, but they exhibit dielectric losses at certain frequencies, which is an important drawback. The chemical composition and structure of the polymeric material must be designed to the needs of particular applications (McCrum *et al.*, 1967).

In the solid state, organic molecules, including macromolecular systems, retain their identity and interact weakly through van der Waals or electrostatic forces. The electron–electron interactions within a macromolecular chain are stronger then those between chains. The electrons are moving in a nonperiodic potential, which varies with time within an isolated molecule because of the existence of many possible conformations. Most polymers are amorphous or partially crystalline solids. The lack of periodic long-range order distinguishes polymers from covalent semiconductors. This fact implies that physical phenomena in an electric field are different in polymers than in covalent semiconductors and dielectrics.

When a charge carrier is injected into a polymer, it changes the electronic charge density at the molecular site that it occupies and at the neighboring molecular sites. This results in intramolecular and intermolecular relaxations, which lower the energy of the system by the relaxation energy E_r (Duke *et al.*, 1978). The intermolecular and intramolecular contributions to relaxation energies can be large. For polymers, usually E_r(intra) = E_r(inter) = 1–2 eV; therefore, molecular anions or cations are stable and contribute in polymeric insulators to conductivity and surface charging. The intramolecular contributions depend on the local molecular structure near the injected charge. Local variations in composition and chemical constitution cause spatial fluctuations in the site energies of charge in these materials. Such fluctuations are important because they create localized molecular-ion states in polymers, which are involved in contact charge exchange (i.e., contact charging of pendant group polymers, e.g., polystyrene), and extrinsic localized molecular-ion states that control the transport properties of molecularly doped polymers. The average value of intermolecular contributions to the relaxation energy depends on the dielectric response of the medium and may be determined from the measurements of electronic motion in the system (photoemission, UV absorption, electron transfer).

Polymeric solids consisting of molecular units characterized by low ionization potential or high electronic affinity exhibit semiconducting properties. To this class of polymers belong unsaturated polymers, macromolecular systems containing aromatic or heterocyclic moieties, etc. The most important is the extent of electron delocalization and the energy needed to transfer an electron from the highest occupied to the lowest unoccupied molecular orbit. The "energy gap" is usually above 1 eV, and the generation of mobile carriers as well as their mobility is thermally activated. To the large class of semiconducting polymers belong such systems as show an ability to form charge transfer complexes (CT complexes) usually with low–molecular-weight additives of low ionization potential or high electron affinity and polarizability. Conductivities of semiconducting polymers of the order of 10^{-6} to 10^{-3} S/cm are related to hopping transport on localized states (Stolka, 1988).

Electronic motion can occur along a one-dimensional molecule. Reduced dimensionality implies that the electronic states are governed by collective ground states called Fermi-surface instabilities. In a one-dimensional coupled electron-phonon system, because of the Peierls instability, distortion of the backbone lattice occurs, which creates a bond alternation and a gap at the Fermi surface. Electronic states are also localized as a result of the inherent disorder in polymers. This fact results in low conductivity and thermally activated charge mobilities, in contrast to energy-band semiconductors for which carrier mobility decreases with increasing temperature as T^{-n} ($n > 0$). Polymeric materials characterized by high extent of delocalization of electronic states in the main chain and the ability to undergo redox reactions (formations of molecular ions and/or radicals) due to molecular doping agents are conductors and show high conductivity, on the order of 10^{-1} to 10^{5} S/cm (Ku and Liepins, 1987).

2. DIELECTRIC POLYMERS

The basic theoretical concepts and theories for the dielectric properties are similar for low– and high–molecular-weight materials in crystalline or amorphous phases (more difficult interpretation in the last case). These basic concepts are presented in the article DIELECTRIC PROPERTIES OF INSULATORS, where the problems of local fields and the continuous-medium approximation are discussed.

Dielectrics are used in capacitors and as electrical insulation. The dielectric constant or dielectric permittivity of a material varies with temperature, frequency, its phase constitution, and structural defects. These factors influence the behavior of induced or permanent electrical dipoles in the polymer exposed to a steady or alternating electrical field. When the polarization lags the external field strength, it results in an electrical energy loss that appears as dissipated heat. It is proportional to the product of the relative permittivity and the tangent of the lag angle θ.

Energy loss in polymers arises also from ion and electron migration. Generally, overheating or cyclic heating results in degradation of a dielectric polymer and breakdown.

2.1 Theoretical Aspects

2.1.1 Conductivity in dc and ac Electrical Fields The relative permittivity of a polymer dielectric ϵ_r is defined as a ratio of the permittivity ϵ to the permittivity of empty space ϵ_0:

$$\epsilon_r = \epsilon/\epsilon_0. \tag{1}$$

Inserting of a dielectric into a parallel-plate capacitor whose plate area A is very large and plate spacing d is small would increase the capacity from $C_0 = (A/d)\epsilon_0$ to

$$C = (A/d)\epsilon = (A/d)(\epsilon_0\epsilon_r) = C_0\epsilon_r. \tag{2}$$

For dc, we have

$$V = \frac{Q}{C} = \int\frac{Idt}{C} \quad \text{and}\; I = C\frac{dV}{dt}. \tag{3}$$

If the dielectric contains free charges (electrons, holes, or ions), a dc field leads to a conductance of the material. Potential difference is connected with current density according to

$$\mathbf{J}_e = \mathbf{E}/\rho_e = \sigma_e\mathbf{E}, \tag{4}$$

where $\mathbf{E}$ is the electrical field [V/m] and ρ_e is called resistivity, and its reciprocal σ_e is electrical conductivity. Usually, volume resistivity ρ_e is given as a volume resistance reduced to a cubical unit volume and expressed in Ω m although the unit Ω cm is used frequently. Similarly, volume conductivity $\sigma_e = 1/\rho_e$ is used and expressed in $(\Omega\text{ cm})^{-1}$ or S/cm.

If the sinusoidal voltage is used,

$$V = V_0 \sin\omega t \tag{5}$$

where V_0 is the maximum voltage and $\omega = 2\pi f$, where f is the frequency and t is time then $I = CV_0 \cos\omega t$; i.e., the current is $\pi/2$ out of phase. This equation applies only to an ideal case, i.e., when a loss-free dielectric of $\sigma_e = 0$ is in the capacitor. For a real dielectric, the current lags voltage by $\pi/2 - \delta$, where δ is a measure of power loss:

$$W = \pi f V_0^2\epsilon_r \tan\delta, \tag{6}$$

where W is expressed in watts (W).

Small values of power loss, or loss factor, which is the product $\epsilon_r \tan\delta$, are characteristic of a good dielectric. The dissipation factor is $\tan\delta = \epsilon_1/\epsilon_2$ where ϵ_1 and ϵ_2 are given by the complex electrical permittivity function

$$\epsilon^* = \epsilon_1 + i\epsilon_2, \tag{7}$$

where ϵ_1 is the real part (the dielectric permittivity or electric inductive capacity) and ϵ_2 is the imaginary part (the dielectric absorption). Their dependence on frequency, temperature, and polymer structure will be discussed in Sec. 2.2.1.

A very important factor of major significance in judging the usefulness of an insulator is called dielectric strength. It will be discussed in Sec. 2.4.

Usually, for low-conductivity plastics—dielectrics—the values of resistivity ρ and conductivity σ are time dependent, and the apparent volume resistivity increases with increasing time. This effect is related to complex polarization phenomena that occur when an electrical field is applied. When a step voltage is applied to an insulator, its resistance and capacitance changes can be represented by known equivalent circuits: series circuit and parallel circuit. They can be used for elucidation of the above-mentioned time dependence of the current. A simple relation between current and voltage like Ohm's law is usually valid only for low fields. At higher electrical fields, super-Ohmic behavior is observed and related to the space charge (electronic or ionic charges trapped in various defects of the material under study). The theories of space-charge–limited currents (SCLC) and of the conductivity dependence on temperature and field for disordered dielectric materials are advanced and make possible the basic understanding of the dc conductance (Kao and Hwang, 1981).

2.1.2 Dielectric Polarization in dc and ac Electrical Fields: Dielectric Relaxations

When a dielectric is inserted between the charged plates of a capacitor, dielectric dipoles are formed whose electric moment is given by

$$\boldsymbol{\mu}_e = q\mathbf{r}, \tag{8}$$

where q is a positive charge separated from a negative charge of the same value by the distance $\mathbf{r}$. The origin of the vector $\boldsymbol{\mu}$ is at the negative charge. The total dipole moment per unit of volume is called the polarization $\mathbf{P}$, which is

$$\mathbf{P} = \epsilon_0\mathbf{E}(\epsilon_r - 1). \tag{9}$$

The field at a molecule in the interior of a dielectric between the plates of a charged capacitor is larger than the applied field **E**. Because of polarization that occurs within and on the surfaces of the dielectric, the dipole moment induced in the molecule depends on local field $\mathbf{E}_{\text{loc}}$, thus:

$$\boldsymbol{\mu}_{\text{loc}} = \alpha \mathbf{E}_{\text{loc}}. \tag{10}$$

The variable α is called the polarizability of the molecule. For N molecules per unit of volume, the total polarization is

$$\mathbf{P} = N\alpha\mathbf{E}_{\text{loc}}, \tag{11}$$

and

$$\epsilon_r - 1 = \mathbf{P}/\epsilon_0\mathbf{E} = N\alpha\mathbf{E}_{\text{loc}}/\epsilon_0\mathbf{E}. \tag{12}$$

The value of $\mathbf{E}_{\text{loc}}$ depends on the model accepted for its calculation. The simplest is the Clausius–Mossotti model from which it follows that

$$\mathbf{P} = (N\alpha/3)(\epsilon_r + 2)\mathbf{E}, \tag{13}$$

or

$$N\alpha/3\epsilon_0 = (M/d)(\epsilon - 1)/(\epsilon + 2); \tag{14}$$

here, M is molecular weight and d is the density. Debye (1945) derived the relation between the permanent dipole moment $\boldsymbol{\mu}$ and dipolar polarizability:

$$\alpha_0 = \mu^2/3kT. \tag{15}$$

The polarization can be divided into two parts: distortion polarization, which is independent of temperature (electronic polarization and atomic polarization), and dipole polarization. Thus we can write the following:

$$\frac{\epsilon_r - 1}{\epsilon_r + 2} - \frac{\epsilon_\infty - 1}{\epsilon_\infty + 2}\frac{M}{d} = \frac{N}{3\epsilon_0}\frac{\mu^2}{3kT}, \tag{16}$$

where ϵ_∞ is dielectric permittivity at very high frequency, related to electronic polarization.

The reexamination of the problem of the internal field by Onsager (1936) leads to a relation that takes into consideration interactions between the molecule and the field. When ϵ_r is large compared with ϵ_∞ (which is always small), the Onsager equation can be expressed as

$$2\epsilon_r/(\epsilon_r + 2)^2 \approx N\mu^2/3kT. \tag{17}$$

It implies many important correlations:

1. The dielectric constant is directly proportional to the number of polar molecules per unit volume.
2. The dielectric constant is proportional to the square of permanent dipole moment.
3. The dielectric constant is proportional to the reciprocal of the absolute temperature.

This equation is true for not very strong polar liquids. For polar liquids with hindered rotation of dipoles and for solids, Kirkwood (1939) generalized the treatment of the internal field. The use of the Kirkwood equation for polymers is not straightforward because of the mutual influence between segments of the chain so that the effective dipole moment decreases.

Orientation polarization occurs when the applied field interacts with the permanent electric dipoles that arise from the asymmetry of the molecule. For most materials, tanδ varies with frequency; the frequency of tanδ maximum is known as the relaxation frequency. The number and amplitudes of individual loss processes depend on the number of dipolar species and on their possible separate or cooperative motions (McCrum *et al.*, 1967). The dipole polarization is connected with reorientation of molecules or molecular segments; thus, the process is interfered with by the "friction" from the surrounding molecules. The reorientation of dipoles involves motion in viscous media, and the polarization process is delayed, reaching an equilibrium only after a relatively long time. When the electric field is removed, a long time is also needed for the polarization to disappear. This phenomenon is called dielectric relaxation. The time needed for the polarization to decay by $1/e$ of the original equilibrium value is called the relaxation time, being the reciprocal of the relaxation frequency.

Relaxation processes are evidently thermally activated, but no simple Arrhenius-type formula can be used for determination of the thermal activation energy and of the shift of the tanδ maximum with temperature. It is usual to plot the dielectric permittivity

ϵ_1 or ϵ_2 as a function of temperature or frequency as is shown in Fig. 1.

The identification and localization of loss peaks in different polymers is usually carried out using the nomenclature first suggested by Deutsch *et al.* (1954). The relaxations observed at the highest temperature (constant frequency) or at the lowest frequency (constant temperature) are called the α relaxations, and the others are called β, γ, etc. in order of decreasing temperature (or increasing frequency).

The broadening of relaxation spectra is still a subject of many experimental and theoretical studies. It is known that the simple Debye relation does not fit the experimental data for polymers, particularly for α and β relaxations. Semiempirical equations describing the broadening of the relaxation spectra [$\tan\delta = f(T)$ or $\tan\delta = f(f)$] have been suggested by many authors, e.g., Havriliak and Negami (1967). More advanced theories describing the temperature dependence of $\tan\delta = f(T)$ [or $\epsilon_1 = f_1(T)$ and $\epsilon_2 = f_2(T)$], including extended exponential relations as well as mode-coupling theory, make it possible to separate individual peaks of which the dielectric relaxation spectrum consists and to correlate the observed maxima with specific motion of particular polar groups or polar segments.

Molecular interpretations of the various loss regions should also take into account the physical structure of polymeric materials. In amorphous polymers, the loss region associated with the glass–rubber transition observed above the glass transition temperature T_g is called the α relaxation. It is related to the hindered rotation of the main chain. Below T_g, this backbone segmental motion is frozen in, and only local movements of small portions of the main chains as well as motions of pendant polar groups occur. Usually, there is a mixture of these effects, which are not easy to separate.

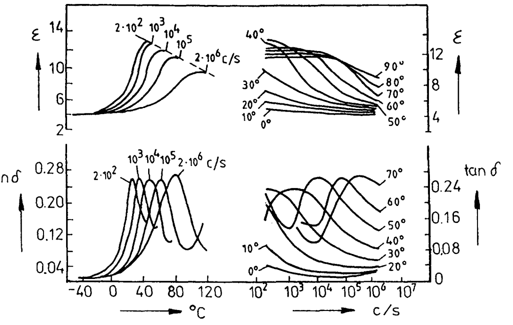

FIG. 1. Dispersion curves of ϵ and of $\tan\delta$ for poly(vinyl acetate) (Wurstlin, 1951).

In crystalline polymers, the interpretation of the loss peaks is complicated (McCrum *et al.*, 1967). At high temperature, low-frequency losses are often called α relaxations, but they are usually associated with the crystalline regions. There are further β, γ, etc. relaxations within disordered or amorphous phases. The highest amorphous peak is attributed to large segments of the main chain (associated with T_g) in amorphous phase, and the lower temperature peaks have a similar meaning as mentioned earlier.

The conformation and position of side groups play an important role in the mobility of the polymer chains, since they determine both the steric hindrance and chain packing. The chain conformation may, in a specific case, facilitate the formation of intermolecular or intramolecular hydrogen bonds leading to lowering of the mobility of main-chain segments and/or side groups. Bulky groups attached to the main chain with lower mobility increase the activation energy and relaxation time of the relaxation. It is interesting to note that large groups attached to side chains will increase partially the main-chain mobility; they still increase the hindrance, but the adjacent polymer chains are farther away. Those two effects will define the magnitude of the main-chain relaxations. The addition of low-molecular-weight material (e.g., plasticizer) to a polymer results in an increased separation of the chains, and the main-chain segment mobility increases. Addition of the plasticizer has only a small effect on side-chain relaxation because the side groups themselves act as plasticizer (internal plasticization). When the added molecules are able to form charge-transfer complexes with groups of main or side chains, an antiplasticization effect is observed to decreased molecular mobility.

Dielectric materials contain—as was mentioned before—freely migrating charges as free ions and/or electrons or holes. The migration of these charges in a dc field causes negative or positive ions to be accumulated on the positive or negative electrode, respectively. Polarization caused by charge migration is called space-charge polarization or ion polarization depending on the nature of the migrating charges. These polarization effects occur simultaneously with the polarization connected with dipole reorientation. Differentiation between the two processes, which show similar behavior, is often difficult. Much effort has been devoted to separating these two phenomena in experiments and theory, but this problem remains still actual.

Similarly to dc resistance, both dielectric permittivity and tanδ are related to the presence of moisture; ac properties are sensitive to the presence of moisture even in the absence of a continuous, low-resistance path. Thus, ac measurements respond precisely and quickly to moisture penetration (polymers with fillers, laminates, etc.). The ac properties are also sensitive to thermal aging, particularly to dielectric discontinuities such as voids, delaminations, etc.

Since ϵ_1, ϵ_2, and tanδ are determined by molecular structure, it is obvious that mechanical losses and electrical losses are closely related. One should, however, say that the mechanical and dielectric loss peaks do not always coincide because nonidentical motions are involved, e.g., nonpolar groups do not contribute to dielectric properties.

If a polymeric dielectric consists of chains built up of bulky, highly polar subunits whose orientation may not be random, the dielectric permittivity ϵ is dependent on direction and described by a third-rank tensor. The anisotropy of dielectric permittivity is important for discussion of nonlinear optical properties of polymers at high electric fields. In characterization of dielectric properties of polymers, the anisotropy of ϵ is usually neglected.

When the dielectric consists of two phases (two components) and one of them with dielectric permittivity ϵ' or conductivity σ' is dispersed in the second phase (matrix) (with ϵ'' or σ''), interfacial polarization occurs and energy is dissipated. This phenomenon was first discussed by Maxwell in 1883 and Wagner in 1914 (van Beek, 1967). The average bulk dielectric permittivity ϵ can be easily calculated, and it depends on the volume fraction of the dispersed phase. The separation of the expression that describes the dielectric permittivity ϵ of the dispersion into real and imaginary parts leads to formulas that contain the conductivity of the better conducting phase. The frequency dependence of the interfacial polarization is identical with that of simple (Debye-type) relaxation. This treatment is applicable for spherical particles without interactions. In polymeric materials, these conditions are rarely fulfilled, and particle shape is important in determining the magnitude of the effect; therefore, the effects of the shape of conducting dispersed particles (ellipsoids) and their orientation parallel or perpendicular to the field has been considered. Interfacial polarization occurs at frequencies below 1 MHz. Dielectric loss in an ac field and its maximum frequency depends on electrical properties of the components and on their distribution.

2.1.3 Dielectric Relaxations in Polymer Solutions The studies of dilute polymer solutions, where intermolecular effects are minimized, lead to much important information on the influence of chain structure on the dielectric behavior of polymers (Stockmayer, 1967). Dipole geometry defines the possible reorientations in electrical field. The dipoles can be connected with

a. flexible side chains (e.g., polyarylates),
b. rigid groups or atoms bound to the backbone [e.g., poly(vinyl chloride)], or
c. rigid groups in the backbone (e.g., polyesters).

Macromolecular dipoles arise from the vectorially summed contributions of individual chain dipoles (Volkenstein, 1963). The determination of dipole moment is a valuable pointer to polymer chain configuration and to polymer sequencing. The rotational isomeric-state model is often applied for calculation of the mean square dipole moment $\langle\mu^2\rangle$. One has to take into consideration the above-mentioned dipole contributions. If there are flexible side-chain dipoles, it is difficult to quantify how those dipoles contribute to the total polarization via backbone reorientation. The perpendicular dipoles are most common and represent the only dipoles present in poly(vinylhalides), unbranched polyoxides, polyimines, and polysulfones. The chemical structure of many monomers results in a long-chain dipole per residue; thus, they may make no contribution to $\langle\mu^2\rangle$ because of sequences of plane reflections. Perpendicular dipoles sum over all chain configurations regardless of long-range interactions, whereas parallel dipoles are subjected to some constraints such as skeletal bonds, leading to excluded volume. The knowledge of $\langle \mu^2 \rangle$ can be useful information concerning the relative equilibrium population of *gauche* and *trans* configurations in the system when reliable experimental data are available.

The rotational isomeric-state model is applicable to isolated macromolecules and to the assembly averaged total dipole. This model takes no account of internal field problems (the external field is usually modified by neighboring dipoles). The study of infinite dilute solutions and solutions in solvents of low dielectric permittivity relying on Debye's equation cannot lead to satisfactory results, particularly for macromolecules. The Onsager model with modifications (nonspherical cavities and elimination of discontinuity at the cavity edge) is more useful. It must be pointed out that the polymeric dipole moment is time dependent as a result of micro-Brownian movement of the chains and entanglements that must be correlated. The solution of the problem is the use of the correlation function approach. The theories of Kirkwood and Fröhlich provide a satisfactory basis for interpretation of the experimental results (Block and Walker, 1982).

The frequency dependences of ϵ_1 and ϵ_2 provide kinetic parameters for the relaxation process, and thermal activation parameters are accessible from variable temperature measurements. One should avoid charge migration, which is common in polyelectrolyte solutions or when macromolecular and solvent phase have different conductivities (the interfacial relaxations disturb the correct evaluation of dipole relaxations).

In semidilute solutions, detailed molecular motions or the interactions between molecules are not clarified as yet. The interpretation of the experimental data is usually done in terms of normal-mode process and segmental-mode processes.

2.2 Experimental Techniques

Electrical property measurements can be divided into low-stress phenomena, which are not particularly dependent on the electrical stress level (these measurement techniques will be described below), and high-stress phenomena, which will be analyzed in the discussion of electrical breakdown (Sec. 2.4.3).

Electrical test procedures often used for plastics materials include measurements of conductivity (resistivity) and measurements of dielectric properties. Techniques for the measurements of all important electrical properties of polymers are described in detail by Bartnikas (1987). Techniques for the measurement of resistivity (or conductivity) are described in ASTMD 257. There are three commonly used methods, which are based on the use of

1. a bridge (e.g., Wheatstone) comparison method;
2. a comparison method using a sensitive current-indicating device; or
3. the voltammeter method.

With the best available equipment, values of resistance as high as 10^{17} Ω can be measured. Insulation resistance is a combination of volume and surface resistance; that is why it is important to preserve correct measurement conditions. The leakage current from the guard to the measuring electrode is shunted in such a way that it is not measured. However, errors are introduced if the resistance between the guard and measuring electrode is less than about 100 times the internal resistance of the current-measuring device. When very high resistances have to be measured, the internal resistance, the time constant of the measurement, and the problem of guarding are increased. The surface of the dielectric measured and of the contacting electrodes must be very clean, because contamination strongly affects both the volume and the surface resistances. Electrode design is very important in the measurement of electrical resistance. It is sometimes specified in the test methods for specific materials. Round rather than square electrodes are most common. Thin coatings of conducting paints are useful, but the effect of dispersant or solvent on the plastic should be taken into consideration. Evaporated metal or thin metal foil electrodes are often applied; in the last case, a minimum of the adhesive (e.g., silicone grease) should be used, preserving good contact with the test specimen.

For resistance measurements to determine changes caused by moisture or elevated temperatures, gold electrodes are most suitable at very high temperature or under corrosive condition. Resistance measurement must be made in the desired surroundings and not after removal from the conditioning chamber. Usually, shield leads with high leakage resistance are used through the walls of conditioning chambers, and the shield is connected to the guard circuit during measurements.

For the tanδ or ϵ_1 and ϵ_2 measurements, an oscillating electrical field is applied to a specimen between two electrodes. In view of the importance of dielectric permittivity and tanδ and their dependence on frequency and temperature, there are many developments of instruments and methodology to measure these quantities. Usually, the measuring systems can be divided into dielectric spectrometer and dielectric thermal analyzer. A dielectric spectrometer scans the frequency response of permittivity and tanδ at a series of temperatures, often by Fourier transform of the "current vs time" response to a step change in the voltage. The dielectric thermal analyzer monitors tanδ at a constant frequency as the temperature is increased with time. The dc step response technique covers 10^{-4} to 10^{6} Hz.

Various methods covering the range 10^{-3} to 10^{10} Hz are mentioned here:

1. Schering-type bridge (capacitance bridge) (10^{-1} to 10^{6} Hz);
2. transformer ratio-arms bridge in which the ratio arms are closely coupled transformers; and
3. microwave bridges (10–70 GHz) or transmission lines (0.3–40 GHz).

Selection from these methods allows measurements to be made to the desired levels of accuracy and the frequency required. Resistance measurements are used to measure indirectly the influence of other factors, such as moisture, that may affect electrical strength and are useful in studying resin cure. Recently, ionic conductivity has been applied successfully to this purpose too. Dielectric thermal analysis instruments are used to investigate rheological properties, the glass transition, and other transition phenomena.

2.3 Materials

2.3.1 General Characteristics of Polymer Dielectrics Various degrees of molecular freedom are possible in polar polymers. If the crystalline lattice is highly imperfect and the shape of molecules is symmetrical so that there is considerable molecular freedom, the dipoles in a crystal may be able to make a substantial contribution to polarization effects. It is evident from Table 1 that dielectric permittivity ϵ_1, dielectric loss (tanδ), and electrical conductivity $\sigma = 1/\rho$ are interrelated and increase in about the

Table 1. Electrical properties of some polymers at room temperature (Ku and Liepins, 1987).

Polymer	Dielectric permittivity ϵ_1 (at 100 Hz)	Dielectric loss tan δ (at 100 Hz)	Volume resistivity ρ [S^{-1} cm]
Cis-polybutadiene	2.05	0.00051	3.1×10^{15}
Low-density polyethylene	2.22	0.0039	2.5×10^{15}
Cis-polyisoprene	2.26	0.0094	7.1×10^{16}
Trans-polyisoprene	2.27	0.00038	7.8×10^{16}
High-density polyethylene	2.30	0.00011	2.2×10^{16}
Polystyrene	2.31	0.00029	2.5×10^{16}
Polycarbonate	2.72	0.00115	2.2×10^{13}
Poly(dimethylsiloxane)	2.86	0.00025	5.3×10^{14}
Poly(phenylmethyl, dimethyl)siloxane	2.87	0.00010	3.0×10^{14}
Poly(diphenyl, dimethyl)siloxane	2.90	0.00041	9.8×10^{14}
Poly(methylmethacrylate)	3.03	0.057	1.2×10^{13}
Chlorosulfonyl polyethylene	5.63	0.138	2.6×10^{13}
Poly(ethylacrylate)	5.56	0.013	1.4×10^{13}
Poly(trifluoropropyl, methyl)siloxane	6.85	0.109	2.7×10^{11}
Poly(chloroprene)	7.83	0.639	8.2×10^{9}
Viton (copolymer of vinylidene) fluoride and hexafluoropropylene	8.55	0.0403	4.1×10^{11}

same fashion as the polarity of the polymer increases.

These insulation properties can be discussed from the viewpoint of dc and ac terms (McCrum *et al.*, 1967). Voltage gradients across insulating systems depend primarily on the leakage rather than on the capacitance. For this reason, insulators for high-voltage application must be formulated in such a way that they show low conductivity. In the case of high-voltage insulation, trapped charges have been taken into consideration, which can be troublesome when a sudden polarity reversal is required.

Specific requirements are to be fulfilled for low–electric-loss polymers, e.g., used in the insulation of transoceanic cables. They are met in general by polyolefins, e.g., polyethylene, which combines very low dielectric loss with moldability, toughness, and flexibility. High-performance thin polypropylene films have also been developed for various types of power capacitors. Extremely low-conductivity materials such as those used in electret microphones are required for various types of high-power capacitors. High-purity, pinhole-free, chemically inert poly(*p*-xylylene) (Szwarc, 1976) and its chlorine-substituted ultrathin film have been developed as insulation barrier coatings for semiconductor surfaces. High-temperature resistant polymers like various types of polyimides are often used as thin insulating layers in microelectronics.

2.3.2 Dielectric Thin Films Dielectric polymer thin films are rarely prepared by thermal evaporation, electron-beam evaporation, or slip casting (melting of the powder) on metallic or semiconductor surfaces; however, these techniques have created more and more interest in the fabrication of microelectronic devices. Mostly used is spin coating from dilute solutions of polymers characterized by appropriate dielectric properties. Care must be taken (rotation speed, temperature, vapor pressure of the solvent, etc.) in order to obtain pinhole-free films. Recently, the spin-coating technique has been used to obtain thin insulating films by spin coating of a dispersion of polymer spheres of low diameter on a metallic or semiconducting surface and melting the obtained monosphere-thick layer (e.g., polystyrene monodisperse lattices). Thicker, but still thin, polymer films can be obtained by extrusion and/or blowing of one-component or multicomponent layered systems.

Chemical vapor deposition and plasma polymerization have been recently applied for obtaining high-quality dielectric films, mostly organosilicon materials. Preparation conditions will decide the quality of the obtained materials, which in many cases are transparent, well adhering to the support, and insoluble.

Very thin films are prepared by polymerization of di-*p*-xylylene. The substrate is exposed to a controlled atmosphere of a pure monomer, and coating occurs as vapor-deposition polymerization (Beach, 1978). If the di-*p*-xylylene is used in plasma polymerization, it forms plasma polymers that contain a minor amount of branched and cross-linked chains, and its solubility suggests a material of low molecular weight. This process has certain similarities to vacuum metallization.

2.3.3 Electrets; Piezoelectric and Pyroelectric Polymers Electrets are dielectrics that create for a long time a strong external electric field. The phenomenon is connected with dipoles oriented during polarization treatment or with the presence of incompensated, stable charge (Sessler, 1982). Permanent polarization is usually obtained by heating or melting and solidifying a polar polymer in an external electric field (thermoelectrets) or by photoexcitation (photoelectrets). There is the possibility to induce charges in a polarized dielectric by γ irradiation (radioelectrets) or by ion implantation. Electrets may be obtained from natural dielectrics—e.g., waxes—or various polymeric dielectrics with low dielectric constant and/or of high T_g.

Most frequently, electrets are obtained by polarization of polar dielectrics in high electric fields. The charge at the surface of an electret is due to the orientation of dipoles; thus, heterocharge is formed. There are also injected charge carriers (homocharge) that disappear much more slowly with time. The resulting charge and the lifetime of an electret depend on the material used and on polarization conditions. There are electrets that can be obtained from nonpolar dielectrics as a result of charge carriers injected from the electrodes or induced by irradiation. Most important are thin-film electrets, which are obtained from good dielectrics by electron-beam irradiation whereby the charge is accumulated at a known distance from the surface of the film. Electrets of high density of charges are also prepared by corona charging and by using controlled breakdown on large surfaces. There is a method of electret preparation by the so-called "wet technique." This consists in contacting the dielectric with a liquid characterized by high conductivity in electric fields. The liquid layer is removed later on.

Electrets are subject to an aging process, but by careful treatment, one can obtain charged materials lasting a long time and creating high electric fields. There are already known techniques that are useful for determination of the charge distribution in the poled material. Important information about the relaxation parameters of oriented dipoles and trapped charges are obtained by well-elaborated, thermally stimulated depolarization techniques (van Turnhout, 1987; see also Sec. 3.2). It makes possible more detailed understanding of electret formation and its aging. Principal applications are electrostatic filters and electroacoustic transducers.

Piezoelectricity is a phenomenon related to the appearance of resultant electric moment connected with charges on the surface of a material under compression or extension (spontaneous polarization). This effect was first observed in crystals with polar axes and without a symmetry center. Pyroelectric effects are similar to piezoelectric in the appearance of opposite charges on the surfaces of a material but under homogeneous heating.

Most piezoelectric polymers are also polymer electrets. Maximum piezoelectricity is roughly related to the dielectric permittivity; thus, it is determined basically by the chemical structure of the polymer. The chain configuration and bulk morphology are equally important for piezoelectricity. Poly(vinylidene fluoride) (PVDF), because of its highly polar C–F bonds and high dipole moment ($\mu_0 = 6.4 \times 10^{-30}$ C m), has the highest dielectric constant ($\epsilon = 8.0$) and shows the highest piezoelectric constant (Wada, 1982).

Fluoropolymers and copolymers with vinylidene fluoride are good piezoelectric polymers. Other polar groups—e.g., C–Cl ($\mu_0 = 7.0 \times 10^{-30}$ C m) and C–CN ($\mu_0 = 12 \times 10^{-30}$ C m)—may also lead to useful piezoelectric macromolecular materials. Poly(vinylidene chloride) chains, because of the presence of bulky chlorine atoms, are prevented from adopting the highly polar all-*trans* conformation. The poly(vinylidene cyanide–vinyl acetate) alternating copolymer exhibits a piezoelectric constant similar to PVDF.

The very important structural feature of PVDF is high crystallinity (40–60%). It can crystallize in three major crystalline forms—α, β, and γ. The α form is obtained when the polymer crystallizes from the melt below 150 °C. The structure of the α crystals is monoclinic with the chains having *trans-gauche-trans-gauche* conformation and a dipole moment that has components normal and parallel to the chain axis. The dipole moments of two chains in the unit cell are antiparallel, and the crystal shows no spontaneous polarization. Drawing the PVDF film below 130 °C to several times its original length results in a new crystal form, the β form. This crystal has the orthorhombic unit cell in which the chains have all-*trans* conformation. These chains have a large dipole moment ($\mu_0 = 7.06 \times 10^{-30}$ C m) per monomeric unit, and they are packed in such a way that the crystal exhibits spontaneous polarization P_c (for the ideal crystal $P_c = 0.3$ C/m^2). In real β-form crystals, P_c is smaller because of defects. The stable β-form crystals should, however, have more than 3% of defects (head-to-head and tail-to-tail defects). The conversion from the α to the β form depends on draw ratio and draw temperature. The β form of PVDF crystals is characterized by the highest molecular packing. The γ form is obtained by crystallization under atmospheric pressure, just below the melting temperature, or by melt crystallization under high pressure. The γ-form crystals can be transformed into the β form by mechanical deformation of the crystal.

The PVDF electrets are prepared by annealing and poling *c*-axis oriented films containing β-form crystals. Typical poling temperature is T_p = 80–120 °C, and the electrical poling field is E_p = 50–150 MV/m. The induced surface charge is opposite to the poling field (heterocharge). There is a small part of irreversible polarization; the remaining part is stable below T_p. The mechanism of the polarization is still a subject of discussion. It is accepted that the piezoelectricity and pyroelectricity of PVDF and its large polarization depend on the number of crystallites in the β form and on its ability to align during polarization. It is correlated also with the dipole residues from amorphous regions and their incorporation into crystallites at grain boundaries. Thus, both chemical structure and physical factors play important roles.

2.3.4 Liquid-Crystalline Polymers

Liquid-crystalline polymers (LCPs) are of particular interest because of their very interesting mechanical properties in the oriented state and their nonlinear optical behavior. Liquid-crystalline side-group polymers contain dipole moments related to the pendant group (some LCPs also have a dipole moment in the backbone chain). The dipole character of LCPs makes it possible to study the molecular dynamics of those systems using broadband dielectric spectroscopy covering the frequency range 10^{-4} up to 10^{10} Hz (Kremer *et al.*, 1990). Thus, it is possible to study both fast processes (e.g., rotation of mesogenic groups around their long molecular axis) and slow relaxations (e.g., relaxation close to T_g).

For LCPs with side groups, five different dielectric relaxations have been found. For combined main-chain/side-group systems, the systematic chemical modification of dipoles revealed three relaxation processes. The α relaxation corresponds to the dynamic glass transition. The rotation of the main-chain mesogen around its long molecular axis is called β_m relaxation, whereas β_s relaxation is correlated with the rotation of the side-group mesogen around its long molecular axis. It is worth noting that for side-group LCPs, a collective relaxation process (δ process) was found and ascribed to the hindered rotation of side groups around the polymeric main chain. Similar behavior was found for combined main-chain/side-group liquid crystalline polymers as well as for some copolymers, in which it is suppressed at the smectic-crystalline transition.

The dielectric relaxation studies also give valuable information on the mobilities in various smectic phases depending on temperature. Recently, low-molecular-mass ferroelectric liquid crystals have been investigated. They show two different collective modes. Some main-chain/side-group LCPs have ferroelectric smectic phases as well. They appear when these system are oriented as a result of surface effects and/or for low magnetic fields. This allows for the combination of typical polymeric features with the properties of the ferroelectric smectic phases. Thus, in addition to their conventional use in displays, a wide field of new applications may be expected, e.g., as piezoelements made from cross-linked elastomers or as pressure sensors.

2.4 Electric Breakdown

2.4.1 Types of Breakdown and Factors Influencing the Electric Breakdown

Electric breakdown occurs when the current flowing through the sample increases, leading to its failure, and the applied voltage cannot be stable (Fisher, 1982). The applied voltage leading to material disruption is called breakdown voltage, and the corresponding voltage gradient at failure is electric strength in kV/mm. The knowledge of the breakdown mechanism is not complete, but one can distinguish the following:

1. Intrinsic breakdown, which is related to pure and defect-free material and occurs at the highest possible voltage. It is due to the increased random motion of electrons, which at the electric breakdown gain higher energy than they lose to the system.
2. Thermal breakdown, which is related to heat emission. If the rate of heating under voltage exceeds the rate of cooling by thermal transfer, thermal breakdown may occur at a limited section of the material. These restricted paths of breakdown are called Wagner breakdowns.
3. Gas-discharge–dependent breakdown is related to electric discharges in gas, which may occur on the surface or voids and on various discontinuities of electrical insulation. It can be due to ionization-induced surface flashover or arcing.
4. Physical-defect–dependent breakdown is affected by all types of cracks, voids, foreign inclusions, and factors that introduce physical deterioration of plastics.

Actual electrical breakdown may involve

two or more types simultaneously or sequentially. The true intrinsic breakdown can never be achieved experimentally, but experiments carried out at low temperature with dc voltage applied for very short times are taken as the intrinsic value.

If the thermal breakdown tests are made at high frequencies (above 1 MHz), failure occurs at relatively low voltages. Usually, $\tan\delta$ increases with increasing temperature, and the rate of heating rises rapidly. Many factors influence the thermal breakdown voltage: geometry (particularly the thickness of the sample), thermal conductivity, dielectric permittivity, absorbed moisture, etc. It depends also on the general tendency for physical degradation of the plastic under study.

Surface discharges are a source of ionization and may cause slow degradation of the polymeric material at its surface or within cracks and voids. Progressive surface degradation (tracking) is particularly important in the presence of surface contaminations. Corona and partial discharge are local effects occurring in gas where the voltage locally exceeds the gas-breakdown potential.

Breakdown connected with physical defects depends also on mechanical stress and vibrations. This type of failure depends on the nature of defects, the time under electrical stress, contaminations, and chemical constitution of the polymers. There is a certain similarity between electrical strength and mechanical strength because electrical breakdown involves physical destruction. In the same temperature regions, both modulus and dielectric strength show significant reductions in magnitude.

2.4.2 Electrical Treeing Treeing is related to sporadic discharges that are intermittent and not steady like corona discharges (Ku and Liepins, 1987). The mechanism of treeing is very similar to electric breakdown. Treeing breakdown starts in the regions of the highest and most divergent electrical stresses. The insulation system consists always of non-absolutely smooth electrodes, imperfect electrode–insulation interface, and not perfectly isotropic material, as well as there being contaminant particles or cavities. These defects influence the appearance of treeing phenomenon. Small channels of degradation develop into a treelike pattern, which may finally bridge the gap between electrodes and cause the failures. The practical importance of treeing has been emphasized in many cases, particularly for polyethylene cables. Some insulations containing stress concentration or even some kinds of trees do not fail in short periods. In fact, reports of long lifetimes of solid insulation suggest that well-designed and well-constructed insulating systems operate within the limits of electrical, mechanical, and thermal stresses for a long time.

2.4.3 Measurement Techniques Measurements of the electric breakdown strength are standardized, and the equipment and procedures for electric breakdown test are clearly described in ASTM D 149. The important features that have to be fulfilled by each equipment are an appropriate device to measure the test voltage at the specimen and not only the primary voltage of the testing transformer, a device for increasing the test voltage at uniform rate, strictly sine wave, and a device for removing the voltage at breakdown.

Usually, the corona test and the arc resistance test are made in connection with electric breakdown test. Standardized procedures are difficult to be developed, especially for volume corona, i.e., for corona discharges in voids at conducting inclusions. ASTM D 2275 is applied to measure the corona resistance. For dry arc resistance, ASTM D 495 is used. A 12.5-kV voltage (open circuit), which produces an arc between chisel-shaped tungsten electrodes, is applied.

A number of works have been carried out to elaborate various methods of treeing test (electrical and water treeing test), each of them having its advantages. ASTM D 3756 describes a test for electrical treeing between a sharply pointed needle and a rounded needle. The only quite well-standardized test for wet-treeing of cables is that of the Association of Edison Illuminating Companies [IC CS5-79].

Tracking tests have been standardized in the United States. There are four types of tracking test:

1. Dust-and-Fog Tracking and Erosion (ASTM D 2132),
2. Differential Wet Tracking (ASTM D 2302),

3. Inclined plane Tracking and Erosion ASTM D 2303, and
4. Comparative Tracking Index (ASTM D 3638).

2.5 Surface Charging

2.5.1 Origin of Surface Electrification The presence of electrostatic charge is recognized by mutual attraction or repulsion with other surfaces, possibly with small discharges (sparks), and by the dust attraction effect. When brought into intimate contact with a neutral material, e.g., by rubbing, polymers become positively or negatively charged on separation. The one that becomes positively charged acts as an electron donor, while the other, which becomes negative, acts as an electron acceptor (Ritsko, 1982; see also TRIBOLOGY).

The sequence of polymers according to their charging behavior is called the triboelectric series. It is a general rule that if two substances become charged by mutual contact, the substance with higher dielectric constant will get the positive charge. The triboelectric series can be established by contact potential differences.

The microscopic nature of electronic states involved in triboelectricity is still under study (Lowell and Rose-Innes, 1980). The molecular-ion model of bulk intrinsic states provides an acceptable microscopic description of the charge-transfer process, but further advances in the understanding of this phenomenon are needed. Very important is the rate of charge decay. It depends on the side groups that constitute the polymer chain. When side-chain substituents are involved in charging the surface, charge decay is faster. The ability of the polymer to bind ions is also a very important factor. A small amount of impurity can alter the surface charging to a high extent. Surface charging is of importance for the flow behavior of polymer powders and is a key process in all xerographic techniques.

2.5.2 Antistatic Agents The electrostatic charge can be reduced by use of antistatic agents. Even a small surface charge density can give rise to an electric field strong enough to cause arcing in air (electrical charge in carpets in dry air). Antistatic agents can be used in formulations by mixing with the basic polymer, but above all, the polymer surface must be treated to optimize the performance of the system. The tendency of polymers to store electric charge was overcome in the past by addition of carbon black or acetylene black to rubber, by addition of metallic powders to plastics, and by blending of metallic or metal-coated fibers with synthetic fibers. At present, conducting polymers, thin vacuum-deposited metal layers, or formation of charge-transfer complexes at the surface are of interest for various applications.

2.6 Applications

Polymers are used in many electrical applications as primary electrical insulation, or they may have a structural function, independent of an electrical function; thus, choice of an appropriate polymer as an insulator depends on its particular application. An interesting survey of various basic electrical properties of polymers with regard to their applications is given by Ku and Liepins (1987).

Useful dielectrics are usually divided into three principal classes: those with $\epsilon_r < 12$, those with $\epsilon_r > 12$, and ferroelectrics. The last class is represented among polymeric materials by some ferroelectric liquid-crystalline polymers. The first category may be divided into subcategories based on operating temperature; however, this division is yet not fully justified because polymeric materials depending on their chemical constitution and structure can be used as insulators and dielectrics up to 400 °C (depending on time of application of severity of temperature conditions).

Polymers fulfill generally well the typical requirements of an insulator:

1. they usually have high enough dielectric strength to withstand an electrical field between the conductors (e.g., in capacitors);
2. they show high insulation resistance to prevent the leakage of the current;
3. they exhibit a good arc resistance to prevent damage in the case of arcing;
4. they show appropriate mechanical properties to resist shock, vibrations, etc.; and
5. they usually maintain their integrity under a wide variety of environmental haz-

ards such as humidity, temperature changes, and radiation.

For domestic wiring insulation, the best electrical properties are not necessary; thus plasticized PVC is firmly established. Ester plasticizers also change the nonflammability of PVC, but some appropriately chosen compositions may compensate this insufficiency. High-quality polyethylene is used for telecommunication cables while polypropylene (biaxially oriented) and poly(ethylenetherephtalate) films are used in capacitor manufacturing.

Among some relatively new developments in thermoplastics, the polymer blends (e.g., polycarbonate/ABS blends, where ABS stands for a mixture of acrylonitrile-styrene and butadiene-styrene copolymers) are chosen for connectors and switch casings, where high impact strength, good surface quality, and low mould shrinkage are required. The low resistivity and high dielectric strength of these materials are relatively unaffected by external moisture, and so they are suitable for waterproof switches.

The permanency of storage of real and polarization charges depends on conductivity, carrier mobility, and dipolar relaxation. Insulating polymers may show a very good long-term charge-storage capability because of the low conductivity and low carrier mobility. Typical examples of polymers that can store real charges and polarization charges are polyolefins and poly(ethyleneterephthalate). Poly(tetrafluoroethylene) (Teflon™) and its fluoro-ethylene-propylene copolymers are examples of materials with good insulating properties, and poly(vinylidene fluoride) is characteristic of small dipolar relaxation.

Applications of polymers in the electronic industry are continuously increasing. Polymer piezoelectrets are used in microphones and small loudspeakers. Polymer dielectrics are rapidly gaining importance as substitutes for inorganic (ceramic-based) insulators. These applications are dominated by polyimide films, which offer particularly useful characteristics:

1. stability up to temperatures as high as 450 °C;
2. high electrical resistivity and breakdown strength, and low dielectric loss;
3. excellent chemical resistance; and
4. coating of substrates with thin films is feasible and patterning can be achieved in lithography.

All these features make it possible for this type of polymer to be applied in microelectronics as microresists and printed circuit boards (Saone and Martynenko, 1989).

Evidently, polymers are used as molded components for chip encapsulation. The encapsulant must be very pure material with an excellent barrier to moisture and contaminant ions, independently of superior electrical, physical, and manufacturing properties. Many organic polymers fulfill these conditions, both thermosetting and thermoplastic materials.

In addition to good dielectric and insulating properties, the polymers are widely used because of good processing characteristics (small and intricate shapes can be readily and economically manufactured), good mechanical properties (resistance to impact loads and stiffness, even at elevated temperatures), dimensional stability, and retention of many properties in hot and/or moist environment over long periods of time.

3. SEMICONDUCTING AND PHOTOCONDUCTING POLYMERS

The conductivity of every material can be enhanced when charge carriers are generated or injected by appropriate radiation. If UV, visible, or near-IR radiation is used, we deal with photoconductivity. In the case of x-ray, gamma-ray, or other, e.g., electron, irradiation, the term radiation-induced conductivity is usually used. High-energy irradiation inevitably results in chemical degradation of the polymer, and these problems are outside of the scope of this article. An ideal, electronically photoconductive polymer should have no free charge carriers (thus, it should show very low conductivity in the dark) and high quantum efficiency of charge-carrier photogeneration, and it should allow fast transportation of the photogenerated charges.

Three classes of polymers are known to exhibit semiconducting and photoconducting properties: polymers with π-polyconjugated multiple bonds (like polyacetylene), polymers with σ-bonded silicon or germanium atoms in the main chain (like polysilanes), and polymers with saturated backbones and pendant aromatic groups [like poly(N-vinylcarbazole)(PVK)]. Another class of polymeric semiconductors comprises molecularly doped polymers consisting of an electrically insulating and inactive polymer matrix doped with charge-transfer (CT) complexes forming additives.

In polymers with extended π-electron systems in the backbone, the molecular p orbitals broaden into filled and empty bands, and the polymer should be an intrinsic metal. However, because of bond alternation (Peierls distortion), there is a finite gap (e.g., around 1.4 eV for polyacetylene) between these bands.

In silicon-backbone polymers, significant delocalization of electrons occurs along the chain, and their electronic behavior is very different from analogous σ-bonded carbon-backbone polymers; the band gap in polysilanes is of the order of 4 eV, while in carbon analogs it is close to 8 eV.

Pendant-group polymers have electronic states similar to those of the pendant aromatic molecules, and so their properties are similar to those of the polymers molecularly doped with chromophores, where the charge transport occurs via hopping among localized sites associated with pendant groups or dopant molecules.

3.1 Theoretical Aspects

3.1.1 Origin of Charge Carriers The charge carriers necessary to transmit the electrical charge through a material can originate from four basic processes: thermal generation, photogeneration, injection, or photoinjection from electrodes. In general, polymers can be p-type or n-type transporting materials. Practically all photoconductive polymers are p type, and only holes are mobile. Although some potentially electron-transporting polymers have been synthesized [e.g., polymers with acceptor-type trinitrofluorenone (TNF) pendant groups], they exhibit poor mechanical properties because of low molecular weight, and they have insufficient electron mobility. Polymeric systems with mobile electrons or bipolar systems can be obtained by doping of the hole-transporting or inert polymers with low–molecular-weight acceptors, for example PVK-TNF.

In polymers, the thermal generation is usually negligible, even in undoped polymers with polyconjugated multiple bonds, because of the large band gap. Photogeneration is intrinsic, when it occurs by photoexcitation of the polymer molecule, or extrinsic, when the light is absorbed by pigments or dyes dispersed in a polymer matrix and the generation process occurs within the dopant molecules. Intrinsic photogeneration is confined to the UV range (i.e., the range of the polymer absorption spectrum), but its efficiency can be increased and action spectrum shifted into the visible range by doping with a suitable electron acceptor that forms a charge transfer complex with, usually donorlike, polymer.

It is generally accepted that the charge-carrier photogeneration occurring within a polymer is a multistep process that can be divided into two main phases, as shown in the scheme in Fig. 2 (Okamoto and Itaya, 1984). The first phase, the efficiency of which is field independent, is the absorption of a quantum by a molecule or a CT complex and its photoionization (most probably via unrelaxed exciplex states), followed by formation of the hole-electron pair, which is separated at some characteristic thermalization length. The efficiency of this first phase is called the primary quantum yield. The sec-

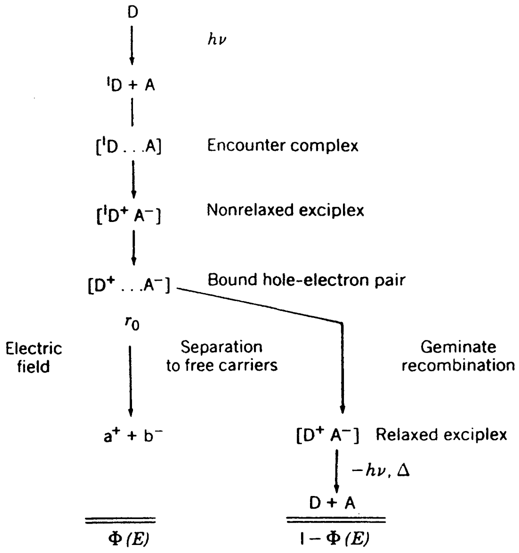

FIG. 2. A scheme of photogeneration of charge carriers; D, electron donor; A, electron acceptor (Okamoto and Itaya, 1984).

ond phase is further separation of the carriers, which contribute to the current if they avoid geminate recombination. This phase is field dependent, its mechanism is similar to the process of ion-pair dissociation in weak electrolytes (Brownian motion in the superimposed field of the gemine carrier and external field), and it has been successfully described by the Onsager theory.

3.1.2 Charge Transport In molecular, disordered solids, the overlapping of electronic orbitals is small, any excess charge is localized on the host molecule, and the existence of extended states ranging over more than several molecules is unlikely; thus, band theory cannot be applied.

In intrinsically photoconducting polymers and in molecularly doped polymers without polyconjugated multiple bonds, the charge-carrier transport occurs via thermally activated hopping (Böttger and Bryksin, 1986) among the chromophore groups or among the dopant molecules. Because all these materials are mostly amorphous and the hopping sites are randomly oriented in space and randomly distributed, there is a fluctuation of wave-function overlap between adjacent hopping sites, so-called off-diagonal disorder. The variations of the polarization energy due to positional disorder result also in the fluctuation of site energies, so-called diagonal disorder. Consequently, there is a very broad distribution of hopping probabilities. This is a reason for the relatively low mobility of charge carriers, in most cases much lower than 10^{-3} cm^2/V s.

If one considers a narrow sheet of charge carriers injected into the sample (like in the time-of-flight measurements; see Sec. 3.2), the distribution of hopping times will cause a spreading of the carrier packet as it propagates through the sample. For a Gaussian distribution of the site energies, the carriers will reach the substrate electrode as a coherent packet (although of increasing width) drifting with time-independent average velocity; the transient time is well defined, and the transport is termed nondispersive.

In many polymer photoconductors, especially at low temperatures, the motion of charge carriers is an incoherent process involving time-dependent hopping frequency, and the transport is dispersive. The current pulse in the time-of-flight experiment is a featureless trace because of the very wide, non-Gaussian spread of the carrier packet. In the pioneering work of Sher and Montroll (1975), the dispersive transport of carriers hopping among a random set of localized isoenergetic sites was described by means of the formalism of continuous-time random walk, with the assumption of off-diagonal (positional) disorder only. At present, it is commonly accepted that the dispersion is mainly due to diagonal disorder. The width of the Gaussian distribution of site energies determines the possibility that carriers attain dynamic equilibrium during a transit, the criterion for nondispersive transport (Bässler, 1984). Monte Carlo simulations for a system with a Gaussian energy distribution in addition to off-diagonal disorder predict all the characteristics of the dispersive transport in polymers: Poole–Frenkiel type field dependence of the carrier mobility, temperature dependence of the mobility, narrowing of the dispersion with increasing temperature leading to a transition from dispersive to nondispersive transport at high temperatures, and changes of the transport properties at the polymer glass transition temperature (Pautmeier *et al.*, 1990). Alternative models based on conventional multiple-trapping transport predict also non-Gaussian dispersive transport, but they are not applicable to polymers with hopping transport.

In spite of the very high concentration of impurities and defects present in polymers, trapping phenomena usually do not affect significantly the hopping transport in photoconducting polymers (Scott *et al.*, 1993). This is because the hole transport sites (chromophore groups or additives) have very low oxidation potential, and it is unlikely that other molecules present in the material (e.g., impurities) can have still lower oxidation potential, unless proper molecules are intentionally chosen and introduced. In terms of solid-state chemistry, the hole hopping transport can be described as a reversible oxidation-reduction process; the localized hole forms a cation radical and can accept an electron from the next neutral molecule, and so the hole ("cation radical") performs a random walk generally in the direction of the applied electric field (Mort and Pfister, 1982).

In polymers with σ-bonded arrays of silicon or germanium atoms in the backbone, the hole transport occurs by hopping via the

σ-derived states rather than via side-chain groups (Stolka *et al.*, 1990). As a result of considerable delocalization of charge carriers along the chain, the transport is nondispersive, and the mobility is around 10^{-4} cm²/V s.

3.1.3 Charge Recombination

Most of the photogenerated charge carriers undergo geminate recombination, and only a small part of the carriers are separated from their initial counter charges. Then, because in semiconducting polymers usually only positive charges are mobile, recombination of carriers occurs when a moving hole meets the immobile electron. The electrons are localized at the photogeneration groups or are trapped in their vicinity. The recombination rate constants in polymers are relatively high, comparable to those found in semiconductors. For materials where both holes and electrons are mobile, like in PVK heavily doped with TNF, the rate of recombination depends on the combination of carrier mobilities μ and concentration n and can be expressed by the equation

$$\frac{dn}{dt} = -\frac{4\pi e}{\epsilon}\mu n^2, \qquad (18)$$

where ϵ is the dielectric permittivity (Pearson and Stolka, 1981).

3.2 Experimental Techniques

The photoconductivity upon steady illumination is given by the equation

$$\sigma_{ph} = g_0 \tau e \mu, \qquad (19)$$

where g_0 is the number of photogenerated carriers in unit volume per second, τ is the lifetime of carriers before recombination, e is the electron charge, and μ is the drift mobility.

Often-used steady-state photoconductivity measurements with sandwich-type samples provided with semitransparent electrodes yield information about the photoconductivity of the investigated material only if the electrode–sample contacts are Ohmic, which is not easily achievable. The measured photocurrent density is equal to

$$j_{ph} = \sigma_d E + \sigma_{ph} E = \sigma_d E + (\phi I_0/d)\tau e \mu E, \qquad (20)$$

where σ_d is the dark conductivity, E is the electric field, ϕ is the quantum efficiency of photogeneration, d is the sample thickness, and I_0 is the total absorbed light (photon/cm² s). The dark current can be measured and subtracted, but the fundamental photoconductivity parameters, ϕ, τ, and μ (in the second term), cannot be separated. For this reason, the steady-state measurements can provide only a comparison of photoconductivity and dark conductivity and the relative action spectra of photoconductivity.

Quantum efficiency and mobility are determined from dynamic measurements by means of time-of-flight (TOF) technique or xerographic discharge (Mort and Pfister, 1982). The TOF method consists of generating a narrow sheet of charges by the use of a short pulse of strongly absorbed light or of an electron beam, and monitoring the current when the carriers drift across the sample in order to determine the transit time τ_T and then the mobility: $\mu = (d/\tau_T)(1/E)$. For nondispersive transport, the transit time is indicated by a sharp drop of the current; for dispersive transport, the current monotonically decreases, and only in the log-log plot of the current vs time can some characteristic point (kink) be distinguished, which is interpreted as the transit time.

In the xerographic discharge technique, the sample is provided only with a bottom electrode. The free surface of the sample is charged to a high potential V_0 by corona discharge, and then the decay of the surface potential, $V(t)$, is monitored after a short pulse of light. If the total charge generated in the sample is small, as compared with the corona-deposited charge, CV_0 (where C is the capacitance of the sample), and if the photoinjection from the deposited charge layer and the charge trapping can be neglected, the quantum efficiency is given by

$$\phi = \frac{1}{I} Ce \frac{dV}{dt}. \qquad (21)$$

When the xerographic discharge experiments are performed under space-charge–limited conditions, which means when the intensity of the light source is high enough to generate in a short time a charge comparable to CV_0, the initial potential decay rate is related to the transit time by the equation

$$\frac{dV}{dt} = -\frac{V_0}{2}\frac{1}{\tau_T}. \tag{22}$$

Consequently, the mobility can be determined from the initial potential decay rate. This method of determination of μ is recommended for materials with dispersive transport, where the TOF technique yields ambiguous results. Space-charge–limited conditions can be easily fulfilled in a two-layer configuration of the sample, when the investigated transport polymer film is provided with highly effective thin photogeneration layer, e.g., evaporated *a*-Se.

Trapping and recombination phenomena can be investigated using thermally stimulated current (TSC) and thermoluminescence (TL) techniques (Bräunlich, 1979). TSC consists in measuring a current flowing as a result of thermal release of trapped carriers in the sample heated with a constant heating rate; TL consists in measuring the light emitted through recombination of the detrapped carriers. The traps in the sample are populated at low temperature by photoexcitation, γ irradiation, or electron-beam or corona discharge. The obtained TSC and TL spectra exhibit maxima that can be attributed to the detrapping from trap levels. The analysis of the shapes, positions, and intensities of the maxima and their dependence on experimental conditions (mainly on heating rate and on electric field) yields information on the trapping parameters and mechanism. Interpretation of the TSC maxima can be ambiguous for low-mobility materials when the shape and position of the maximum can be controlled by the transport process (the so-called transport peak); for these reasons, simultaneous measurements of TSC and TL are recommended.

3.3 Materials

Photoconductivity is exhibited by many different types of polymers prepared by various methods of synthesis, like free-radical polymerization, ionic polymerization, polycondensation, ring-opening polymerization, Ziegler-Natta polymerization, electrochemical polymerization, and photopolymerization. Taking into account their structure, they can be divided into several main groups.

3.3.1 Polymers with Polyconjugated Multiple Bonds Polymers with unsaturated backbone show low-energy optical transitions. The most studied polymer with conjugated π-electron backbone is polyacetylene $(CH)_x$ (PA), which has two possible forms: *cis* and *trans* (Fig. 3; see also Secs. 4.1.1, 4.1.2, and 4.3.2). Pristine *cis*-PA is almost an insulator, with conductivity below 10^{-10} S/cm; it displays photoconductivity only in the UV range. *Trans*-PA has conductivity around 10^{-6} S/cm, is photoconducting, and shows the transport properties of a semiconductor. A large positive value of the thermopower coefficient indicates *p*-type conduction.

Perfectly conjugated polymer single crystals of macroscopic dimensions (even several centimeters) can be prepared by solid-state polymerization of diacetylene monomers. Because of the deficiency of free charge carriers, polydiacetylenes are essentially insulators, with conductivities of the order of 10^{-10} S/cm or less, but they show relatively high photoconductivity in the visible range. Polydiacetylene single crystals exhibit interesting nonlinear optical properties with high third-order susceptibility.

Many other polymers with polyconjugated multiple bonds show photoconductivity, even in the visible and in the near-IR ranges, but their dark conductivities are usually also high (Stolka, 1988).

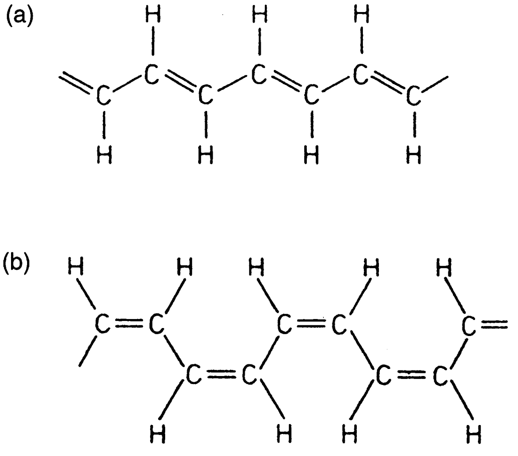

FIG. 3. Schematic structures of polyacetylene in two possible forms: (a) *trans*, (b) *cis*.

3.3.2 Polymers with Aromatic Amine Groups Many polymers containing an aromatic amine group show substantial photoconductivity, among them the most important photoconducting polymer, poly(N-vinylcarbazole) (PVK), this being the first practically applied and commercialized organic photoconductor (Mort and Pfister, 1982).

Pristine, purified PVK shows photoconductivity only in the UV range; the photogeneration spectrum has several steps in coincidence with the PVK absorption spectrum, which means with the excitation into subsequent higher singlet states. The primary quantum yield for PVK is around 0.14, and the thermalization length is in the range 22.5 Å (for excitation into the first singlet state) to 30 Å (for excitation into the third singlet state). The absolute quantum yield for photogeneration of holes is around 10^{-3} at a field of 10^5 V/cm and approaches the value 0.05 at 10^6 V/cm. The hole mobility at a field of 10^5 V/cm is around 10^{-6} cm²/V s.

PVK has been doped with numerous CT complexes forming additives like tetracyanoethylene, tetracyanoquinedimethane, chloranil, or Lewis acids; the most intensively investigated and practically used is the system PVK-TNF. It is photoconducting also in visible light because the CT band of this complex extends through the visible range. For the system with 1:1 molar ratio TNF to PVK monomer, the primary quantum yield in the visible range ($\lambda = 550$ nm) is 0.23, the thermalization length is 35 Å, and the absolute quantum yield is around 10^{-2} at 10^5 V/cm and approaches 10^{-1} at 10^6 V/cm, being the same for holes and electrons. The PVK-TNF system is bipolar; with increasing TNF concentration, the hole mobility decreases below 10^{-8} cm²/V s for the 1:1 molar ratio, while the electron mobility increases up to around 10^{-6} cm²/V s at the field 5×10^5 V/cm.

PVK has rather unfavorable mechanical properties. Its brittleness creates considerable technical problems, especially if it is to be used in the form of thin film. For this reason, several attempts have been made to obtain polymers with carbazole, or other aromatic amine pendant groups, having better application properties: various vinyl backbone polymers, polyacrylates, polymethacrylates, and copolymers of vinyl carbazole with different comonomers (including acceptor-type comonomers). Some of these polymers were sensitized with TNF and other electron acceptors. In a few cases, their mechanical and film-forming properties are improved, but usually at the expense of the photoconducting properties. Even if some of these materials exhibit higher hole mobility than PVK, their photogeneration efficiencies are lower.

3.3.3 Polymers with Large Polynuclear Aromatic Groups A variety of polymers with pendant-condensed aromatic groups have been synthesized and their photoconducting properties have been investigated (Stolka and Pai, 1978). Polymers with naphthalene, pyrene, chrysene, or acridine as pendant groups show usually low photoconductivity, constrained to the UV range only. In some cases (for example in polymers with anthracene groups, like polyvinylphenylanthracene), their photoconductivity is comparable to that of PVK, but because of oxidative instability, poor mechanical properties (brittleness), and difficult synthesis, these polymers have no practical importance.

3.3.4 Inorganic Semiconducting Polymers Polymers with silicon and germanium backbones are insulators in the pure state, but the band gap in some cases is only around 4 eV, i.e., two times smaller than in saturated polymers with a carbon backbone. In some sense, they resemble polyconjugated polymers; the absorption spectra display a red shift effect with increasing molecular weight, typical for polymers with electrons delocalized along the chain. The conductivity of polysilane derivatives can be considerably enhanced, up to around 0.1 S/cm, by suitable doping with a strong electron acceptor, e.g., polysilastyrene becomes a semiconductor when doped with arsenic pentafluoride (Miller and Michl, 1989).

It has been found recently that many polysilane derivatives are excellent photoconductors. In the pure state, they are photoconducting only in the UV range; long chain segments of *trans* conformation are the lowest-energy chromophores. These polymers can be made photoconducting in the visible range by suitable doping, for example with TNF. In poly(methylphenylsilane) (PMPS), the quantum yield of hole generation is electric-field dependent, and for high fields, it approaches 1%.

Similarly as in many amorphous organic and inorganic solids, charge transport occurs via thermally assisted hopping and is controlled by the distribution of the energies of the transport sites and their average separation. Insensitivity of the hole mobility to the nature of side groups shows that the hopping sites are associated with σ electronic states of the backbone. Because of delocalization of the charge along the chain, in polysilanes the transport sites are not localized states (like carbazole pendant groups in PVK) but domains of *trans* conformers separated by conformation irregularities.

In silicon- and germanium-backbone linear polymers, holes are the majority carriers, transport is nondispersive, and mobility around 10^{-4} cm^2/V s is usually reported at room temperature. Carrier mobility is temperature and field dependent and sensitive to the glass transition temperature T_g. Below T_g, the mobility exhibits a single activation energy over a broad temperature range; for PMPS, it is 0.24 eV at 2.5×10^5 V/cm and decreases below 0.2 eV at 6×10^5 V/cm. At high fields and temperatures, the hole mobility may approach 10^{-2} cm^2/V s. The activation energy of mobility decreases strongly above T_g, and in some cases, the mobility becomes practically temperature independent (e.g., for polysilane derivatives with aliphatic side groups). The field dependence of the mobility and of its activation energy in these polymers indicates the Poole–Frenkel effect of barrier lowering by a factor $\beta_{PF}E^{0.5}$; however, the experimentally obtained value of β_{PF} is about two times lower than the theoretical Poole–Frenkel coefficient $\beta_{PF} = (e^3/\pi\epsilon\epsilon_0)^{0.5}$ (Stolka *et al.*, 1990).

In PMPS, the trap-free, nondispersive transport results in a nearly rectangular TOF pulse, with hole mobility independent of sample thickness. The hole mobility can be reduced by doping with molecules with lower oxidation potential, creating traps for holes and resulting in trap-controlled hopping. However, when the energy level of the dopant site is close to the energy level of the transport site in the polymer, dopant molecules are transport active, and heavy doping may result in a substantial increase of the mobility. In PMPS doped with *N,N'*-bis(4-methylphenyl)-*N,N'*-bis(4-ethylphenyl)-[1,1'-(3,3'-dimethyl)biphenyl]-4,4'-diamine, the hole mobility at $E = 2.5 \times 10^5$V/cm increases by ca. three orders of magnitude up to the unusually high value 10^{-1} cm^2/V s (Stolka and Abkowitz, 1993).

3.3.5 Molecularly Doped Polymers

The molecularly doped polymers have gained a lot of interest as photoconducting materials for two reasons. First, in these materials, one can combine good mechanical properties of a chosen polymer matrix with appropriate electronic properties of dopant molecules (Ulański *et al.*, 1981). In particular, it is possible to introduce different types of dopants, e.g., dye molecules in order to extend the photoconductivity action spectrum (sensitization) and transport molecules to enhance the carrier mobility. However, to gain high mobility, up to 50 wt % of dopant (donor or acceptor type) is added to the polymer (Scott *et al.*, 1993), and so the mechanical properties of the polymer matrix are changed to a great extent.

Second, solid solutions of various dopants in an inactive polymer matrix are model systems for the investigation of charge generation and transport in photoconducting polymers. Investigations of polycarbonate (PC) doped molecularly with N-isopropylocarbazole (NIPC) have allowed for direct determination of the influence of concentration of generation and transport sites (i.e., carbazole groups) on the basic photoconduction parameters in PVK. It was shown that the vinyl chain of PVK plays no active role in the photoconduction process. Photogeneration efficiency increases with increasing NIPC concentration because of an increase of primary quantum yield. This results from an increase of the thermalization length due to higher carrier mobility at higher concentration of hopping sites (i.e., dopant molecules). The hole mobility exhibits exponential dependence on the average separation between NIPC molecules. The mobility increases with temperature, and the determined activation energy rises with decreasing dopant content; both the mobility and its activation energy are field dependent. An addition to the PC-NIPC system of a second donor-type dopant, triphenyl amine (TPA), with ionization potential lower than NIPC introduces effective traps for holes, resulting in trap-controlled hopping. The hole mobility first decreases with increasing TPA concentration. However, when the decreasing separation between the TPA molecules allows overlapping of electronic orbitals, another effective channel for hole hopping among TPA molecules is formed, and the hole mobility starts to increase again (Mort and Pfister, 1982).

3.4 Applications

Photoconducting polymers were the first electroactive polymers, and in general the first electroactive organic materials, to be practically used on a commercial scale. Polymer photoconductors, first of all the PVK-TNF system, compete successfully with inorganic materials in application in electrophotography as a result of sufficiently good electrical properties (almost trap-free transport) and the ease of production of large-area, homogeneous films at low price. In practical electrophotographic devices, the organic photoconductors are often used in the two-layer configuration, with separated photogeneration layer and transporting layer. In such a configuration, the problem of removing immobile electrons from the bulk of *p*-type photoconductors is avoided (this problem does not exist in bipolar PVK-TNF).

Large-area solar cells are another potential and much-wanted application of photoconducting polymers. Such devices have not yet been realized because of low conversion efficiency. The low costs of producing are frustrated by poor stability against solar UV light (Stolka, 1988).

4. CONDUCTING POLYMERS

Polymers with extended π-electron systems in the backbone exhibit electronic properties very different from common polymers; they have low ionization potentials and high electron affinities. As a result of these properties, they can be easily reversibly oxidized or reduced by suitable dopants, and, when doped, they can show very high conductivity, in the best cases comparable with the conductivity of metals. For this reason, they are called synthetic metals.

The conducting polymers belong to the class of synthetic metals together with other molecular conductors: charge-transfer complexes made of segregated stacks of acceptor and donor molecules, like tetrathiafulvalene-tetracyanoquinodimethane, and the so-called Krogman salts containing stacks of PtX_4 or IrX_4 (X = CN or C_2O_4), like potassium cyanoplatinate oxidized by bromine. All these systems have in common the quasi 1-D character of the charge-carrier transport, because the charge delocalization is confined to quasi 1-D structures: the polymer chains or the stacks of molecules (Ku and Liepins, 1987).

4.1 Theoretical Aspects

4.1.1 Basic Concepts Conducting polymers are in general disordered systems, and band theory elaborated for crystalline semiconductors should not be directly used; however, periodicity of the π-conjugated backbone makes possible a description of electronic structure in terms of energy bands. An idealized picture of polyacetylene shows a planar *trans*-$(CH)_x$ chain with all the bonds of equal length. Each carbon atom in the chain has in an addition to three σ electrons also one π electron. Molecular-orbital theory predicts that with increasing chain length, the energy gap between valence and conduction bands vanishes, and for high molecular weight, the *p* orbitals of the π electrons would form a half-filled energy band with the Fermi level in the middle. The polymer should be an intrinsic metal. However, the linear-combination-of-atomic-orbitals theory shows that the polyene chain is stable only if it undergoes dimerization, i.e., if alternation of bond lengths occurs. In general, a one-dimensional metal cannot be stable, because all linear chains of atoms undergo distortion and lower their symmetry leading to the creation of collective electronic ground states of reduced symmetry called Fermi-surface instabilities (charge-density waves, spin-density waves, or bond-order-alternation waves).

The self-induced metal-insulator transition, called Peierls transition, is in *trans*-$(CH)_x$ a consequence of the dimerization accompanied by a distortion of the electronic charge density creating a band gap of around 1.4 eV. Perfectly dimerized *trans*-$(CH)_x$ has two equivalent structures, which differ only in the sequence of bond alternations: single/double or double/single. If both structures are present on one chain, they are separated by a topological defect. This radical defect can move by bond flipping along the chain, not changing its energy because these two structures have the same energy (the system is degenerate in energy). At the defect, the π-wave functions change phases, and their amplitudes approach zero; the radical defect is described as a neutral soliton. A solitary wave travels without changing shape or speed on collision with another soliton. A soliton is not a point defect, but it extends over about 15 carbon-carbon bonds. The neutral soliton creates a new state in the band gap; it is a species without charge, but it has spin $\frac{1}{2}$ and can be detected by EPR. The charged soliton is an anion or cation defect, which carries charge but no spin (Lu, 1988).

Spinless transport was observed in PA but also in other polyconjugated polymers that are not degenerate in energy. In such polymers, like polypyrrole, polythiophene, poly(*p*-phenylene), or poly(*p*-phenylene sulfide), the two structures of different sequences of bond alternation have different energies: the aromatic structure has lower energy than the quinoid one. Therefore a mobile soliton cannot exist because it would migrate immediately to reduce the length of the quinoid structure. In these polymer chains, in order to restore the initial aromatic structure on the other side of the defect, the defect has to contain both a soliton and an antisoliton. Such a pair constitutes a polaron, which is a species carrying a charge and a spin $\frac{1}{2}$. In other words, the polaron is a radical ion (cation or anion) associated with distortion of the lattice around the charge. If two such coupled electron-photon states are present on the same chain, they react exothermically and form a bipolaron, a spinless double-charge carrier. The direct evidence of formation of solitons, polarons, and bipolarons comes from optical spectroscopy. Photoexcitation of an electron-hole pair, followed by charge-pair separation, results in the formation of a localized defect characteristic of the given polymer: *trans*-polyacetylene shows a photoinduced absorption band associated with the soliton level, and other polyconjugated polymers, able to form bipolaron states, show two photoinduced absorption bands corresponding to the optical transitions between the band edges and the two polaron levels in the gap (Frommer and Chance, 1988).

4.1.2 Doping and Charge Transport

The fundamental effect of doping in terms of semiconductor physics is to generate free carriers, and only in this respect can the term "doping" be used for the description of the processes of oxidation or reduction of the polyconjugated polymers by electron acceptors or donors. The mechanism of doping of conducting polymers is, however, very different from that for crystalline semiconductors. One of the main sources of this difference is a large deformability of the macromolecules. The dopant molecules are introduced between polymer chains, so that morphological changes occur on doping. Because the dopant molecules are not built into the rigid crystal lattice, they can be removed, and so the doping is reversible. The concentration of dopants in highly conducting polymers may approach 50 wt %, and so the terms "polymer salt" or "charge-transfer complex" are often preferred over the term "doped polymer" (Wegner, 1981).

Because of the charge transfer between the polymer chain and the dopant, the polymer chain is electrically charged; injected charges distort the charge-density waves on the chain and through electron-phonon coupling can alter the macromolecular geometry. In consequence, a defect is formed on the chain, and a new level is created in the band gap. The type of defect formed depends on the structure and state of the polymer. In the case of *trans*-$(CH)_x$, the interaction of the dopant with an existing neutral soliton yields a positive soliton for acceptor dopant (*p* doping) or a negative soliton for donor dopant (*n* doping). Direct oxidation (reduction) of *trans*-$(CH)_x$ by an acceptor (a donor) dopant yields a positive (negative) polaron, introducing two new levels in the band gap. At low doping and at low temperatures, the charged defect on the chain is localized by the Coulombic binding energy to the ionized dopant. With increasing doping, on some chains two polarons will be formed; on collision, they will convert into two uncorrelated charged solitons. The conductivity increases accompanied by a decrease of EPR signal intensity. In bipolaron-supporting polymers, introduction of the dopant yields also an ionized polymer chain, and polarons (radical ions) are formed. With increasing concentration, the polarons interact, eliminating radicals and producing correlated pairs of ions, i.e., bipolarons. The spinless conductivity in these polymers is attributed to bipolaron migration (Frommer and Chance, 1988).

The doping of polyconjugated polymers results in dramatic changes in absorption spectra. In *trans*-$(CH)_x$, upon oxidation by electrochemical doping, a new absorption band emerges associated with the polaron (radical cation); with increasing dopant concentration, this band evolves to the absorption band of the charged soliton (cation). In bipolaron-supporting polymers, the polaron absorption bands emerging at low dopant concentration convert to bipolaron absorption at high doping. The growth of the new absorption bands with increasing dopant concentration is accompanied by a decrease of the absorption band of the neutral polymer.

An unusual property of conducting polymers—spinless conductivity—was observed for the first time for *trans*-$(CH)_x$ with low dopant concentration, and it was related to charge transport by charged solitons. However, an isolated charged soliton cannot jump to the next, defect-free chain because it would require high energy to rearrange the bond alternation. According to the Kivelson model (1981), such a jump is possible if a neutral soliton is present on the next chain. Because the neutral soliton is more readily ionized than the defect-free chain, it is unlikely that enough neutral solitons would remain to support the increasing conductivity with increasing doping. Therefore, Kivelson's model cannot explain the spinless conductivity in *trans*-$(CH)_x$ at higher dopant concentration; evidently, it cannot explain also the spinless conductivity in other polyconjugated polymers that are not soliton supporting. A more general model of spinless transport assumes that it is executed by bipolarons [in *trans*-$(CH)_x$, the bipolaron would be formed by a pair of uncorrelated charged solitons], which can jump between chains with relatively low activation energy (Frommer and Chance, 1988). However, also this model lacks generality to the polymers with the highest doping level, where the conductivity can be described by conventional electronic mechanisms involving hopping or tunneling (Schimmel *et al.*, 1990).

The macroscopic conductivity of a conducting polymer is a function of intrachain conductivity and interchain conductivity. Each of these components is a function of many factors. The intrachain conductivity depends on conjugation length, density, and extent of defects, and interactions with dopants. The interchain conductivity in a general sense comprises not only the charge transfer between adjacent chains, but also the transport between highly conducting regions and between morphological entities, like fibers in Shirakawa-type polyacetylene (Ehinger and Roth, 1985). Therefore, the interchain conductivity depends on various morphological factors: chain packing and the orientation of the chains relative to each other, homogeneity of doping, crystallinity, if any, and size of crystallites, and morphology on the supramolecular scale (size and separation of fibers, grains, etc.) (Wegner and Ruhe, 1989). The models describing the mechanism of conductivity in doped polyconjugated polymers have to take into consideration both the characteristics of low-dimensional systems, e.g., specific charge carriers, like solitons and bipolarons, and the characteristics of polymeric materials, e.g., disorder and heterogeneity at various scales of magnitude, molecular relaxations and phase transitions, possible fractal structures, and percolation phenomena.

4.2 Experimental Techniques

The simple two-electrode method for measurements of the dc conductivity in conducting polymers may yield erroneous results because of unknown contact resistance. Also the temperature dependences of the conductivity and current–voltage characteristics can be affected by contact effects. For these reasons, a collinear four-probe method is preferably used. The method consists in measuring the voltage drop V between two inner electrodes caused by a known current I flowing between two external electrodes; the conductivity of the investigated material is given by the relation

$$\sigma = (I/V)(l/s), \tag{23}$$

where l is the distance between the inner (voltage) electrodes and s is the sample cross-sectional area.

In highly conducting materials, Joule's heat may disturb the measurements of the current–voltage characteristics at higher fields and currents. Also, the conductivity measurements at helium temperatures can be distorted by Joule's heat because of very small heat capacitance at low temperatures. Heating effects can be minimized by use of the pulse technique, consisting in measuring the voltage signals occurring at the inner electrodes caused by short, rectangular pulses of the current.

The conductivity of samples of irregular shapes (but flat and uniform in thickness) can be measured by a modified four-probe method, the van der Pauw technique, where small, pointlike electrodes are placed arbitrarily at the periphery of the samples. Two measurements are performed with commuted current and voltage electrode connections; for calculation of the conductivity value, a correction factor, numerically calculated and published by van der Pauw, is needed. Another modification of the four-probe method, the Montgomery method, is similar to the van der Pauw method but is applied to anisotropic materials; this method allows one to determine components of the resistivity tensor, i.e., the anisotropy ratio.

ac conductivity measurements have proved to be a very useful tool in investigations of the mechanism of charge transport in conducting polymers. The frequency dependences of conductivity are, together with the temperature dependences of conductivity, characteristic of various charge transport mechanisms. Most conducting polymers are inhomogeneous materials, with high conducting regions separated by barriers and low-conductivity regions; these barriers dominate the dc conductivity measurements. The ac conductivity measured at sufficiently high frequencies may give an insight into the conduction mechanism of highly conducting islands.

In the frequency range up to 10 MHz, conventional bridge techniques and automatic impedance analyzers are used. In the GHz microwave range, the method of the perturbation of a resonance-cavity Q is applied. This method consists in measurement of the frequency shift and of the broadening of the resonance line caused by introduction of the sample into the resonance cavity. It allows for calculation of the complex dielectric constant; the real part is related to dielectric properties of the material, and the imaginary part is related to ac conductivity. This method can be applied for samples smaller than the wavelength and the skin depth.

Thermopower measurements are widely used for characterization of conducting polymers, because the thermopower effect is not affected by the charge transport, and so it is less sensitive to inhomogeneities of conducting polymers than conductivity measurements. The analysis of the thermopower data, including the temperature dependence of the Seebeck coefficient, yields information concerning the sign of majority charge carriers, their density and mobility, and the conduction mechanism. In particular, it allows one to distinguish between the metallic and semiconducting types of conductivity (Pukacki, 1993).

4.3 Materials

4.3.1 Synthesis The number of conducting polymers and synthesis techniques is large and fast growing. One can distinguish four major types of synthesis yielding polymers with conjugated backbone: Ziegler-Natta polymerization, electrochemical synthesis, polycondensation, and pyrolysis (Ku and Liepins, 1987).

The most frequently applied Ziegler-Natta polymerization is the so-called Shirakawa synthesis of polyacetylene (PA) using various modifications of catalyst $[\mathrm{Ti}(\mathrm{O}\text{-}n\text{-}\mathrm{C_4H_9})_4\text{-}\mathrm{Al}(\mathrm{C_2H_5})_3]$ system. When $\mathrm{CH{\equiv}CH}$ is introduced over the catalyst solution under appropriate conditions, a $(\mathrm{CH})_x$ film is formed on the surface. The choice of the kind and concentration of the catalyst, and of the temperature (typically in the range 180–450 K), are critical. At low temperatures, the *cis* conformation dominates, yielding a reddish material; at high temperatures, the bluish *trans* conformation prevails.

Typical electrochemical polymerization may be illustrated by the synthesis of polypyrrole (PPy). A single-compartment electrochemical cell with two parallel electrodes (anode made of platinum) contains an electrolyte solution, for example, tetraethylammonium tetrafluoroborate in acetonitrile, and pyrrole. When a current is passed through the cell, under galvanostatic control, electropolymerization onto the platinum electrode occurs, accompanied by simultaneous oxidation. The resulting PPy film, "doped" *in situ* with counterion (BF_4^- in this case), is black and conducting. Other polymers, like polythiophene and its derivatives and polyaniline, can similarly be electropolymerized. All these polymers can be readily reversibly reduced and oxidized electrochemically.

Polycondensation comprises a great number of polymerization techniques, allowing the synthesis of various conducting polymers. For example, poly(*p*-phenylene) can be prepared by oxidative polymerization of benzene with the aid of the aluminum chloride–cupric chloride system, or by coupling of dihalobenzenes with the aid of copper as the catalyst (Ullman reaction), but also by condensation of aromatic nuclei in the presence of organometallic reagents or by decomposition of diazonium salts. Other polymers, like poly(*p*-phenylene sulfide), polyquinolines, polyquinoxalines, or pyrrones, have also been prepared by a variety of polycondensation techniques. The precursor polymer routes constitute a special class of polycondensation consisting in synthesis, as an intermediate, of a "prepolymer" that can be processed (e.g., solution cast as a film and oriented by stretching) and then converted by some elimination reaction to the nonprocessable polyconjugated polymer.

Pyrolysis, when applied to some polymers, like polyacrylonitrile or polyimides, leads to elimination of heteroatoms and formation of extended aromatic structures for which graphite can be a prototype. Charge carriers are delocalized along conjugated ladder-type chains.

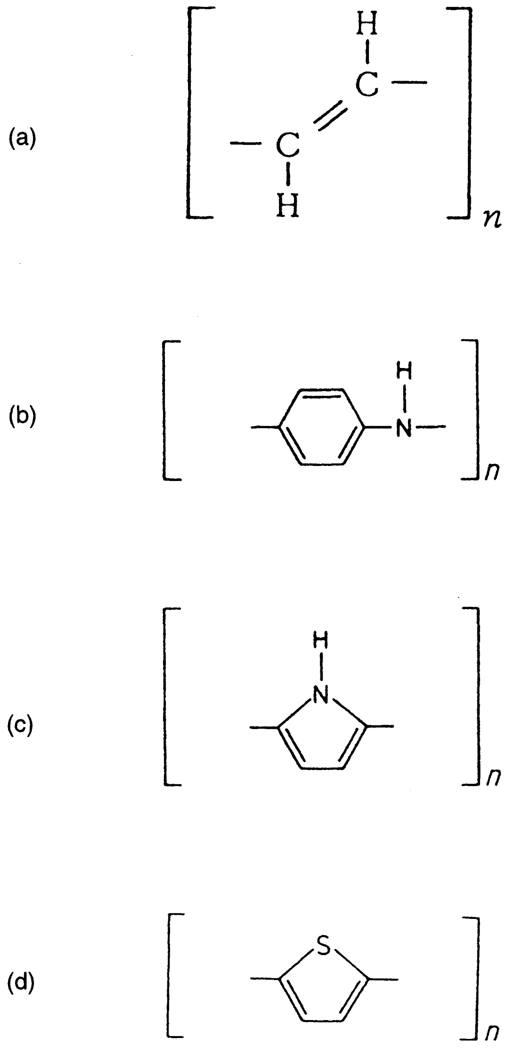

FIG. 4. Schematic structures of (a) *trans*-polyacetylene, (b) polyaniline, (c) polypyrrole, (d) polythiophene.

4.3.2 Characteristics Among numerous conducting polymers, three, polyacetylene, polypyrrole, and polyaniline (Fig. 4), seem to be the most representative.

Polyacetylene is the simplest polyconjugated polymer. It was obtained in a highly conducting state for the first time by Shirakawa *et al.* (1977), and this disclosure marks the beginning of intensive studies on conducting polymers. Its role as a model, quasi 1-D conductor with soliton-type excitations is emphasized in Sec. 4.1.

As obtained, PA is usually a mixture of *trans* and *cis* forms; isomerization to the more stable *trans* form occurs upon doping or heating. When doped with alkali metals, PA shows *n*-type conductivity and is highly environmentally unstable. Doping with oxidative agents, like iodine, bromine, SbF_6, or AsF_5 results in *p*-type conductivity. The value of conductivity of doped PA depends both on the synthesis method and on the doping and may reach 10^5 S/cm (Naarmann and Theophilou, 1987); however, typically it ranges from 10^2 to 10^3 S/cm. The differences in conductivity arise from differences in morphology, influencing the hopping conductivity between the polyacetylene chains, and from differences in conjugation length, influencing the charge transport along the PA chain.

Only the so-called "high-σ" PA, obtained by the Naarmann method, stretched, and highly doped, shows metal-like temperature dependence of conductivity at high temperatures, and it remains high also in the zero-temperature limit. The thermopower of "high-σ" PA is linearly proportional to temperature, as for the ideal metallic diffusion, indicating that it is dominated by quasi 1-D metallic conduction in highly conducting regions. The macroscopic conductivity shows largely nonmetallic behavior because it involves also charge transport through some kind of barriers, e.g., sp^3 defects.

The conductivity of unstretched PA, for example, the Shirakawa-type PA consisting of randomly oriented fibrils of diameter typically about 200 Å, is not only much smaller but also it tends to zero in the zero-temperature limit, showing the absence of continuous metallic paths. The temperature dependence can be fitted by an equation describing tunneling between small metallic islands controlled by the charging energy of the islands:

$$\sigma = \sigma_0 \exp[-(T_0/T)^{0.5}], \tag{24}$$

where σ_0 and T_0 are constants (Kaiser, 1993).

Polypyrrole was the first electrochemically synthesized conducting polymer (Diaz *et al.*, 1979), and it receives considerable interest due to the combination of relatively high conductivity with environmental stability, good mechanical properties, and simplicity of preparation. The PPy films are obtained from the monomer directly in the conducting (oxidized) state because the oxidation potential of PPY polymer is lower than that of the monomer; doping occurs simultaneously with the electropolymerization because the counterions incorporate into the polymer in order to maintain the electrical neutrality of the film. The electrolyte consists of a solvent (usually acetonitrile or water), pyrrole, and various ions, so that PPY can be easily doped with a variety of counterions. The doping (oxidation) is reversible, and PPy can be electrochemically transformed into neutral, nonconducting form.

The PPy films are amorphous and flexible, but with very low ultimate elongation. Their conductivities range in most cases from 1 to 100 S/cm, and the temperature dependence of dc conductivity (σ_{dc}) is described usually by the Mott law developed for variable-range hopping (VRH) (Mott and Davis, 1979) in disordered materials:

$$\sigma_{dc} = \sigma_0 \exp[-(T_0/T)^{0.25}], \tag{25}$$

where σ_0 and T_0 are constants (this equation holds essentially only in the low-temperature regime). However, the density of states at the Fermi level calculated from the fit to the VRH model is unacceptably higher than that obtained from independent ESR studies; also the metal-like behavior of the thermopower is in contradiction to the VRH model. The present understanding of the charge-carrier transport in PPy involves the concept of percolation on a fractal network. The measurements of spin dynamics by NMR at various temperatures indicate an anomalous diffusion in fractal structures of effective dimension $\delta = 1$ at low temperatures; the δ increases with increasing temperature. It is in agreement with the frequency dependence of the ac conductivity (σ_{ac}) following the equation

$$\sigma_{ac} \propto \omega^s \tag{26}$$

with $s = 1 - \delta/3$. At elevated temperatures, the effective dimension increases, indicating an increasing role of the interchain hopping. For three-dimensional hopping at high temperatures, the dc conductivity is given by

$$\sigma_{dc} = \sigma_0 \exp(-2\alpha R) \exp(-E_A/kT), \tag{27}$$

where R is the distance between the neighboring hopping sites, E_A is the energy barrier between the sites, and α is the inverse localization length. The investigations of 3,4-cycloalkyl-substituted PPy fully support this mechanism, showing direct correlation of R with the size of the substituent (Ruhe *et al.*, 1989).

Polyaniline (PANI), known for many years as so-called "aniline black," has attracted considerable research interest only recently, when its unusual electrochemical and optical properties were uncovered (MacDiarmid and Epstein, 1989). Polyaniline is unique among conducting polymers because its electronic properties can be altered both by redox processes involving electron transfer and by acid-base chemistry involving protonation. PANI exists in five forms very different in electrical and magnetic properties. An insulator-conductor transition, like for other conducting polymers, occurs upon charge-transfer doping, and the conducting PANI form, emeraldine salt, can be obtained directly from the leucoemeraldine, which is a large–band-gap insulator. Additionally, protonation of the semiconducting PANI form, the emeraldine base, yields the emeraldine salt by a conversion of the quinoid ring to the benzoid structure with an associated spin unpairing resulting in conductivity changes by 10 orders of magnitude. The conducting PANI form, emeraldine salt, shows good chemical stability. PANI was categorized initially as an intractable polymer; then several methods were reported to dissolve this polymer, for example, in strong acids, but an important advance was the elaboration of the counterion-induced processability of conducting PANI (see Sec. 4.3.3.).

4.3.3 Processable Conducting Polymers

Practically all initially obtained conducting polymers were not processable (insoluble and nonmelting). Insolubility causes serious problems in characterization of the molecular structure of conducting polymers since many investigation techniques can be applied only for polymer solutions. For commercial applications, it is also necessary to have materials processable with conventional plastic technologies.

The insolubility of conjugated polymers in the conducting state was related to side reactions, like cross-linking, caused by free radicals, radical ions, and ions present in the doped polymers. For these reasons, the first approaches to processing conducting polymers were limited to systems obtained via tractable precursor polymers. Nonconducting precursors can be dissolved in order to produce films or fibers; these films or fibers can be further processed, e.g., oriented by stretching, and then converted into a conducting, but no longer processable, state. Highly oriented, anisotropic PA films are obtained in this way, using the so-called Durham route (Edwards and Feast, 1980).

Further progress in processing of conducting polymers was achieved by solubilization of polyconjugated polymers by substituting side groups in them. The most known and investigated are polythiophenes (Fig. 4) substituted with alkyl chains, like poly(3-octylthiophene) (Elsenbaumer *et al.,* 1986). They are soluble in several common organic solvents and are melt processable at temperatures below 200 °C, so that they can be blended with thermoplastics and elastomers using standard techniques and then doped in order to transform the poly(3-alkylthiophene) into the conducting state.

Counterion-induced processability of conducting PANI was achieved by using a suitable functionalized acid to protonate the base form of PANI (Cao *et al.,* 1993). Polyaniline soluble in common organic solvents was synthesized by introducing counterions of large size, which reduce the interchain interactions. Using sulfonic acids, like dodecylbenzene sulfonic acid, soluble polyanilines in the conducting state were obtained. Diesters of phosphoric acid with alkyl substituents, being protonating agents for the emeraldine base, cause also plastification and solubilization of the protonated, conducting emeraldine salt; conducting films can be obtained by casting as well as by hot pressing (Laska *et al.,* 1993). Various other protonic acids acting as surfactants can be used. The conductivity obtained in PANI films cast from solutions is quite high, usually in the range 1–400 S/cm.

4.3.4 Heterogeneous Conducting Polymer Composites

Making polymer composites is one of the most effective and flexible methods in getting speciality materials. Great progress has been made in obtaining fully organic, heterogeneous, electrically conducting systems (Kryszewski, 1991). One can distinguish several main groups in terms of their composition, morphology, and conductivity.

Conducting colloid composites. Stable colloids can be made of different conducting polymers in aqueous and nonaqueous media allowing one to cast films or to press pellets of the dried dispersions. In these systems, conducting grains are surrounded by an insulating steric stabilizer. Colloidal polypyrrole (PPy) can be obtained in the form of spherical particles of diameter in the range 50–500 nm, depending on the preparation conditions, and yields films with conductivity in the range 0.1–2 S/cm. In the case of polyaniline (PANI) colloids, the grain size can be smaller; the cast films of PANI with poly(vinyl acetate) stabilizer show a conductivity of ca. 6 S/cm (Aronson *et al.*, 1991).

Blends of processable conducting polymers with inert polymers. In most of these composites, the conducting phase is made of poly(3-alkylthiophene)s (P3AT), because these polymers are soluble in common organic solvents and also can be melt-blended without decomposition (Laakso *et al.*, 1989). Further progress in such composites is expected as a result of works on the counterion-induced processability of PANI (see Sec. 4.3.3). Very high effectiveness of the conducting phase formation has been achieved by so-called gel decoration. Conducting gels of ultrahigh-molecular-weight PE and poly(3-octylthiophene) (P3OT) were prepared by gelation from solutions in decalin followed by doping with iodine. No percolation threshold was found down to 0.0005 vol fraction of P3OT, and already above 0.02 vol fraction, the conductivity saturates reaching values in the range 10^{-3} to 10^{-2} S/cm. The conducting network is formed of conjugated chains either absorbed or entangled within the PE network (Heeger *et al.*, 1991).

Mixtures of insulating polymer matrices and fillers made of conducting polymers. From the point of view of preparation, these mixtures can be most readily related to polymer–carbon-black composites. The particles of insoluble and/or infusible polymers, e.g., PPy or PANI powders, play the role of conducting filler. Utilizing the high thermal stability of polyaniline tosylate (up to 250 °C for short intervals in nitrogen) it is possible to prepare blends with a variety of conventional thermoplastics (Kulkarni *et al.*, 1991).

Composites obtained by polymerization of conjugated polymers within an insulating matrix. Some monomers, like pyrrole, can penetrate insulating polymeric matrices and, after subsequent polymerization, form conducting networks. This can be easily done with porous materials, such as paper, for which conductivity as high as 10^{-1} S/cm has been reported. Often used is the electrochemical method in which pyrrole penetrates an insulating substrate on a precoated electrode and electropolymerizes *in situ.* Conducting fibers have been obtained by chemical polymerization of pyrrole within the voids of never-dried poly(*p*-phenylene terephthalamide) fibers. At 0.57 vol fraction of PPy, the conductivity is ca. 2 S/cm (Rector *et al.*, 1991). Another route for manufacturing conducting fibers consists in polymerization of acetylene in gel fibers containing 2 wt % of ultrahigh-molecular-weight PE (Chiang *et al.*, 1988). The fibers comprise up to 80 wt % of PA, and after doping with iodine, their conductivity is 1200 S/cm; fibers drawn 2–3 times show after doping a conductivity around 6000 S/cm.

Conducting polymer salts with polymeric counterions. Very specific PPy composites can be produced in one step by electrochemical synthesis using polymeric counterions, like poly(p-styrenesulfonate) (PSS) or other anionically derivatized polymers, including elastomers. In such materials, the insulating phase, i.e., polycounterions, is an intrinsic part of the conducting phase. It has been demonstrated that the conductivity behavior of such composites is controlled by the polycounterion conformation (Glatzhofer *et al.*, 1987). Choosing proper sulfated polymers, one can get thermoplastic and elastic PPy composites (Wernet, 1991).

Reticulate doped polymers consisting of a crystalline network of "organic metals" penetrating a polymer matrix. Reticulate doped polymers (RDP) are obtained by crystallization of conducting charge-transfer (CT) complexes or salts *in situ* in a polymer matrix (Jeszka *et al.*, 1981). When conditions are optimized, a continuous network consisting of microcrystals penetrates the polymer matrix allowing one to obtain conducting materials with extremely low loading, below 0.003 vol fraction. A great number of various systems have been elaborated (Ulański, 1990). The CT complexes and salts used as the dopants include organic semiconductors, organic metals, and organic superconductors. The best systems exhibit conductivities above 1 S/cm at merely 1 wt % of the dopant; the films are transparent, flexible, and environmentally stable. A modified reticulate doping method, the so-called zone-casting technique, allows production of anisotropic composites with conducting crystals forming parallel paths, showing very high anisotropy of conductivity, 10^6 or more; another modification yields films that are only surface conducting.

While the number of polymeric conducting composites is quickly growing, the conductivity mechanism in such systems is not fully understood. Most of the models considered are oversimplified, related to polymer/conducting filler (e.g., carbon black) mixtures. In general, in heterogeneous systems, different mechanisms can contribute to the charge-carrier transport: high-mobility motion in ordered regions (e.g., within crystalline inclusions or along nondefected, oriented polymer chains); hopping among localized states in disordered regions; tunneling between highly conducting islands—all controlled by, generally speaking, the percolation process.

4.3.5 Superconducting Polymers The search for superconducting polymers was motivated by Little's hypothesis (1964) that a quasi one-dimensional polyconjugated chain with side groups in which oscillations of electronic charge can be induced may exhibit high-temperature exciton-type superconductivity. No such polymer was found; moreover, there are theoretical arguments that such a 1-D chain, isolated because of bulky side groups, cannot sustain long-range order.

The first discovered superconducting material without metallic elements was crystalline poly(sulfur nitride), $(SN)_x$. The $(SN)_x$ crystals are obtained by solid-state polymerization of S_2N_2 crystals, obtained by pyrolitic conversion of S_4N_4 in the presence of silver wool as a catalyst. The superconductivity transition temperature depends on crystal perfection and ranges from 0.26 to 0.35 K. Several experimental observations, like the specific heat anomaly and, first of all, the Meissner effect, show that $(SN)_x$ is a bulk type-II superconductor in which electron–electron Umklapp scattering between electron and hole pockets of the Fermi surface occurs rather than the usual electron–phonon–electron interactions (Gill *et al.*, 1982–83).

Recent works on organic superconductors are concentrated on other synthetic metals—molecular CT complexes. The first such system, tetramethyltetraselenafulvalene phosphorus hexafluoride, exhibits superconductivity below 0.9 K under pressure of 12 kbar. Other systems are superconducting also at ambient pressure: *bis*-ethylenedithiolotetrathiafulvalene with iodine, $(BEDT\text{-}TTF)_2I_3$, when transformed into the so-called β^* phase, shows a superconductivity transition at around 7 K (Yagubskii, 1993). Superconducting polymer composites were obtained recently by reticulate doping of polycarbonate with $(BEDT\text{-}TTF)_2I_3$ (Laukhina *et al.*, 1995). The highest superconductivity transition temperature reported so far for organic systems, approaching 33 K, was found for fullerenes, C_{60}, intercalated with alkali metals M, of general formula M_3C_{60} (Fischer and Bernier, 1993) (see FULLERENES).

4.4 Applications

Practical use of the basic property of conducting polymers, the electrical conductivity, was limited for a long time by problems with processing and stability. The first commercialized conducting, fully organic polymeric systems were the transparent, flexible, and stable films obtained by the reticulate doping technique (see Sec. 4.3.4). Conductive and transparent films are produced also by dispersing particles of an intrinsically conducting polymer (e.g., polypyrrole or polyaniline) in an inactive polymer matrix (Roth and Graupner, 1993).

Remarkable progress in the application of conducting polymers as antistatic materials, electromagnetic shielding, sheathing for electric power cables, and conducting fibers and textiles can be expected as a result of the discovery of processable (from solution or from melt) conducting polymers with improved environmental stability. Conducting films or fibers made of composites of conducting polymers with high-performance polymers yields conductivity materials of outstanding mechanical properties. The technique of decoration of a preexisting gel network by a conducting polymer should be a useful technique for producing conducting composites with very low content of conducting polymers (Heeger, 1993).

Numerous attempts have been made in order to exploit practically unusual electrical and optical phenomena induced by the injection of carriers into the π-electron system of conducting polymers. Reversibility of the electrochemical doping of PA has allowed construction of light-weight, high-power-density rechargeable batteries. Doped PA forms a Schottky-type contact to various substrates, making possible construction of photovoltaic devices, and because the band gap of PA matches perfectly the solar energy spectrum, PA-based solar cells have been built.

At present, various polymer batteries have already been commercialized. Typically, they contain a polymer anode (e.g., with PPy or PANI as the electrochemically active material), an electrolyte based on lithium salt solution, and a lithium or lithium alloy counterelectrode. The high charge-storage capacity of conducting polymers has been utilized also in the construction of capacitors with anode and cathode made of polypyrrole showing energy-storage density values two orders of magnitude bigger than conventional capacitors.

Doping/dedoping-induced changes in the absorption spectra of conducting polymers are utilized for electrochromic devices. The undoped polymer, if its energy gap is greater then 3 eV, is transparent in visible light; after doping, it has a high absorption coefficient (10^5 cm^{-1}), and thus thin films are sufficient for effective attenuation of the transmitted light. Displays made of electrochromic polymers exhibit a broad viewing angle and high stability of the image without the need of a permanently applied electric field, in contrast to the displays made of liquid crystals.

The very high third-order nonlinear optical susceptibility of conjugated polymers with subpicosecond response times and high damage thresholds are the reasons for great interest in these polymers as nonlinear optical materials for photonics.

Many other potential applications of conjugated polymers are reported: chemical sensors, making use of changes of conductivity of these polymers due to redox reactions; separation membranes, utilizing drastic changes of permeability of conducting polymers upon oxidation; electronic devices, using the ability of these materials to form rectifying junctions, Schottky barriers, etc.; LEDs built of polymers like poly(p-phenylene vinylene) showing electroluminescence; and drug release devices, where the drug molecules, incorporated as counterion into the conducting polymer, can be released during the reduction (Salaneck *et al.*, 1991).

GLOSSARY

Aromatic Amine Group: A group often present in pendant groups of photoconducting polymers, consisting of a nitrogen atom with adjacent aromatic group(s).

Bipolaron: A correlated pair of ions, being the effect of interaction of two polarons. Bipolarons carry double charge and no spin.

Charge-Transfer Complex: Product of molecular interaction between electron donor and electron acceptor.

Conductor: A material in which carriers are plentiful; either the valence band is only partially filled or the valence and conduction bands overlap.

Dispersive Transport: A hopping transport in which Gaussian statistic is not applicable because of the very broad spread of the hopping times extending into the time range of the experiment.

Electrophotography: A technique of image copying consisting in exposing of a corona-charged layered photoconductor to the image reflected from the original so that dark areas remain charged. Then the latent image is developed by electrostatic attraction of the toner particles to the charged areas and is transferred to a sheet of paper.

Ferroelectric: A material that exhibits spontaneous polarization and electric hysteresis.

Hopping Transport: A conduction mechanism in which charge carriers hop among localized sites of dimensions smaller than the average intersite distance.

Insulator: A material with few carriers of low mobility, characterized by a wide energy gap in terms of the band structure model.

Peierls Transition: A metal-insulator transition in one-dimensional systems induced by a symmetry-reducing distortion (e.g., dimerization in *trans*-polyacetylene).

Photoconductor: A semiconductor whose conductivity is sensitive to light because of the creation of electron-hole pairs by absorption of photons.

Piezoelectric: A material that becomes polarized when stressed.

Polaron: A defect formed by ionization of a polyconjugated polymer, consisting of a radical ion associated with a distortion of the lattice around the charge.

Polyconjugated Polymer: Polymer with an extended π-electron system in the backbone (with unsaturated backbone).

Relaxation Time: The time required for a disturbed system to reach $1/e$ of the final equilibrium configuration.

Relaxation Frequency: The reciprocal of the relaxation time.

Soliton: A defect in *trans*-polyacetylene, being the domain wall across which the bond alternation on the chain is reversed. The neutral soliton is the radical defect; the charged solitons are the anion or cation defects carrying charge but no spin.

Synthetic Metals: A class of conducting materials generally not containing metal atoms and usually consisting of organic molecules or macromolecules. Synthetic metals have low-dimensional structures and exhibit high electrical conductivity, in the best cases metal-like, with respect to the value of the conductivity and temperature dependences of conductivity and of thermopower. Some of these materials also exhibit superconductivity at low temperatures.

Time-of-Flight Technique: A method of determination of charge-carrier mobility consisting in measurement of the transit time of a packet of charges across the sample.

Xerographic Discharge Technique: A method of determination of quantum efficiency of photogeneration and of charge-carrier mobility, consisting in monitoring of the decay of the surface potential of the corona-charged sample after a short pulse of light.

INTRODUCTION

The basic mechanical properties of a solid are its stiffness, strength, and toughness. Stiffness, the ratio of load to deflection, depends on the material and on the shape of the body. The material property itself is a modulus, a ratio of stress to strain (or a compliance, a ratio of strain to stress). The strength of a material is the stress at which the material fails by fracture or by irreversible deformation. Toughness is a measure of the work required to fracture a material. Polymeric materials come in endless chemical variety, and these materials display an enormous range of mechanical properties. Materials may be manufactured in forms that have high stiffness and strength, as fibers to reinforce tires, for example. Equally, low stiffness and low strength may be desirable for gaskets and packing materials. The properties of some typical polymers are compared with the properties of other materials in Table 1.

A complication is that polymer mechanical properties are strongly dependent on time and temperature. A polymer may appear as a stiff and rigid solid when subject to impact loading, but either as a soft elastic rubber or as a viscous liquid when the loading persists over a long time. All solids tend to flow at high temperatures, and for metals this is a serious problem for designers of jet engines. Very few users of polymers can afford to ignore the change of properties with temperature. Many natural and synthetic materials are also highly sensitive to water content and other environmental effects. Further, naming the chemical species is not enough to define the material; the molecular weight and processing conditions can have strong effects on polymer mechanical properties. Failure is strongly affected by the conditions of loading. This is a general phenomenon, as, for example, steel becomes more brittle when cold, but in polymers the range of behavior can be extreme. A single sample may be a brittle solid with very little extensibility at −10 °C, a tough solid that extends 30%–100% before breaking at room temperature, and a fluid with the consistency of soft chewing gum at 150 °C.

Polymers consist of long molecular chains. There are strong covalent bonds along the chain and much weaker bonds (hydrogen or van der Waals bonds) between chains. If the chains are frequently linked into a network, the result is a "thermosetting" polymer that does not melt. If there are only a few crosslinks, these stabilize the

[a] Compressive strength.

form of the material, even when the chains are in a mobile liquidlike state, giving an elastomer. Elastomers are soft and very extensible because the free chains between crosslinks can be extended by covalent-bond–angle rotation. Entanglements between long linear chains can act as temporary crosslinks, giving rubbery behavior at short time scales.

In a polymer glass, the chains are locked into one configuration. Above the glass-transition temperature T_g, the chains are mobile. Many properties change at T_g, including the coefficient of thermal expansion and the heat capacity, but for our purposes the changes in mechanical properties are most important. The modulus falls drastically as the temperature is increased through T_g, and the extension to failure will also change. This makes T_g a most important parameter for a polymer. Elastomers have a T_g below ambient (~ -60 °C for natural rubber) and polymers normally considered glassy have a T_g above ambient (~ 100 °C for polystyrene, PS). The chains move with a finite speed, and so a slow experiment sees them in motion, while a rapid one sees them fixed. T_g is thus frequency dependent. A true state of no motion is attained at temperatures below T_g^∞, which is some 50 K below the tabulated and practically useful value of T_g.

A polymer may be an amorphous glass, rubber, or liquid, or it may contain a degree of order. The order may be within crystalline or liquid-crystalline (LC) elements, but except in a few special cases the crystals or LC domains are very small and imperfect. In the crystalline case, the materials are described as "semicrystalline" and are modeled as containing two phases: ideal crystallites and ideal amorphous material. The fraction of crystalline phase in this model is the "degree of crystallinity," which can vary from 0.2 to 0.9. The semicrystalline material is a composite, and so its mechanical properties depend on the properties of both phases and on their arrangement. Most semicrystalline polymers are used at temperatures between T_g and the crystalline melting point T_m.

When extending the chain requires covalent-bond bending or stretching, the chain will be stiff in tension. As the bonds between chains are weak, any chain orientation will then give anisotropic mechanical properties. The ratio of perpendicular elastic moduli in tension may be as much as 100:1 in an oriented crystalline fiber, less in oriented glassy material. Failure modes that depend on chains slipping past each other and brittle failure that involves breaking bonds will also be strongly affected by chain orientation. Because chains are long, large-scale structures may be involved in deformation, and so response and relaxation times can be very long. Polymers often show a delayed elastic response, where the recovery on unloading takes a long time.

These general concepts explain the broad features of the mechanical properties of solid polymers. In detail, they are often insufficient to explain the actual properties, because of the complicated internal structure of the materials. In addition, many commercial polymers are blends or copolymers, and may contain rigid mineral filler particles and additives such as plasticizers and antioxidants that significantly affect their properties.

1. MECHANICAL PROPERTIES AND TESTING

Most mechanical testing of solid polymers uses standard tests that set out particular sample dimensions, geometry and rate of deformation, temperature, and humidity. These are excellent for quality control and very useful for comparison between materials. They are described in full detail in ASTM and DIN handbooks (ASTM, 1994; DIN, 1994). These tests can be used to measure the stiffness of a molded bar, its impact strength, or the tear strength of an elastomer. Some have been set up to test for a specific practical problem, such as stress cracking of polyethylene in detergent. The problem with this type of test is that extrapolation to different conditions of loading is difficult and uncertain. There is a continuing effort to design and validate tests for failure that have a good scientific basis and are also rapid and useful.

A picture of the polymer properties can be built up using more fundamental tests, which are

1. creep testing—measurement of displacement as a function of time at a constant load to give a time-dependent creep compliance $J(t)$;
2. stress-relaxation testing—measurement of load as a function of time at a constant displacement to give a time-dependent relaxation modulus $E(t)$;
3. dynamic mechanical testing—measurement of the amplitude and phase of displacement under a load that is a sinusoidal function of time. This gives a complex modulus $G^*(\omega) = G'(\omega) + iG''(\omega)$ or an equivalent complex viscosity $\eta^*(\nu) = G^*(\omega)/i\omega$. Thermal transitions in the material are more easily seen when the ratio G''/G' (often called the loss tangent or $\tan\delta$) is plotted as a function of temperature.

By linear-viscoelastic theory (described in Sec. 2.2.1, below) the results of these tests can used to predict behavior under more general conditions of loading (Ferry, 1970; Arridge, 1975). Unfortunately, most polymers are not linear in their mechanical behavior; that is, their stiffness depends to some degree on the value of the applied load. The conditions when this becomes important can be determined by plotting the compliance after a fixed time of creep for a range of loads. This isochronous stress–strain curve will be a horizontal line in the linear region. Good prediction of mechanical properties under general loading conditions can only be made for small deformations unless a much larger database is built up.

Commercial dynamic mechanical testing instruments are the fastest way to find the temperature dependence of mechanical properties. They apply a forced vibration to a small sample in shear, bending, or tension. The sample is held in a temperature-controlled enclosure, and the mechanical response is measured over a wide range of temperatures and at a range of frequencies. An example result is shown in Fig. 1. G', the in-phase or storage shear modulus, falls by a factor of several hundred near the glass-transition temperature, T_g = 100 °C. At the transition, there is a peak in the loss tangent $\tan\delta$. In this case, there is also a clear peak in the loss modulus G'' and a secondary tran-

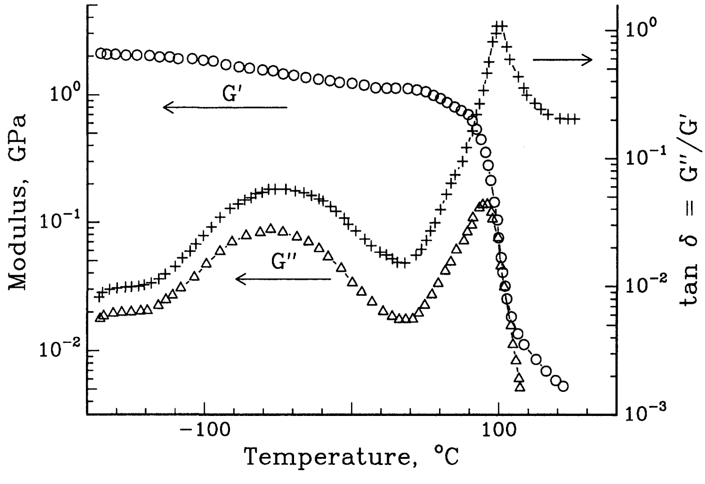

FIG. 1. Dynamic mechanical properties of unplasticized poly(vinyl chloride) (PVC). At $T_g \sim$ 100 °C the storage shear modulus G' falls dramatically, where there are peaks in both $\tan\delta$ and the loss modulus G'. A secondary transition at about −60 °C is clear in $\tan\delta$ and G'. Redrawn from Peterson and Ranby (1970).

sition below T_g at about −60 °C. These tests can be performed in tension or in shear. The conventional symbols for tensile modulus and compliance are E and D. For shear modulus and compliance they are G and J.

Elastic properties at high strain rates can be determined by ultrasonic modulus measurements; these are simple in principle and have many advantages. For unoriented materials, and for oriented materials when the acoustic waves propagate down symmetry axes of the sample, the relevant modulus component is simply the density times the square of the wave velocity. In an isotropic material longitudinal waves give E, transverse waves give G, and so any of the other elastic properties can be calculated. For example, the values for nylon 6 (and nylon 66) obtained in this way are $E = 4.0$ GPa, $G = 1.43$ GPa, bulk modulus $K = 6.5$ GPa, and Poisson's ratio $\nu = 0.40$. A pulsed laser beam focused onto the specimen has been used to find the longitudinal modulus of a fiber. The pulse creates a shock wave that moves at the speed of sound along the fiber, so that timing the shock wave gives the fiber modulus. Testing for failure at high strain rates requires special testing machines that use hydraulics or compressed air to deform the sample rapidly. They can be used for strain rates of 10–100 s^{-1}. Higher rates require ballistic testing.

2. ELASTIC PROPERTIES

2.1 Rubber Elasticity

Rubber elastic materials can be deformed reversibly to very large strains, three to ten times their original length. Their shear modulus is typically 1 MPa or less while their bulk modulus is ~1 GPa. An elastomer contains crosslinked amorphous polymer chains. The number of units between crosslinks must be reasonably large so that the chains can take up a range of configurations. The temperature must be above T_g so that the chains are not locked into one configuration.

The physical principle of rubber elasticity is that the material force restoring an elastomer to its original shape is entropy driven. An ideal rubber has no change in internal energy on deformation, only an entropy change. Simple thermodynamics shows that in this case the restoring force at constant length will be proportional to the absolute temperature. Measurements of force as a function of temperature at constant length, or measurements of length as a function of temperature at constant force (corrected for thermal expansion), are used to find out how well a given material can be modeled as an ideal rubber (Treloar, 1975; Flory, 1969). A stretched rubber shrinks on heating, and, as may be tested with an office elastic band, rapid release after stretching causes the material to cool.

Even with no crosslinks, many long-chain polymers show rubbery behavior in some range of temperature and time scale. This is because physical entanglements between the chains restrain them like crosslinks for short times. The range of the "rubbery plateau" where the modulus is constant increases with molecular weight, but the actual "plateau modulus" is independent of molecular weight. Practical elastomers are generally reinforced by the addition of rigid particles and/or by the polymer crystallizing on extension. The increase in stiffness and strength when carbon black particles are added to rubber to make tires depends strongly on the size and the surface condition of the particles. When the filler affects a large fraction of the material, it may become much less extensible. In semicrystalline polymers above T_g, the crystals act as reinforcing particles and also as cross-linking sites physically fixing the amorphous chains. However, full rubbery behavior may not be developed because the amorphous chains are short and highly constrained.

2.1.1 Statistical Principles In brief, the elastomer at equilibrium contains molecular chains in the form of random coils. When stretched these have fewer possible configurations, and it is this entropy change that drives the elasticity. Even though real molecules have restricted angles of bond rotation, a long chain can be accurately described as a set of n freely jointed links of length l, where n is less than the number of bonds in the chain. As long as the chain is not near to full extension, its three-dimensional random walk starting at the origin has a Gaussian probability distribution for the position of the end of the chain:

$$P(x,y,z)dx\,dy\,dz = \left(\frac{b}{\sqrt{\pi}}\right)^3 e^{-b^2(x^2+y^2+z^2)}dx\,dy\,dz, \tag{1}$$

where $b^2 = 3/2nl^2$. The mean square end-to-end distance for the chain, $\overline{r^2}$, is equal to nl^2. The entropy associated with the possible chain conformations is $S = C - kb^2(x^2 + y^2 + z^2)$ where k is Boltzmann's constant. Consider deforming this chain so that the end moves to x', where $x' = \lambda_1 x$. The entropy change is

$$\Delta S_x = -kb^2x^2(\lambda_1^2 - 1). \tag{2}$$

For a general deformation to $\lambda_1 x$, $\lambda_2 y$, $\lambda_3 z$, we may integrate over the distribution $P(x,y,z)$ or equivalently replace x^2, y^2, and z^2 with $\overline{r^2}/3 = nl^2/3 = 1/2b^2$. For an ideal chain with no change of internal energy on bond rotation, $\Delta A = -T\Delta S$, and so the free-energy change on deformation of an assembly of N such chains deforming at constant volume is

$$\Delta A = (NkT/2)(\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3). \tag{3}$$

The restoring force $F = (\partial A/\partial l)_T = (\partial A/\partial \lambda)_T$ for an initial unit cube. Some simple forms of deformation give useful results. For shear, $\lambda_1 = \lambda$, $\lambda_2 = 1/\lambda$, $\lambda_3 = 1$. In pure shear, the shear strain $e = \lambda - 1/\lambda$ and so

$$\Delta A = (NkT/2)(\lambda^2 + 1/\lambda^2 - 2) = (NkT/2)e^2,$$
$$F = \sigma = NkTe. \tag{4}$$

Thus the shear modulus $G = NkT$. If the deformation is uniaxial at constant volume, $\lambda_1 = \lambda$, $\lambda_2 = \lambda_3 = \sqrt{1/\lambda}$, giving

$$\Delta A = (NkT/2)(\lambda^2 + 2/\lambda - 3),$$
$$F = NkT(\lambda - 1/\lambda^2). \tag{5}$$

This is also the nominal stress—the force divided by the original cross-sectional area A_0, here unity. The actual cross-sectional area A is $1/\lambda$, and so the true stress is $\sigma_t = G(\lambda^2 - 1/\lambda)$. For biaxial deformation, where $\lambda_1 = \lambda_2 = \lambda$, $\lambda_3 = 1/\lambda^2$,

$$\Delta A = (NkT/2)(2\lambda^2 + 1/\lambda^4 - 3),$$
$$F = 2NkT(\lambda - 1/\lambda^5). \tag{6}$$

The above results were derived for an assembly of ideal statistical chains. There are two very important facts about these relations of load and displacement. One is that for most real elastomers they are a good first approximation only. Even for unfilled material, they are not sufficient to interpret a wide range of mechanical data. There are several reasons for this: The real materials are only 80%–90% ideal; even for ideal chains, we have not considered the possibility of fluctuations in the positions of cross-links, nor the effect of a length distribution of chains. Short chains will come near to full extension and non-Gaussian behavior even at low network extensions. Theories exist to treat these complications (Treloar, 1975; Flory, 1969), but most real mechanical data, particularly at high strains, are fitted using phenomenological methods described in the next section. The other important fact is that the relations in Eqs. (4)–(6) do not depend on an entropic basis or a thermodynamic derivation. Exactly the same relations can be derived by pure mechanics, when strains are allowed to be large and a simple constitutive relation between stress and strain is assumed.

2.1.2 Phenomenological Models of Large-Strain Behavior

A general deformation at finite strains is complicated by the fact that finite shear strains change directions in the material. We can choose a set of axes such that the shear-strain components go to zero. In this case, the axes are not rotated by the deformation, and the resulting pure strain can be described by the deformation ratios along x, y, and z: λ_1, λ_2, and λ_3. The finite extensional strains are $\epsilon_{xx} = (\lambda_1^2 - 1)/2$ and so on, while the corresponding stresses are σ_{xx} = (nominal stress)$/\lambda_2\lambda_3$. The work done in deforming the body, which in an elastic material is the stored energy, must be some function of the deformation ratios. It is called the strain-energy function, W. For an isotropic material, the strain-energy function has to be independent of the choice of coordinate axes. There are three independent functions of the deformation ratios that have this property. They are called the strain invariants, I_1, I_2, and I_3, and are

$$I_1 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2,$$
$$I_2 = \left(\frac{1}{\lambda_1^2} + \frac{1}{\lambda_2^2} + \frac{1}{\lambda_3^2}\right)I_3,$$
$$I_3 = \lambda_1^2\lambda_2^2\lambda_3^2. \tag{7}$$

For an incompressible material $I_3 = 1$, so setting $W = 0$ at the original state of the material when $\lambda_1 = \lambda_2 = \lambda_3 = 1$, a general form for the unknown function W is

$$W = \sum_{i=0}^{N} \sum_{j=0}^{N} C_{i,j}(I_1 - 3)^i (I_2 - 3)^j. \qquad (8)$$

If only one term is kept in this power-law expansion, the term with $i = 1$, $j = 0$, the result is identical to the simple statistical theory of the previous section. Assuming a particular simple constitutive relation for the material gives the same result, and a material with this behavior may be called neo-Hookean. More common for real materials is to keep two terms; either the expression for W or the expression for stress in uniaxial tension derived from it may be called the Mooney–Rivlin equation:

$$W = C_1(I_1 - 3) + C_2(I_2 - 3),$$
$$\sigma = \left(\lambda - \frac{1}{\lambda^2}\right)\left(2C_1 + \frac{2C_2}{\lambda}\right). \qquad (9)$$

Practical calculations and finite-element models are likely to use the above expression for the strain-energy function. It is only an approximation and becomes very inaccurate for large tensile elongations. In physical terms, this is because the elongated material is changing its structure; the chains near full extension are no longer Gaussian and Eqs. (1) and (2) no longer apply. Figure 2 shows data for uniaxial elongation, and the fit for $\lambda < 4$ using Eq. (5). The fit with Eq. (9) is slightly better at low strains, but the difference is hardly visible on the scale of Fig. 2. A purely empirical equation for the tensile stress that only needs one parameter is the MRS equation:

$$\sigma = E\frac{\epsilon}{\lambda^2}\exp\left[A\left(\lambda - \frac{1}{\lambda}\right)\right]. \qquad (10)$$

When $A \sim 0.5$ this fits the upturn in stress in Fig. 2. The strain-energy function can also be expressed as the sum of similar functions of each of the deformation ratios, $W = \Sigma_1^3 w(\lambda_i)$. This may be useful when the data are not easily expressed in terms of the invariants. The following form of $w(\lambda)$ has been found to fit the data with three terms:

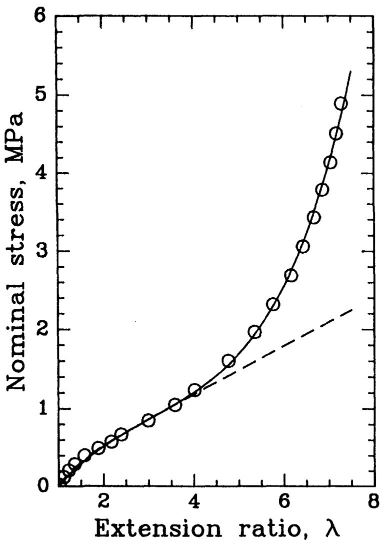

FIG. 2. Data for the uniaxial extension of a rubber, fitted by Eq. (5) for extension ratios below 4 (dashed line) and fitted by Eq. (11) for the full range of extensions (solid line). The data were taken from Treloar (1969).

$$w(\lambda_i) = \sum_n \frac{\mu_n}{\alpha_n}(\lambda_i - 1)^{\alpha_n},$$
$$\sigma_{ii} = \sum_n \mu_n \lambda_i^{\alpha_n} + P. \qquad (11)$$

Figure 2 shows how well this fits the data. A good fit is not surprising with six adjustable parameters. The point is that the *same* parameters fit the shear and biaxial extension data for the same material.

2.2 Viscoelasticity

Real polymers, whether in an apparently solid or liquid form, generally have both viscous and elastic parts to their mechanical behavior and are therefore viscoelastic. The moduli and the viscosity both decrease as the temperature is raised. The elastic properties of solid polymers are nonlinear at deformations greater than 1% or 2%, and accurate measurements at lower strains show that some have no linear region at all. The viscosity of polymers is also nonlinear, commonly decreasing with shear rate. The complex flow properties are very important for processing the polymers.

Much analysis of polymer viscoelasticity has dealt with the linear case, where material properties are independent of the magnitude of the stress, and the effects of stress or strain steps at arbitrary times are additive. (This is called the "Boltzmann superposition principle.") Linear theory is the starting point for modeling, and empirical methods can be used to predict the nonlinear behavior from linear viscoelasticity. It is important to remember that linear viscoelasticity is only a first step in describing or understanding polymer properties.

2.2.1 Models of Linear Viscoelasticity Linear viscoelasticity is a combination of linear Hookean elasticity and Newtonian linear viscosity. The simplest models of linear viscoelastic behavior have a combination of a few Hookean linear elastic springs and Newtonian linear viscous dashpots. A series combination of a spring and a dashpot is called a Maxwell element, and gives a simple model of stress relaxation. A spring and a dashpot in parallel is a Kelvin or Voigt element, and this models creep. The behavior of these networks is analogous to that of electrical circuits containing capacitors and resistors.* To get any combination of creep and stress-relaxation behavior, a combination of three or four basic units is required, such as the three-element "standard linear solid" or a series combination of Maxwell and Voigt elements.

All polymers that stress relax or creep do so over several decades of time. A Maxwell element with spring of modulus G and dashpot of viscosity η under a fixed strain ϵ has a stress-relaxation modulus $G(t) = \sigma(t)/\epsilon = \exp(-t/\tau)$ where the relaxation time $\tau = \eta/G$. The stress decays from 80% to 10% in one decade of time, from 0.2τ to 2τ. To model variation over a wider span of times, several Maxwell elements are placed in parallel, each with its own relaxation time τ_i, and a final relaxed modulus G_∞ is added:

$$G(t) = G_\infty + \sum_{I=1}^{I=N} E_i e^{-t/\tau_i}. \tag{12}$$

To create a model to fit real data, the sum is turned into an integral, and a logarithmic time scale is used, to give

$$G(t) = G_\infty + \int_{-\infty}^{+\infty} H(\tau) e^{-t/\tau} d(\ln\tau). \tag{13}$$

Here $H(\tau)$ is the relaxation-time spectrum, which gives the contribution to stress relaxation associated with relaxation times between $\ln\tau$ and $\ln\tau + d(\ln\tau)$. An equivalent model for creep, using an array of Voigt elements in series, gives an expression for the creep compliance $J(t)$ in terms of the instantaneous elastic compliance J_0 and the retardation time spectrum, $L(\tau)$:

$$J(t) = J_0 + \int_{-\infty}^{+\infty} L(\tau)[1 - e^{-t/\tau}]\, d(\ln\tau). \tag{14}$$

It seems that by this analysis, data for modulus or compliance as a function of time are merely transformed by a Laplace transform into an equivalent representation. Is there an advantage? One is that molecular theories of polymer viscoelasticity give a relaxation-time spectrum. If this is a discrete spectrum then the summing of an exponential series, as in Eq. (12), will give the modulus as a function of time, $G(t)$, for comparison with experimental data. Within the limits of linear theory $G(t)$, $J(t)$, $H(\tau)$, $L(\tau)$, and $G^*(\omega)$ are all related, and in principle any can be derived from any other (Ferry, 1970; Arridge, 1975). There are practical problems in some of these transformations, including for the time spectra the necessity for getting data over 10–15 decades of time. This normally requires the use of time–temperature superposition.

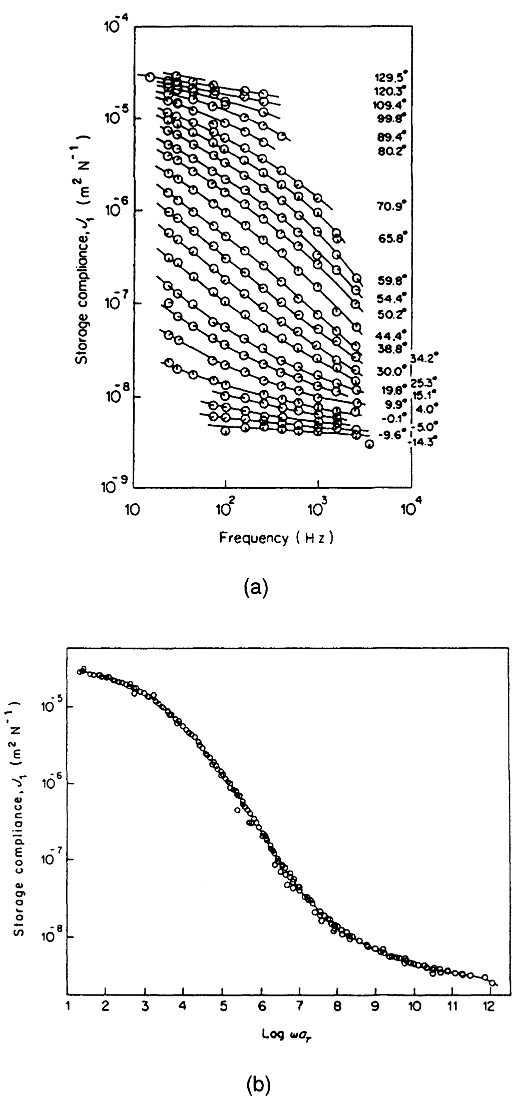
2.2.2 The Glass Transition and Time–Temperature Superposition Qualitatively, polymers soften and flow more as the temperature is raised, or as the time scale of the deformation is extended. It is found that the plots of modulus (or other elastic property) as a function of log(time) at two temperatures can be superimposed by a horizontal shift of the time scale, by $\log(a_T)$. This works at temperatures above T_g. It is made more exact by a small vertical shift of the modulus data, b_T, which takes into account the thermal expansion of the material and the increase of rubbery modulus with absolute temperature:

---

*The dissipative dashpots should be made the resistors, and the energy-storing springs the capacitors, although springs are always drawn to look like resistors do in circuit diagrams. Worse, to allow charge to be equivalent to strain and potential to stress, every parallel arrangement is analogous to the series electrical case, and vice versa.

$$G(t,T_1) = b_T G(t/a_T,T_2). \tag{15}$$

This relation allows data taken over a limited range of times and temperatures to be turned into a master curve over many decades of time. A data set taken from the work of Ferry is shown in Fig. 3, in its original form [Fig. 3(a)] and after shifting to form a master curve over 11 decades of time [Fig. 3(b)]. The shift factor a_T is not a function of time, and was found empirically to have the following form, which is called the WLF equation:



(a)

(b)

FIG. 3. (a) Storage compliance of poly(*n*-octyl methacrylate) measured in the frequency range 20–400 Hz at temperatures from −14 to 129.5 °C. (b) A master curve obtained by shifting the data shown in (a) to give the compliance at 100 °C over 11 decades of frequency. (From Ferry, 1970.)

$$\log a_T = -\frac{C_1(T - T_S)}{T - T_S + C_2}. \tag{16}$$

To a first approximation, when the reference temperature T_S is taken to be T_g as measured from volumetric thermal expansion, $C_1 \simeq 17$ and $C_2 \simeq 52$ for *all* polymers. A better fit for a wide range of materials is obtained by setting $C_1 = 8.86$ and $C_2 = 101.6$ and making T_S an adjustable parameter, generally found to be about $T_g + 50$ (Ferry, 1970). This universal behavior can be explained in terms of the free volume in the liquid and its relation to molecular mobility.

2.2.3 Nonlinear Viscoelasticity The equations describing nonlinear viscoelasticity may involve entirely empirical forms, complicated representations, or both of these together. Generally the range of materials and conditions over which any equation is applicable is quite limited. Thus polymer liquids are dealt with separately from polymer solids. An example of an empirical correlation between linear and nonlinear viscoelasticity in polymer liquids is the Cox–Mertz rule:

$$\eta(\dot{\gamma}) = |\eta^*(\omega)|_{\omega=\dot{\gamma}}. \tag{17}$$

This means that the steady-state viscosity at a shear rate $\dot{\gamma}$ is equal to the magnitude of the complex viscosity, as defined in linear theory and measured in oscillatory flow with a frequency equal to the constant shear rate. There is no theoretical justification for the Cox–Mertz rule. One of many models for polymers is called the Oldroyd fluid *B*. Its nonlinear constitutive equation for fluid flow is

$$\boldsymbol{\sigma} + \tau\frac{\delta\boldsymbol{\sigma}}{\delta t} = \eta\left(\dot{\boldsymbol{\Gamma}} + \tau'\frac{\delta\dot{\boldsymbol{\Gamma}}}{\delta t}\right). \tag{18}$$

Here $\boldsymbol{\sigma}$ is the stress tensor, $\dot{\boldsymbol{\Gamma}}$ is the strain-rate tensor, and τ and τ' are material constants. This level of complication can model shear-thinning and normal forces in polymer flow, but it is still a Maxwell-type model, and a relaxation-time spectrum needs to be introduced to model a real material.

In solids, nonlinear viscoelasticity is often concerned with creep. Figure 4 shows a schematic surface plot where the height is strain, and the two axes are stress and log(time). The surface can be defined by a few experiments, measuring creep at two different constant loads, and strain as a function of stress at a fixed time of loading. Interpolation and a modest extrapolation then give the strain under a wide range of loads and times, but only for a constant stress. If the loading sequence is more complicated, loading followed by partial unloading for example, these data are of no help. Alternative empirical approaches include power-law formulas similar to those used to describe creep in metals. These are used when the total strain is small, and again for constant-stress loading. For elastomers at large strains the MRS formula has been described in Sec. 2.1.2, Eq. (10).

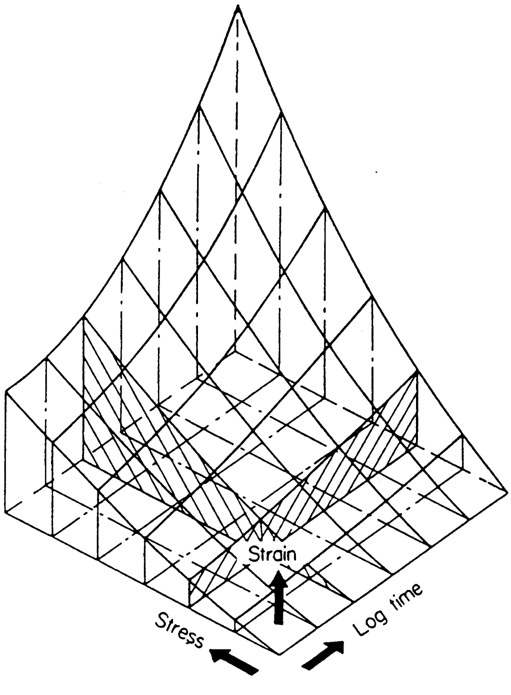


FIG. 4. Schematic plot of nonlinear elastic behavior. The height of the surface is the strain. Sections are shown at constant stress—a creep curve—and at constant time—an isochronous stress–strain curve. Two or more creep curves and one isochronous stress–strain curve may be enough to define the strain surface for design purposes. (From Ward, 1979.)

Creep and recovery experiments often show that the strain cannot be separated into a function of stress only and a function of time. In this case a multiple integral representation of the strain function has occasionally been used, although it contains a large number of parameters. A large amount of data must be collected before the consistency checks allow the representation to be anything more than curve fitting. In principle, the method is an extension of the Boltzmann superposition principle of linear viscoelasticity. In that case, the strain caused by stresses $\Delta\sigma_1$ at time $\tau_1 + \cdots + \Delta\sigma_n$ at time τ_n is given by

$$e(t) = \Delta\sigma_1 J(t - \tau_1) + \cdots + \Delta\sigma_n J(t - \tau_n). \tag{19}$$

In the multiple-integral approach, second-order terms of the form $\Delta\sigma_1\Delta\sigma_2 J_2(t - \tau_1, t - \tau_2)$ are added to the expression for $e(t)$, then third-order terms $\Delta\sigma_1\Delta\sigma_2\Delta\sigma_3 J_3(t - \tau_1, t - \tau_2, t - \tau_3)$ and so on. The J_N are functions of time that must be determined. When the stress is a continuous function of time, each set of terms becomes a multiple integral. This can be useful, but only if it is found that the data can be fitted with very few terms.

2.3 Anisotropic Elasticity

All polymer molecules are intrinsically anisotropic, and so if the molecules are oriented, in a glass or in a crystal, the material will be elastically anisotropic. A generalized Hooke's Law gives a modulus or compliance that is no longer a scalar, but a fourth-order tensor. The 3D set of equations for the linear region is conventionally given in a contracted form:

$$\sigma_p = \sum_{q=1}^{q=6} c_{pq}\epsilon_q \quad \epsilon_p = \sum_{q=1}^{q=6} s_{pq}\sigma_q. \tag{20}$$

Here **C** is the matrix of elastic constants, components c_{pq}. Each c_{pq} is the ratio σ_p/ϵ_q when all other strain components are zero. **S** is the compliance matrix, components s_{pq}. Each s_{pq} is the ratio ϵ_p/σ_q when all other stress components are zero. Indices 1, 2, and 3 refer to normal stress and extensional strain along x, y, and z respectively. Indices 4, 5, and 6 refer to shear in the yz, xz, and xy

planes (Fig. 5). Thus σ_{11} is contracted to σ_1 and σ_{23} is contracted to σ_4. External stability requires that $c_{pq} = c_{qp}$, and this reduces the number of independent components from 36 to 21. If the material has orthotropic symmetry (where there are three mutually perpendicular twofold symmetry axes), the number is reduced to 9, with a compliance matrix of the form

$$\mathbf{S} = \begin{vmatrix} s_{11} & s_{12} & s_{13} & 0 & 0 & 0 \\ s_{12} & s_{22} & s_{23} & 0 & 0 & 0 \\ s_{13} & s_{23} & s_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & s_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & s_{66} \end{vmatrix}. \qquad (21)$$

A common case of anisotropic elasticity in polymers where orthotropic symmetry exists is a sheet biaxially drawn or drawn at constant width, such as the polyethylene sheet used for plastic bags. Conventionally, in this case the z axis is taken as the draw direction of the sheet, x is transverse to the draw direction and in the plane of the sheet. The y axis is then the normal to the sheet. The polymer molecules tend to lie in the plane of the sheet, but more along z than along x. The extensional compliances in the machine and transverse directions in the plane of the sheet are s_{33} and s_{11}, respectively. They will be different and both will be less than that of an isotropic material, while the compliance perpendicular to the sheet, s_{22}, is higher. The out-of-plane compliance is difficult to measure in real thin sheets, and is also of little practical importance in many cases.

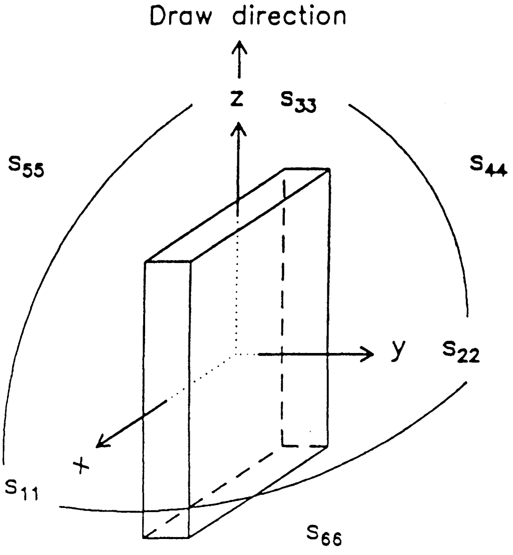

FIG. 5. Axes and compliance component directions for a polymer sheet with orthotropic symmetry (from Grubb, 1993).

If the drawing is uniaxial and the sample dimensions along x and y not too different, then the x and y axes become equivalent. This is called transverse isotropy or fiber symmetry, and such samples then require only five independent elastic constants. The x or 1 axis may be chosen as the unique (fiber draw) axis, but in polymer fibers the z or 3 axis is more common. This is because the molecular-chain axis becomes oriented along the fiber axis by drawing and the chain axis is usually labeled the c, z, or 3 axis in polymer crystals. In this case $s_{22} = s_{11}$, $s_{23} = s_{13}$, $s_{55} = s_{44}$, and $s_{66} = 2\ (s_{11} - s_{12})$.

The full compliance or stiffness matrix has been determined in only a few cases, so theoretically derived components are often used for perfect crystals, and estimates for amorphous or semicrystalline materials. Normally a few measurements are made and individual components are reported as Young's moduli or shear moduli. Consider a material with orthotropic symmetry that has a tensile stress σ applied along z. Here $\sigma_1 = \sigma$, all other stresses are zero, and there will be strains ϵ_1, ϵ_2, and ϵ_3. The tensile or Young's modulus in the 3 direction, E_3, is the ratio σ/ϵ_3, so that $s_{33} = 1/E_3$. The Poisson's ratios for this experiment are defined as $\nu_{31} = -\epsilon_1/\epsilon_3$ and $\nu_{32} = -\epsilon_2/\epsilon_3$. Thus s_{31}, which by definition is ϵ_1/σ when other stresses are zero, is equal to $-\nu_{31}/E_3$. This relation may also be expressed as $\nu_{31} = -s_{31}/s_{33}$. A shear experiment in the yz plane of the orthotropic material will give the shear modulus $G_{23} = 1/s_{44}$. Thus the compliance terms along the diagonal of the compliance matrix, Eq. (20), are the inverses of the three Young's moduli and three shear moduli, and the off-diagonal terms relate to the Poisson's ratios.

In a fiber used as a primary mechanical component such as a tire cord, the most important elastic constant is the tensile modulus in the fiber direction, $E_{\parallel}$. The tensile modulus in the transverse direction, $E_{\perp}$, may also be important, but all transverse properties are difficult to measure. The torsional modulus about the fiber axis $G_{\parallel} = 1/s_{44}$ is the only other property likely to be determined.

3. YIELD AND FRACTURE

A polymer may be brittle, failing in tension without visible plastic deformation, or may be extremely ductile, deforming to 5 or even 50 times its original length before failing. Cross linking inhibits flow, and so thermosets and elastomers may be truly brittle. Other polymers such as polystyrene are macroscopically brittle with no visible plastic deformation, but they yield and flow very locally near the crack before fracture. Tougher glassy polymers such as polycarbonate will yield, but fail in tension after 10%–20% extension. The very highly ductile materials are semicrystalline polymers tested above the T_g of their amorphous component. Below this T_g they are brittle. Multiphase polymer systems are more difficult to generalize. Adding 10% by volume of ~1 μm rubber particles to polystyrene gives "high-impact polystyrene" (HIPS), which is a tough material that fails in tension at about 50% strain. A block copolymer with glassy and rubbery domains (polystyrene and polybutadiene) can yield and draw to three times its own length, but most of the post-yield deformation is reversible.

A brittle material tested in tension fails at a low extension because of cracks initiated at flaws. In compression the cracks cannot grow and the polymer will yield and flow. The compressive strength is greater than the tensile strength not only because of a higher extension to failure but also because the modulus is larger in compression. Except for elastomers, polymers cannot be considered incompressible, and so the hydrostatic component of the stress field causes a volume change. Simply comparing this volume change with that caused by thermal expansion indicates that the change from tension to compression is equivalent to a large drop in testing temperature. As noted before, reduced mobility of the polymer chains at low temperature or high testing rates gives a higher elastic modulus. Many real situations involve bending, where part of the sample is in compression and part in tension. The effects described here combined with the nonlinear viscoelasticity of polymers can make failure in bending very difficult to analyze properly. Many reported bending (flexural) strengths have been obtained by applying linear elastic analysis.

Polymers may yield by shear or by crazing. Crazes are cracklike objects where the two faces are bridged by many fine (~20 nm diameter) fibrils of polymer. The volume fraction of fibrils and thus the relative density of material in the craze is 50% or less, and so there is a large volume increase when crazes form. This means that crazing cannot occur unless there is a net hydrostatic tensile component to the stress field. Shear yield is also affected by hydrostatic pressure. For most polymers the best criterion for shear yield in a general stress field is the von Mises criterion with a pressure-dependent yield stress:

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 6(\tau_y + \alpha P). \tag{22}$$

Here σ_1 to σ_3 are the principal stresses, that is, the stresses along axes chosen so that the shear stresses σ_4 to σ_6 are zero. The left-hand side is the elastic-energy density due to shear strain (change in shape). The term P is the hydrostatic pressure, $P = -(\sigma_1 + \sigma_2 + \sigma_3)/3$, and τ_y is the yield stress at zero pressure, which depends on temperature and strain rate. The coefficient α increases as temperature is increased to near T_g. At a fixed temperature the yield surface is a tapering cylinder, centered on the $\sigma_1 = \sigma_2 = \sigma_3$ axis and getting broader as P increases. There are many suggested criteria for crazing, but all involve some dilatation. In terms of stress, an expression that fits the data in plane stress ($\sigma_3 = 0$) is

$$\sigma_1 - \sigma_2 = A + B/(\sigma_1 + \sigma_2), \tag{23}$$

where A and B are constants. Figure 6(a) shows these criteria for shear and crazing at $\sigma_3 = 0$ superimposed along with the straight line of zero pressure $\sigma_1 = -\sigma_2$. Figure 6(b) shows the changes expected if $\sigma_3 < 0$ (a compressive stress). All yield is suppressed, and the line of zero pressure moves to the right. Deformation will tend to change from crazing to shear yielding when compressive stresses are applied.

Crazes are often associated with tensile failure, which occurs when a crack grows through the weaker craze material. Crazing is intrinsically inhomogeneous, although a region containing many small crazes may appear uniform on its larger scale. Shear

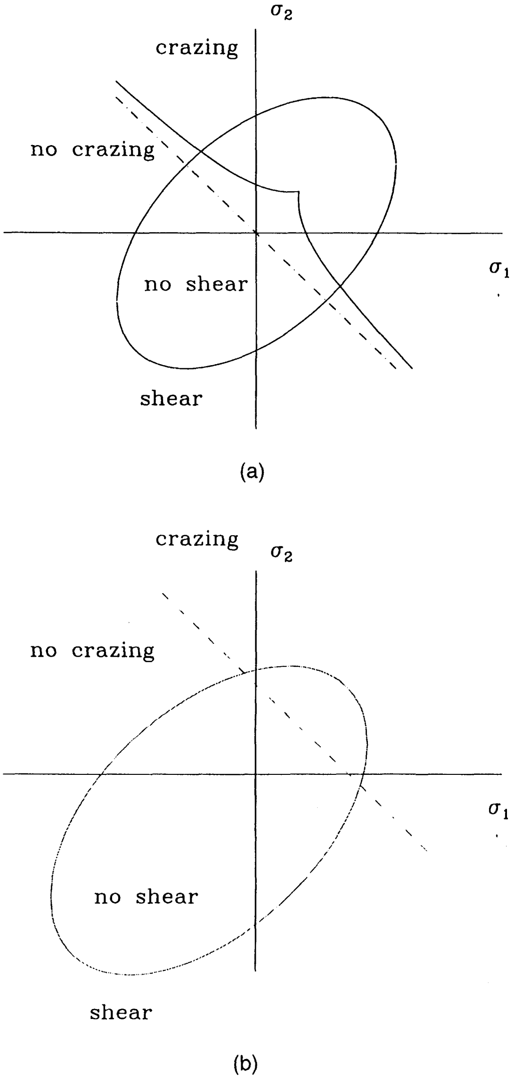

FIG. 6. Schematic plots of yield criteria for shear and for crazing. The ellipse is the von Mises criterion for shear, yielding, Eq. (20). The material will undergo shear yield when the stress is outside the ellipse. The cusped line in (a) for $\sigma_3 = 0$ is Eq. (21), and the material will craze to the right of this line. In (b) $\sigma_3 < 0$; the ellipse increases in size and shifts to the lower left. The crazing criterion moves to the upper right. In this case only biaxial tension will be sure to produce crazing.

yield may be inhomogeneous or uniform throughout the body of the material being deformed. In polymers, it is nearly always inhomogeneous. In compression or shear, localization of deformation must be due to an intrinsic strain softening of the material. This is similar to the shear-thinning behavior seen in polymer liquids. The more common experiment is tensile deformation, and this is more complicated.

3.1 Localized Shear Yield in Tension

The process of localized shear yield in tension is easy to demonstrate in a semicrystalline polymer. Cut two long strips from a plastic bag (probably made of polyethylene), cutting parallel to two different sides so that the long directions of the two strips are perpendicular. Pull on the strips. They will both deform inhomogeneously, in one case with a well-defined very narrow zone of deformation that moves slowly along the strip. After this "neck" has passed, the material has undergone a large extensional strain—it has been drawn. The draw ratio or extension ratio, which is (final length)/(initial length), may be 3 to 5. The neck is the zone of localized shear deformation. It is easy to see the process because the material strain hardens, and this stabilizes the neck. The two strips behave differently because the film used to make the bag is already oriented. The conventional stress–strain curve that would result from repeating this experiment in a tensile-testing machine is shown in Fig. 7. This

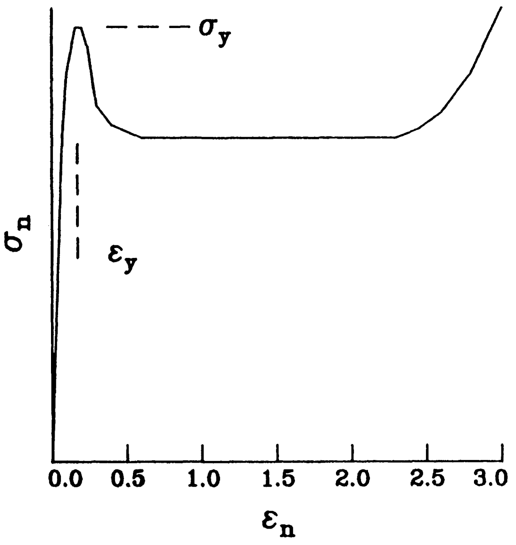

FIG. 7. Conventional stress–strain plot for a ductile semicrystalline polymer that deforms by necking. The neck forms at the yield point, which is a stress maximum, and moves through the sample at a constant drawing stress.

plots the nominal stress σ_n = force/A_0 vs the engineering or nominal strain $\epsilon_n = \Delta l/l_0$. There is a maximum in the nominal stress at the yield point σ_y, ϵ_y when the neck first forms. The long horizontal post-yield portion at the draw stress σ_d corresponds to travel of the stable neck, and the final increase in σ_n is when the neck reaches the end of the sample. This process may be called "cold drawing" or necking. In most materials, including glassy polymers, this necking down would continue until failure. Here the increasing molecular orientation in the extending region eventually increases its strength enough so that it supports the rising local stress. This defines the "natural" draw ratio.

The conventional plot of Fig. 7 cannot correspond to material behavior beyond the yield point, when some material has deformed and the rest has not. Further, the localized deformation and the load drop may be due to the local reduction in cross-sectional area. The material need not strain soften, it need only strain harden by too little to compensate for the lower area carrying the load. The effect of change in area from A_0 to A is clarified by replotting the data as true stress σ_t = force/A vs nominal strain. This plot, shown schematically in Fig. 8, is Considère's construction. At constant volume (a normal assumption for plastic deformation) there will be an extremal value of $\sigma_n = \sigma_t(1 + \epsilon_n)$ at points where a line drawn from $\sigma_t = 0$, $\epsilon_n = -1$ (i.e., $\lambda = 0$) is tangent to the curve in Considère's construction. The steeper tangent touches the curve at the yield point, and the lower one touches it at stress and strain in the region that the neck has passed through.

The lower curve (a) in Fig. 8, which has a sharp drop in σ_t, is the transformed conventional stress–strain curve, but this is not likely to be the actual behavior of the material. One possibility is the upper curve (b) where there is no decrease in true stress and therefore no strain softening. Measurement of the actual cross-sectional area in the neck is needed to give any information about the material properties between the two tangent points. Even this is not sufficient, for two reasons. One is that the strain rate is very nonuniform, being much higher in the neck region. The other is that the stress is far from simple tension in the neck region, because of the sudden change in cross section.

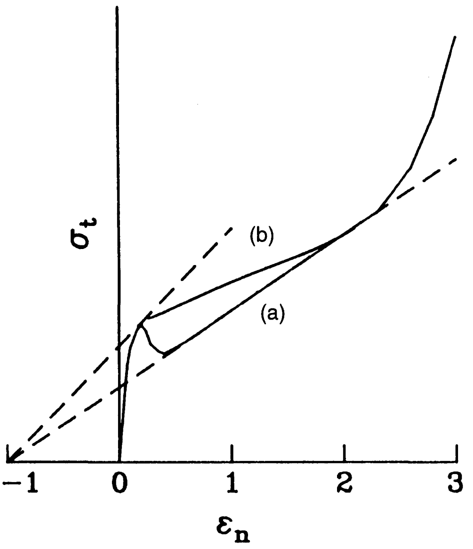

FIG. 8. Considère's construction; a plot of true stress vs nominal strain. The lower curve, *a*, is the transformed conventional stress–strain data from Fig. 7. A constant nominal or engineering stress, which was a horizontal line in Fig. 7, becomes a line passing through the point (−1,0). Material following the upper curve *b*, where there no strain softening, would give the same conventional stress–strain result.

This explains how it is that new material entering the neck can deform without reaching the yield stress. Exact modeling of the necking process requires a 3D finite-element model using nonlinear elasticity, and the anisotropy induced by deformation.

At one time it was thought that the heat generated in the deformation process played a vital role in necking, and this may be the case when the process is done at high speed. Then the local heating produces local softening, which supports local flow. It is certainly true that in commercial fiber drawing, where many filaments are deformed in an array, the heat radiated from one neck influences the position of the necks in neighboring fibers. In this way the positions of the deformation zones in all the fibers are stabilized. However, drawing at very slow rates at room temperature gives basically similar results for draw ratio and drawing stress, so that the effects of heat are only secondary in most cases.

The draw ratio of necked material is controlled by the extensibility of the molecular network. That is, the deformation after yield is like that of an elastomer, with the molecular entanglements acting as crosslinks. If the drawing is done slowly and at high temperature, the molecules have a chance to disentangle during draw. The elongation increases and the draw stress falls. Careful control allows draw ratios of 20–30 compared with the usual 3–5 in polyethylene. Even greater draw ratios can be obtained by pretreating the material to reduce the entanglement density, by dissolving and precipitating high–molecular-weight polymers.

3.2 Localized Shear Yield in Compression

In compression the deformation of glassy polymers is often localized into shear bands or kink bands, and this must be due to the intrinsic strain-softening property of the material. A single large shear band may develop that has well-defined boundaries and may be 0.1–0.5 mm across. If deformation is continued, the single shear band will pass through the entire sample. The sample will then fail by shear fracture within this shear band. The more diffuse shear zones contain many fine-scale shear bands. Continued deformation in this case increases the average shear strain so that a kink appears in the specimen. Isotropic crystalline polymers strain soften little or not at all, and so the yielding is more homogeneous.

Well-oriented high-performance polymer fibers are well known to be weak in axial compression. The compressive strength is only 10%–20% of their tensile strength. Direct measurement of the properties of a 10–30-μm-diameter fiber in compression along its axis is obviously very difficult. In compression the modulus falls with increasing strain either because of reduced chain orientation, or because of intrinsic softening by bending of the aligned chains. At strains of only ~0.1%, kink bands form. They are well-defined narrow bands of sheared material that extend through the fiber. Microscopic studies show that the molecular chains undergo sharp bends at the boundaries of kink bands. The lattice images are almost like those of twins, but molecular continuity requires that the molecules shear past each other to form the kink band. Applying tensile load to the kinked fiber pulls the kinks out of it, but in some cases the tensile strength is reduced by the compressive damage to the fiber. Modeling kink formation in fibers indicates that the process is one of fibril buckling, but in these well-ordered materials the deformation is related to the crystalline slip systems, with specific crystallographic rotations preferred for different materials.

3.3 Crazing and Brittle Fracture

Many glassy polymers are brittle, fracturing with no visible plastic deformation. The energy required to form cracks in these materials is $\sim 100\ \mathrm{J\ m^{-2}}$, while a simple model for the energy needed to break the molecular chains predicts $\sim 1\ \mathrm{J\ m^{-2}}$. In metals, a similar discrepancy is caused by plastic deformation in the region of the crack tip, which absorbs a lot of energy. The same is true in polymers, but the plastic deformation often has a special form called a craze. A craze contains voids and fine fibrils of oriented polymer (~30 nm in diameter). The voids make a continuous phase, bridged by the fibrils that pass from one side of the craze to the other. At the surface of a growing craze, the homogeneous glass flows in a very localized region to give an oriented fibril. The process is very like fiber drawing, and the extension ratio is controlled by the extensibility of the molecular network (Kramer and Berger, 1990). If the molecular weight is too low to form entanglements, there is no network; the craze is not stable, and it immediately breaks down into a crack. If the entanglement density is high, the extensibility is low, and the stress required to form a craze increases. The shear yield stress is not much affected by the entanglement density, and so crazes do not form in highly entangled material. The deformation near crack tips then occurs by shear. Crosslinking at low densities also inhibits crazing. Figure 9 is a summary of results from many polymers, blends, and crosslinked PS. The high values of network strand density ν correspond to highly entangled or crosslinked materials; these have low extensibility and deform by shear in deformation zones (DZ).

Crazes have been introduced as associated with cracks, but crazes form first, and cracks form when the craze material breaks down. In some materials such as ABS and i-PP many small crazes form on deformation, so many that the light scattering from craze

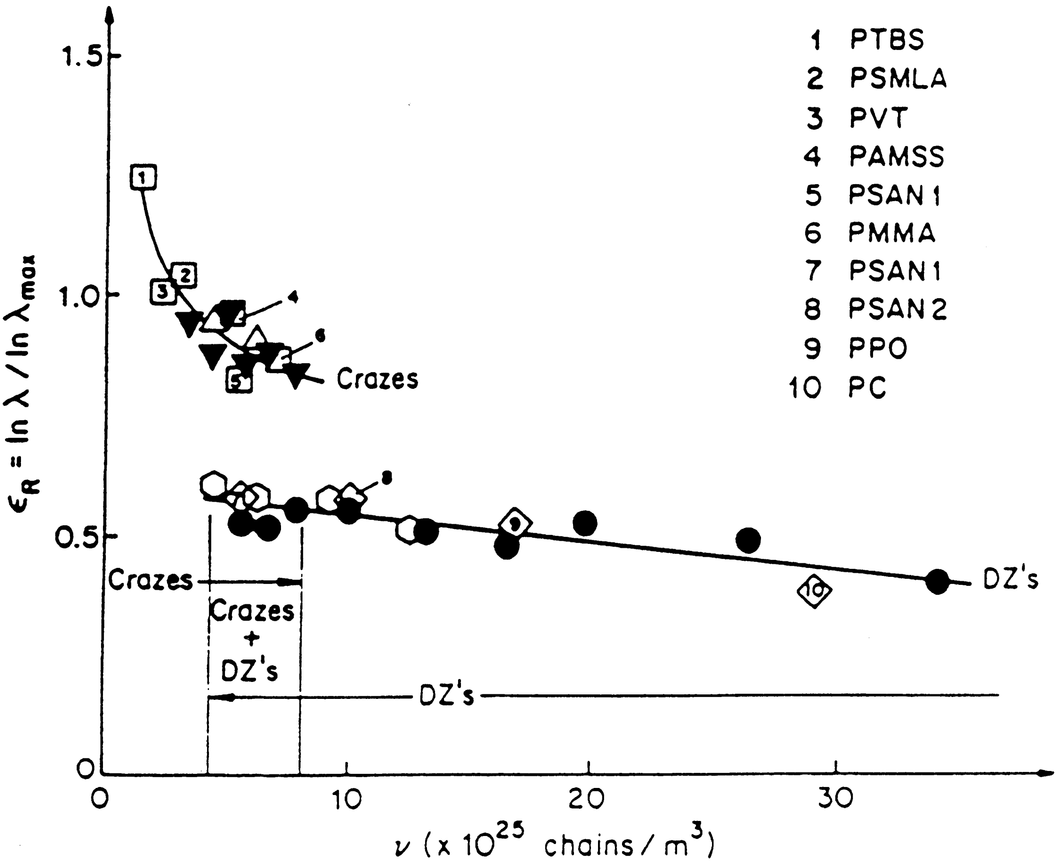

FIG. 9. True strain ratio ϵ_r in crazes and shear deformation zones (DZ) in a range of polymers, copolymers, and blends. Filled triangles and circles represent crosslinked PS. The higher crosslink density materials (higher ν) have lower extensibility and deform by shear instead of by crazing. (From Henkee and Kramer, 1984.)

surfaces turns the material white. The energy required to form these many crazes makes the material tough. In the case of i-PP, parts can be designed with a thin region that acts as a hinge. This region may be "stress whitened" at its first use, and then withstand thousands of bending cycles after this nominal "failure." The case of i-PP also illustrates that semicrystalline polymers also craze. Crazes in glassy polymers are straight and regular in simple tension, while those in crystalline materials are irregular. Figure 10 shows both types of craze in a thin film of i-PS that contains spherulites in a glassy matrix. The spherulitic structure of semicrystalline polymers gives it highly inhomogeneous and anisotropic mechanical properties on the local scale, and this makes the craze path tortuous.

3.4 Ductile–Brittle Transition

The classic ductile–brittle transition in metals is that above some transition temperature failure is ductile, and below it, failure is brittle. This is explained by the lower flow stress at higher temperatures. The same effect is seen in polymers; as already mentioned, both semicrystalline and glassy polymers tend to be brittle below T_g and ductile above it. The brittle crack propagation is usually associated with crazing and plastic flow with shear yielding. Thus the yield criteria of Fig. 6 show that brittle failure will be suppressed by the application of hydrostatic pressure. The viscoelastic properties of polymers ensure that a higher strain rate requires a higher flow stress. Thus failure under impact is more likely to be brittle. As with metals, the presence of a notch or pre-

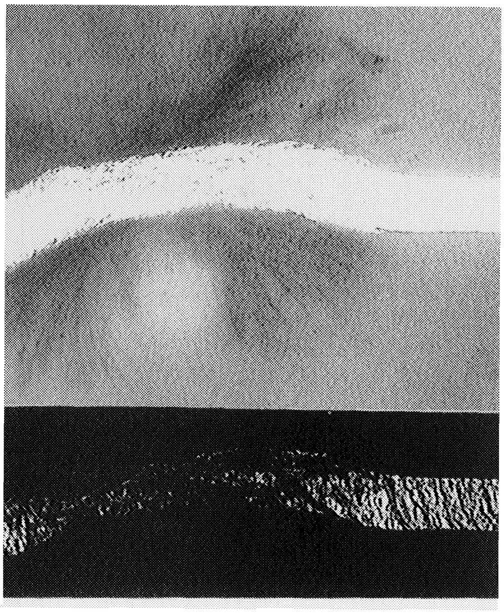

FIG. 10. Electron micrograph of a craze in partially crystallized isotactic PS. The upper image shows the spherulitic lamellar structure, made visible by staining with RuO_4. Because the drawn craze material is much thinner, it appears as a crack in this exposure. The lower image is a shorter exposure of the same area. The regular craze fibril structure is seen in the amorphous area at the right-hand side. The structure within the semicrystalline region is very confused.

existing small crack tends to make the failure brittle. This is because initiation of a crack can no longer be a barrier to fracture. To make for the worst case, and to remove the effects of small flaws in the sample, most impact testing of polymers is done on notched samples.

The environment of the polymer can have a great effect on crazing and fracture. Often the effect of a liquid environment is to weaken the material, and this is very important for practical design. The inner shell of a refrigerator must withstand the effects of butter and other oils. If the liquid can diffuse into the polymer and soften it, the effect on the craze is severe. Capillary forces draw the liquid into the craze. The region at the growing tip and the fine fibrils are quickly penetrated even if the diffusion coefficient is very low. The swollen polymer has a lower T_g and can disentangle more easily, so that the craze fibrils elongate more. The volume fraction of polymer in the craze falls, the strength of the craze falls, and cracks form. Even if there is no penetration of the liquid into the polymer, it can still affect craze formation and lower the material strength. Crazes have a very large specific surface area, and if the liquid reduces the energy of these surfaces, the energy to form the craze is reduced.

Crosslinking suppresses flow, and thus it is to be expected that an increase in crosslink density will tend to make the failure brittle. However, the opposite effect can also be obtained, if the initial material is one that flows very easily and forms weak crazes. This material appears weak and brittle. A little crosslinking reduces the extension ratio of the craze material, and increases the stress required to form a craze. The failure becomes ductile, and remains ductile until the crosslink density becomes much greater.

The thickness of the sample being tested also affects the mode of failure. A thick sample approaches the conditions of plane strain, and there is a triaxial tension within the material. A thin sample has no constraint in the thickness direction, so is in the condition of plane stress. Thus a thick sample may craze and crack, while a thin test piece may be ductile. At intermediate thickness, there can be shear at the outside edges and voiding in the center of the sample.

4. FATIGUE AND WEAR

Fatigue, failure due to repeated stresses or strains, is practically very important. The fatigue strength of a polymer may be four or five times less than its static tensile strength. Fatigue testing of a viscoelastic material requires that the frequency be carefully chosen. Frequencies greater than about 1 Hz may increase the temperature of the specimen significantly. The test frequency should be kept close to the real frequency of loading in the field in this case, although this may require long tests. Constant-stress and constant-strain tests will give very different results. Constant-stress tests show a reduction in fatigue strength for most polymers with increasing temperature; constant-strain tests will have the opposite trend. Constant strain should be chosen when appropriate to the end use of the material, as for polymer strips used as hinges, or sealants. In this case a crack may form and reduce the stress on the remaining material, and it is important to know whether the crack formation would correspond to failure in the real situation.

The fatigue life of polymers is found to be much reduced if there is complete unloading or a compressive stress in part of each fatigue cycle. This is counter to the expectation that fatigue is worse when the mean stress is raised, and is related to the destruction of the fibril structure at the craze tip when stress is reversed.

The measurement of wear and abrasion is entirely empirical. Different standard test machines use different forces and rubbing rates, and the results are difficult to interpret at best. A pair of polymeric materials may have a wear rate ratio of 2:1 on one machine, and have the opposite result, a ratio of 1:2, on another. One reason for this is that consistent results for wear of a polymer rubbing against a metal surface require control of the exact form of the surface roughness of the metal. Wear and abrasion are closely related to friction, as pieces are pulled off the sample by frictional forces during wear. Relying on this simple concept is very dangerous. Early replacement hip joints were made of PTFE on one side and surgical steel on the other. PTFE was chosen because its coefficient of friction is very low, but the wear rate of PTFE against metal in the joint was very high, and all the joints failed in a short time. Now ultrahigh–molecular-weight PE is used wherever wear and low friction are important: in replacement joints, ski bases, and industrial conveyer systems. Tires should have low wear rates combined with high friction over a wide temperature range. This is difficult to achieve, as the best adhesion comes from soft materials that do not wear well.

GLOSSARY

Craze: A cracklike object in a polymer that is bridged by many fine fibrils of oriented material.

Degree of Crystallinity: Polymers that can crystallize generally form very small crystals with many defects and a large interfacial area. Many of their properties are modeled as those of a mixture of some fraction X_C of perfect crystals and $1 - X_C$ of ideal amorphous material. X_C is the degree of crystallinity.

Dynamic Mechanical Testing: Also called dynamic mechanical analysis or DMA, this test involves applying a sinusoidally varying load to the sample, and measuring the amplitude and phase of the displacement that results. Tension, torsion, simple shear, and bending are common modes of loading.

Elastic Constant: Generally, an element c_{pq} of the compressed (6×6) elastic constant matrix **C** or an element s_{pq} of the compressed compliance matrix **S**. Either matrix describes the elastic properties of an anisotropic material.

Elastic Moduli: Ratios of stress to strain. If the stress is hydrostatic, the ratio is the *bulk modulus;* if it is a uniaxial tensile stress, the ratio is the *Young's modulus,* unique only for isotropic materials.

Elastomer or Rubbery Material: A material that contains mobile linear chains connected together to form an insoluble and infusible network. It differs from a thermoset by having a much lower density of connection points, called *crosslinks.*

Extension Ratio: The ratio (final dimension)/(initial dimension), λ; this may be called the *draw ratio* for tensile deformation (see **Strain**).

Fiber Symmetry: While technically a fiber is a long fine filament, any sample may have fiber symmetry of its mechanical properties if it has one unique axis (the fiber axis) and isotropy in the plane perpendicular to that axis.

Glass Transition: On cooling a liquid its viscosity increases dramatically over some temperature range and it becomes a glass. In the glassy state, large-scale motions do not occur and the liquid disorder is frozen in place. The glass-transition temperature T_g describes where the transition occurs.

Kink Band: A well-defined region where local shear has caused a reorientation of the polymer chains. Kink bands in well-ordered crystalline polymers become similar to twins in crystals.

Necking: Local reduction in cross section caused by localized shear during tensile deformation.

Rubber Elasticity: The property of elastomers that allows very large recoverable elastic deformations. The restoring force in an ideal rubber elastic material is due only to the entropy changes in the molecular chains when they are stretched.

Strain: The displacement per unit length; if the initial and instantaneous lengths are l_0 and l, the commonly used "nominal" strain is $(l - l_0)/l_0$. For large strains the correct or "true" extensional strain is $\ln(l/l_0) = \ln(\lambda)$.

Thermoset: A polymer where the chains are connected together to form an insoluble and infusible network. The network is often formed chemically by the application of heat to a liquid mixture, giving the name.

Time–Temperature Superposition: The principle that the mechanical response of a polymer at a different temperature is the same as its response at the same temperature after a different time of loading.

Viscoelasticity: The combination of elastic and viscous response to applied stress. In *linear viscoelasticity* the response is always linear with the applied stress.

INTRODUCTION

Polymers, or macromolecules, are large molecules made up of many (often many thousands) chemical groups or repeat units. Often the same group is repeated many times, or a few groups are repeated many times. In this article, we will discuss the naming of polymers and the methods to determine the chemical groups, the molecular weight, and the architecture of the polymers. Our discussion is limited primarily to macromolecules synthesized from petroleum, usually called synthetic polymers. We mention also large-volume commercial polymers derived from vegetation; cellulose is an example. For simplicity we do not include polymers dominant in biochemistry and medicine, biopolymers.

1. NAMING OF POLYMERS

Polymers may be named according to several different conventions. We name a polymer by the *kinds* of different repeat units in the macromolecule. Homopolymers have the same chemical constituent repeated many times and are represented by A–A–A–A–A–A–A–A, where A represents a repeat unit. In copolymers a fixed number of chemical constituent units are repeated. Diblock copolymers are of the form A–A–A–A–A–A–B–B–B–B–B, and a triblock copolymer refers to the form A–A–A–A–B–B–B–B–C–C–C–C, or, more commonly, A–A–A–A–B–B–B–B–B–A–A–A–A. Alternating copolymers are of the form A–B–A–B–A–B–A. These copolymers may be considered homopolymers with an A–B repeat unit. Random copolymers have at least two chemical groups repeating in random

order. A graft copolymer is composed of a homopolymer backbone and another repeat unit as a branch. (Grafts will also be discussed as branches.) Telechelic polymers are made with reactive groups on both ends of a linear chain to be used in subsequent reactive processes (see thermoset polymers, below). Polymers with rigid backbones form liquid-crystalline phases, and these are often called mesophase polymers. Ionomers are polymers with pendant groups that can be ionized in solutions.

Polymers may be named by the *number* of repeat units. For example, the oligomers of poly(methylene) are ethane, propane, butane, and the higher alkanes. Sometimes oligomers are given different common names than their polymers. For example, the oligomer of poly(oxyethylene) is called poly(ethylene glycol) while the polymer is called poly(ethylene oxide). Telechelic polymers are usually oligomers. A monomer is the starting material from which a polymer is made. Ethylene is the monomer for polyethylene. Some authors will refer to a repeat unit in a polymer as a monomer.

We may also name polymers by their macrotopology or *architecture.* Chains can have a linear, branched, ladder, or ring topology. Most branching occurs with random lengths with random origins along the backbone. A graft copolymer is a chain with one homopolymer for the backbone and another for the branch. Chains branched along a backbone with equally spaced branches of equal length are called combs. Stars are chains in which all the branching starts at one central point. Dendrimers are polymers in which branching occurs with a specified branch length and with a specified multiplicity of branching at each branch point. Large dendrimers approach spherical shape. Lattice animals are chains that have a finite probability of branching at each repeat unit and thus show the structure of Cayley trees. As the branching density increases, branches will themselves have branches on them. Finally a point will be reached, the *gel point,* where the entire structure acts as one molecule. These gels or *cross-linked polymers* can either be created by a chemical reaction of monomers conducive to branching or be produced by adding cross-linking agents into normally uncross-linked polymers. The formation of epoxies is an example of the former; the vulcanization of rubber, an example of the latter. Many properties of polymers are dramatically affected by the character of their branching.

Polymers are often named by their method of *chemical synthesis.* Polymers derived from natural substances are called natural polymers, e.g., cellulose or xanthate gums. Many synthetic polymers are made by addition polymerization or condensation polymerization. They are often referred to as a class by their method of synthesis as addition or condensation polymers. Often the mode of preparation indicates something about the expected molecular-weight distribution of the polymer. In addition polymerization, the repeat unit in the polymer and the reacting monomer used to create the polymer have the same chemical composition. This often produces polymers with carbon backbones and pendant substituent groups. Examples include polyethylene, polypropylene, and polystyrene. Poly(ethylene oxide) is an example of an addition polymer without a purely carbon backbone. Addition polymers can be made in reactions that involve free radicals or ionic groups. Generally polymers that involve these ionic groups in their reaction processes can be made with narrow molecular-weight distributions. In general, condensation polymers have repeat units resulting from the reaction of two different monomers. The resulting repeat unit is different from either monomer. The backbone of these polymers often contains noncarbon atoms (like oxygen or nitrogen) at regular intervals. Polyesters, polyamides, and polycarbonates are examples in this category.

Polymers are also named by the *processing conditions* used to form them into their final object. In thermoset polymers, a reaction occurs during the forming process that often causes the polymer to cross-link. Thermoset polymers cannot usually be reprocessed. Telechelic polymers are the oligomers with reactive ends often used as a starting material for thermoset polymers. Examples of thermoset polymers are polyurethanes and epoxies. Almost no chemistry occurs during the processing of a thermoplastic material. Thermoplastic polymers become solid when cooled from the melt because of a phase transition, e.g., crystallization, or by supercooling the liquid into a glass. Common thermoplastic polymers are polyethylene, polystyrene, and poly(ethylene terephthalate). Thermoplastic polymers can be reprocessed.

Polymers made from repeat units that contain an *asymmetric* carbon atom may have variations in chemical structure because of the polymerization process. For example, the repeat unit $-CH_2CHx-$, where x represents an atom or chemical group other than hydrogen, may polymerize head-to-head or head-to-tail, where "head" refers to the CH_2 group and "tail" refers to CHx. In addition, there are two possible stereoregular arrangements: one in which the arrangements of groups about each asymmetric carbon are the same, isotactic, or one in which the arrangements alternate, syndiotactic. Another possibility is a random distribution, atactic. The stereochemical regularity affects the physical properties of the polymer, mainly through the ability to crystallize.

Finally, the polymer is known by its chemical name and *chemical composition.* In Table 1, we give the common chemical name of some common polymers and the chemical structure of the repeat unit. The common chemical name is often derived from the name of the chemical species the polymer is made from, the monomer. For example, polymethylene, $CH_3-(CH_2)_n-CH_3$ is commonly called polyethylene since it is produced, mainly, from ethylene as a monomer.

2. METHODS TO DETERMINE OVERALL CHEMICAL COMPOSITION

The chemical composition of a polymer is specified by the constituent atoms and their chemical-bonding arrangement. Many analytical techniques are available for elucidating the chemical composition. Selection of appropriate methods depends on several factors, including amount and form of the specimen, surface or bulk characterization, and whether information about structure beyond the molecular level is desired. Elemental-analysis methods yield little beyond atomic

Table 1. Common chemical names of some polymers and their chemical structure.

Common chemical name	Chemical structure
Polyethylene	$-(CH_2CH_2)_n-$
Polypropylene	 $-(\underset{\displaystyle CH_3}{\underset{\vert}{CH}}-CH_2)_n-$
Polyisobutylene	 $-(\overset{\displaystyle CH_3}{\overset{\vert}{\underset{\displaystyle CH_3}{\underset{\vert}{C}}}}-CH_2)_n-$
Polyisoprene	 $-(CH_2-\underset{\displaystyle CH_3}{\underset{\vert}{C}}=CH-CH_2)_n-$
Polybutadiene	$-(CH_2-CH=CH-CH_2)_n-$
Polystyrene	Polyacrylonitrile	 $-(\underset{\displaystyle CN}{\underset{\vert}{CH}}-CH_2)_n-$
Poly(vinyl alcohol)	 $-(\underset{\displaystyle OH}{\underset{\vert}{CH}}-CH_2)_n-$
Poly(vinyl chloride)	 $-(\underset{\displaystyle Cl}{\underset{\vert}{CH}}-CH_2)_n-$
Poly(vinyl acetate)	 $-(\underset{\displaystyle OCOCH_3}{\underset{\vert}{CH}}-CH_2)_n-$

Table 1. Continued.

Common chemical name	Chemical structure
Poly(vinylidene fluoride)	 $-(\overset{F}{\underset{F}{C}}-CH_2)_n-$
Poly(methyl acrylate)	 $-(\underset{COOCH_3}{CH}CH_2)_n-$
Poly(methyl methacrylate)	 $-(\overset{CH_3}{\underset{COOCH_3}{C}}-CH_2)_n-$
Poly(formaldehyde)	$-(OCH_2)_n-$
Poly(ethylene oxide)	$-(OCH_2CH_2)_n-$
Poly(phenylene oxide)	Poly(ethylene terphthalate)	Poly(hexamethylene adipate)	$-(NH(CH_2)_6NHCO(CH_2)_4CO)_n-$
Poly(tetramethylene hexamethylene urethane)	 $-[O(CH_2)_4O-\overset{O}{\overset{\|}{C}}-\overset{H}{N}(CH_2)_6\overset{H}{N}-\overset{O}{\overset{\|}{C}}]-$
Poly(carbonate)	Poly(tetrafluoroethylene)	 $-(\overset{F}{\underset{F}{C}}-\overset{F}{\underset{F}{C}})_n-$

composition. The constituent atoms of most commercial and naturally occurring polymers have low atomic numbers that influence the choice of techniques for elemental composition. The principal techniques for chemical composition are nuclear magnetic resonance (NMR) and infrared (IR) spectroscopies. These techniques not only are able to differentiate among the many chemical groups of polymers, but also are quantitative. In addition, these techniques have the advantages of firm theoretical foundations for predicting spectra and, as a result of their wide application, availability of spectral databases accessible by computer-aided search routines for identification of unknowns.

NMR measures transitions between nuclear-spin states of the constituent atoms in the presence of an applied magnetic field. The applied magnetic field at a particular atom is perturbed by the neighboring atoms that provide the sensitivity of the method to chemical bonding. Infrared spectroscopy determines the frequencies of the vibrations of the constituent atoms in the potential field of the chemical bonds. Raman spectroscopy is another vibrational method that complements infrared spectroscopy in several respects, but because of instrumental difficulties it is not as widely used as IR. Under favorable conditions, both NMR and vibrational spectroscopies can be used to determine not only the types of chemical groups but also their number.

2.1 Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance spectroscopy (see MAGNETIC RESONANCE AND QUADRUPOLE RESONANCE, NUCLEAR) is widely used by organic chemists to deduce chemical configurations. For modest molecular weights, less than 500 g/mole, the chemical structure can be determined on samples in the liquid or solution forms. The high molecular weight of polymers prohibits detailed characterizations, but appreciable information concerning the repeat unit, or units in the case of copolymers and polymer blends, can be obtained provided the polymer is in solution, the melt phase, or a solid phase in which motional averaging within the time frame of the NMR measurement is allowed. The information derived includes stereochemistry and content of head-to-tail, head-to-head, or tail-to-tail arrangements. In many cases, it is desirable to characterize polymers in the solid state. Ordinarily, this would lead to exceedingly broad NMR lines that obscure the chemical shifts that reveal details of the structure. Fortunately, the techniques of proton decoupling have been developed to produce narrow lines and improve resolution and sensitivity in solid-state NMR.

Although many nuclei produce NMR signals, the most important in polymer characterization are the proton, fluorine, and carbon-13. Proton nuclear magnetic resonance spectroscopy is a powerful method for determining the structure and dynamics of organic molecules in solution (Bovey *et al.*, 1983). The basis of the technique is resonant transitions between energy levels of nuclear spins in the presence of applied magnetic fields. As the energy levels are sensitive to the local electronic environment of the nucleus, detailed quantitative information is obtained from the transition frequencies (chemical shifts) and intensities. The extremely narrow NMR spectral lines (approximately a few hertz) are observed for solutions because of rapid molecular motions that average interactions. As a result of the narrow spectral bands, features attributed to sequences of chemical groups are revealed. By taking advantage of the high resolution capability of NMR when applied to liquid samples, aspects of polymer structure, stereochemical configuration, branching, copolymer sequences, and molecular dynamics are elucidated.

The method may be adapted to nuclei other than protons. Fluorine NMR has been applied to fluorine-containing polymers (Bovey *et al.*, 1983); and with developments in fast Fourier transform spectroscopy and co-adding signals to improve sensitivity, NMR based on the carbon-13 (^{13}C) nucleus at natural abundance is now possible. More details concerning polymer structure are obtainable by ^{13}C NMR because of the greater chemical shifts of ^{13}C. In cases in which it is possible to dissolve the polymer, chemical microstructure, including stereochemistry, branching, and end groups, may be probed by ^{13}C NMR. Figure 1 illustrates the power

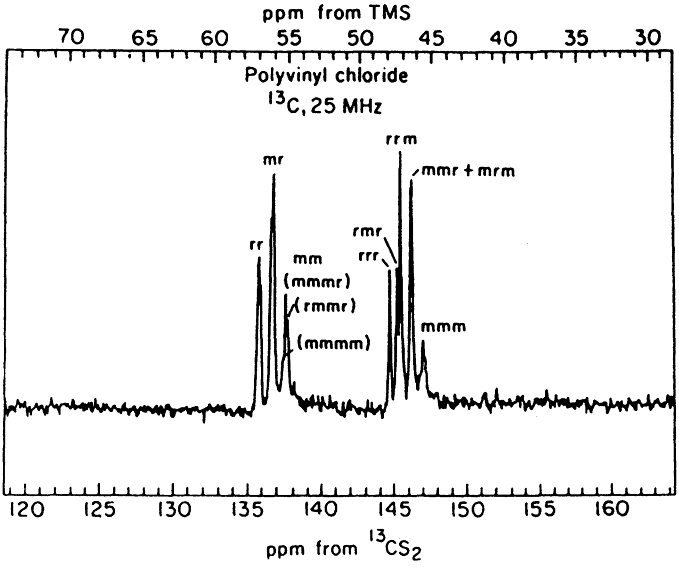

FIG. 1. 25-MHz ^{13}C NMR solution spectrum of poly(vinyl chloride). The individual resonances are labeled with the sequence of meso (m) and racemic (r) dyads (reproduced from Ivin, 1976).

of ^{13}C NMR for analyzing the stereochemistry of poly(vinyl chloride). In this figure, the cluster of NMR lines ca. 47 ppm arise from the CH_2 carbon and the lines ca. 56 ppm from the CHCl carbon. The individual NMR lines in each group are identified with specific arrangements of the chemical repeat units, $-CH_2CHCl-$. The halogen atoms of neighboring repeat units may occupy positions that are on the same side, meso (m), or opposite side, racemic (r); these two arrangements yield different ^{13}C chemical shifts that are further influenced by the next-nearest neighbors. Monomer sequences of lengths up to pentamers exhibit distinct chemical shifts.

Another application of ^{13}C NMR is determination of branch types, distributions, and concentrations. An example of quantitative information that can be obtained is illustrated in Fig. 2 for a low-density polyethylene. Resonances from methylene carbons at least four carbons removed from a branch point, branch, or chain end contribute to the intense line at 30 ppm. The remaining lines are attributable to a branch point, chain, or branch-end carbon, or carbons situated within three carbons from a branch point, chain, or branch-end carbon. In this figure, the assignments of chemical shifts to the different kinds of branches are given where Am = amyl, Bu = butyl, and Et = ethyl.

Thus far, the discussion has focused on polymers in solution; however, for various reasons it may be desirable to characterize the material in the solid state. The solid-state NMR method (Havens and Koenig, 1983) has the advantages that no special sample preparation is necessary, insoluble solids may be evaluated, and any changes in the sample due to sample preparation are avoided. Generally, NMR of solids is characterized by broad distributions of resonance frequencies that obscure the small chemical shifts from which much information is obtained on liquid or solubilized polymers. The linewidths of solid specimens arise from strong dipole–dipole interactions and the absence of motional averaging in the time scale of the NMR measurement. Linewidths of solid specimens recorded under conditions typical of liquid-state spectra may be 20 kHz or more.

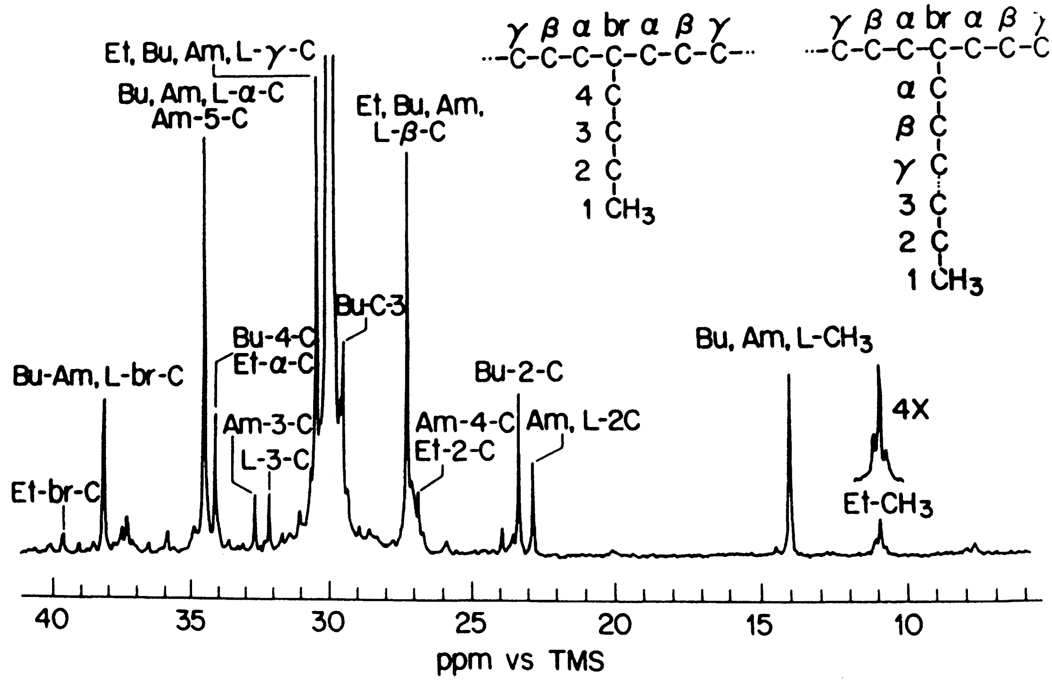

FIG. 2. ^{13}C NMR spectrum of low-density polyethylene, The individual resonances are labeled by the branch type (Am = amyl, Bu = butyl, and Et = ethyl). (Reproduced from Bovey *et al.*, 1983.)

High-resolution techniques have been implemented to eliminate or reduce solid-state line broadening, thereby achieving ^{13}C spectra of solid materials whose bandwidth approaches that typical of the liquid state. High-resolution ^{13}C NMR relies on high-power proton decoupling that practically eliminates dipolar broadening by protons and high-speed sample spinning to average out chemical-shift anisotropy of the ^{13}C nucleus. The effect of these two techniques on the NMR spectrum is to reduce the broad band typical of solids to narrow bands that reveal information typical of liquid-state samples.

One additional technique is used to improve sensitivity in solid-state NMR. The low natural abundance of ^{13}C (about 1%) means that NMR signals are inherently weak, and furthermore, because of the long spin-lattice relaxation times of the ^{13}C nucleus, substantial improvement in sensitivity by co-adding pulses requires excessively long measurement times. However, the time between pulses in the Fourier transform experiment can be shortened by a technique termed cross-polarization. In this method, the protons are used as a source of magnetization to transfer polarization from the protons to the carbons. The greater abundance of the protons allows the system to reach equilibrium more quickly.

Through incorporation of these techniques, high-resolution solid-state NMR has become an important tool for characterization of solid polymers. Figure 3 demonstrates the capabilities for analysis of epoxy-based composites. A number of distinct lines are evident in Fig. 3, including features assigned to the carboxyl carbon of the reactive species, labeled 4 in the figure, and the same carbon after reaction, labeled 4′. The degree of conversion of the reactant to polymer is determined from the intensity ratio of these two lines. The comparison of the two spectra in Fig. 3 reveals that the thermally polymerized resin achieved a higher conversion to polymer than the photo-cured resin.

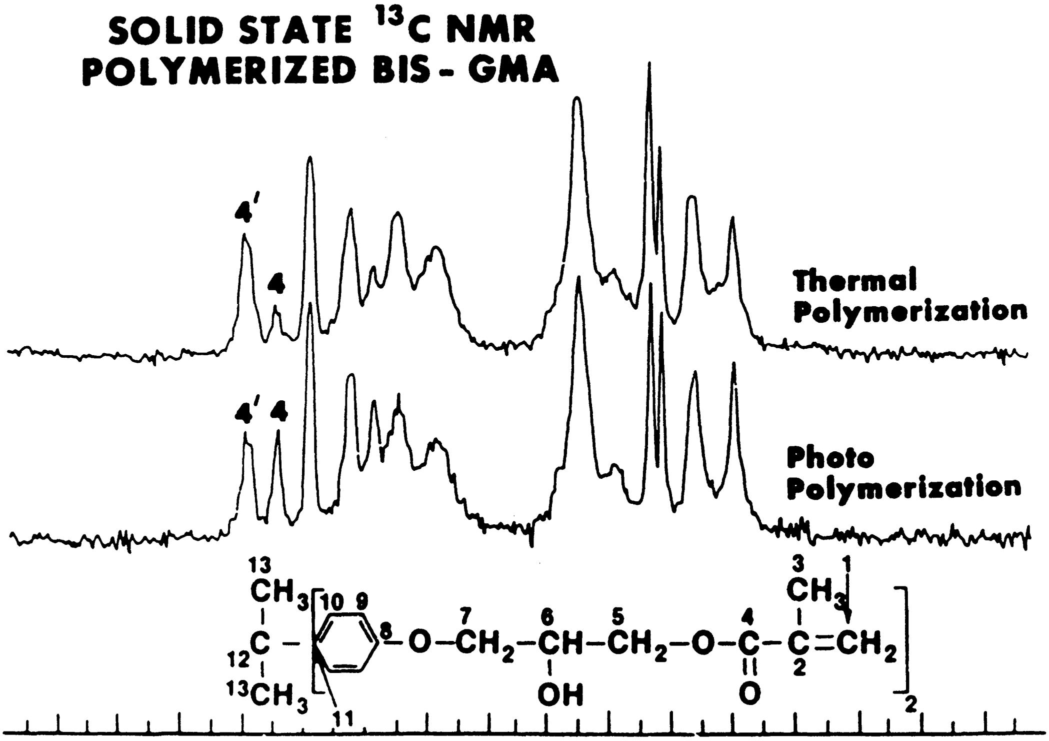

FIG. 3. ^{13}C NMR spectra of vinyl ester polymer matrix composite resin in the solid state. The two spectra compare polymerization by thermal activation and by uv light. Resonances attributed to reactive chemical species are identified.

2.2 Infrared Spectroscopy

Infrared spectroscopy is a widely used technique of polymer identification for which a large number of reference spectra of polymers, monomers, and additives are available. When combined with computer-aided search routines, this technique allows for rapid identification of unknown samples. Infrared spectroscopy is a type of vibrational spectroscopy that measures the absorption or reflection of light associated with the vibrations of the atoms in the potential field defined by the chemical bonding arrangements. The vibrational frequencies are determined by the potential field and the masses of the atoms involved in the vibrations. An isolated polymer containing N atoms will have $3N - 6$ vibrational modes, and in principle, the infrared spectrum would contain a like number of bands. However, for symmetry reasons some vibrations will be inactive in the infrared while others will have low probabilities of absorption. In addition, the vibrations tend to be localized over several atoms rather than over the entire molecule, and as a consequence, the infrared spectrum is more representative in terms of the number of bands and their frequencies to the composition of the chemical repeat unit. Nonetheless, as with infrared spectroscopy of small molecules, the infrared intensities are proportional to the number of absorbing species and the probability of absorption (Beer's law).

The IR spectra of polymers reveal details of not only chemical composition, but also of physical structure. Qualitative and quantitative information can be obtained on chemical composition of polymers, copolymers, polymer blends, composites, additives, and compounding ingredients. IR spectral frequencies and intensities are also sensitive to chemical order, i.e., stereochemistry, branching, end groups, and degradation products. The IR spectra of solid polymers provide information on the type and amount of crystalline forms, the degree of crystallinity, orientation of macromolecules, chain conformations, and the local environment of constituent chemical groups. IR spectroscopy is by far the most widely used method for characterization through vibrational properties although both inelastic neutron scattering and Raman spectroscopy have application to polymers.

Low sensitivity and inflexibility in sample type had been problems with infrared spectroscopy that have now been overcome with Fourier transform infrared spectroscopy (FTIR). Both of these problems relate to low sensitivity of conventional dispersive IR. The several hundredfold increase in signal-to-noise ratio (sensitivity) made possible with FTIR has greatly expanded the role of infrared spectroscopy for microsampling and nontransmission types of sampling. Commercially available accessories exist for specular reflection, diffuse specular reflection, diffuse reflectance sampling, and photoacoustic detection in addition to the surface-probe technique of attenuated total reflection. A wide variety of specimen types from particles to intractable solids can be examined by these techniques. All of these methods probe the surface to a large degree. Specular and diffuse specular reflection measure the index of refraction as a function of infrared wavelength. The reflection and absorption spectra are related through the Kramers–Kronig relationship. Diffuse reflection (DRF or DRIFT) is a combination of transmission and reflection of radiation by the sample. This technique is ideally suited to microsampling with spectra obtainable from a nanogram of material. Reflectance techniques are sensitive to the state of the solid specimens—different preparation methods may yield spectra in which the relative band intensities vary. This spectral sensitivity, however, may afford advantages of greater specificity in identification.

Photoacoustic spectroscopy (*q.v.*) (Carter, 1992) differs from the above-mentioned sampling techniques in that IR absorption is detected by the acoustic signals produced by the heat generated by the IR-absorbed radiation. The unusual feature of this detection method in contrast to transmission approaches is that the signal increases with absorption, rather than decreasing as is the common observation. Photoacoustic detection is suitable for studying intractable solids, specimens that cannot be prepared as thin films without destroying identifiable features.

Incorporation of a microscope into FTIR instrumentation and the use of optic-fiber waveguides for remote excitation and detection are current features that expand the type of samples and sampling arrangements that may be amenable to infrared studies.

3. MOLECULAR-WEIGHT DISTRIBUTIONS AND THEIR DETERMINATION

In contrast to small molecules that may be processed to high purity, synthetic polymers almost never exist as single–molecular-weight entities. Exceptions are oligomers of synthetic polymers and naturally occurring biopolymers. For example, normal hexatriacontane, n-$C_{36}H_{74}$, a paraffin that is an oligomer of polyethylene, may be obtained in a highly pure form from which large single crystals may be prepared. Proteins are biopolymers that occur with a single molecular weight. The molecular weights of synthetic polymers are characterized by a distribution, rather than a single value. This molecular-weight distribution arises from the chemistry of producing the polymer or, in commercial cases, is a result of the blending of the same homopolymers to produce particular final properties of the plastic piece or to obtain specific processing properties for the polymer.

3.1 Naming Molecular-Weight Distributions and Their Moments

If n_i is the number of polymer molecules with molecular weight m_i, then the total mass of molecules with molecular weight m_i is $w_i = m_i n_i$. The number molecular-weight distribution is the fraction of molecules at a given molecular weight and is given by $n_i/\Sigma n_i$. The weight molecular-weight distribution is the fraction of mass at a given molecular weight and is given by $w_i/\Sigma w_i$. Many methods to determine the molecular weight actually measure moments of the molecular-weight distribution, not the total distribution. We may define some important moments of the molecular-weight distribution as follows: the number average moment M_n,

$$M_n = \sum w_i \Big/ \sum n_i;$$

the weight average moment M_w,

$$M_w = \sum m_i w_i \Big/ \sum w_i;$$

the z-average moment M_z,

$$M_z = \sum m_i^2 w_i \Big/ \sum m_i w_i;$$

the z + 1-average moment M_{z+1},

$$M_{z+1} = \sum m_i^3 w_i \Big/ \sum m_i^2 w_i;$$

and the viscosity average molecular weight M_v,

$$M_v = \sum \left(w_i m_i^a \Big/ \sum w_i \right)^{1/a},$$

where a is the power coefficient in the Mark–Kuhn–Houwink–Sakurada equation discussed later (Sec. 3.2.6).

The ratio M_w/M_n is called the polydispersity index and is often used as a measure of the breadth of the molecular-weight distribution. Depending on the available methods of synthesis, polymers can have wide or narrow distributions. For example, polystyrene prepared by anionic polymerization can be obtained with a polydispersity index of as little as 1.05. Polymers made by condensation polymerization are normally expected to have polydispersity indexes near 2. Commercial polyethylenes often have M_w/M_n ratios as high as 30.

3.2 Methods to Determine Moments of the Molecular-Weight Distribution

3.2.1 Membrane Osmometry Osmometry is one of the many colligative methods that count the number of molecules in solution. Colligative methods like melting point depression, boiling point elevation, and osmometry determine the number average molecular weight of molecules by measuring the change in a thermodynamic property of the solvent as a result of the addition of a small number of solute to a solvent. The change in the thermodynamic property arises from the entropy of mixing resulting upon the addition of the solute molecules to the solvent. In osmometry, the osmotic pressure of a dilute solution containing polymers, π_s, is compared with that of a pure solvent, π_0. A semipermeable membrane separates the two solutions. Solvent can go through the membrane while polymers cannot. See Fig. 4

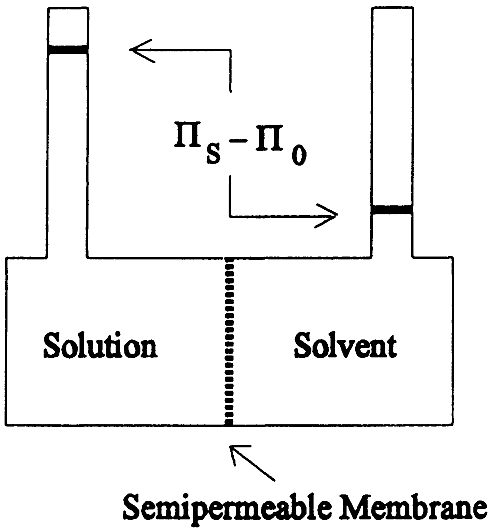

FIG. 4. Schematic of membrane osmometer. π_s is the osmotic pressure of the solution at concentration c. π_0 is the osmotic pressure of the solvent.

for a schematic of the experiment. As a result, one can measure the osmotic-pressure differential between the solution and solvent.

This measurement is sensitive enough to measure molecular weights of a polymer up to about 100 000 g/mole with good precision. It has a lower limit of approximately 8000 g/mole. This lower limit arises from the fact that the membranes available for the measurement allow polymers smaller than about 8000 g/mole through the membrane. Colligative properties can measure the molecular weight of any polymer, homopolymer, copolymers, etc., as long as the polymer can be dissolved in a dilute solution. These measurements can be made without additional measurements or assumptions about the chemical composition of the polymer or its architecture. The osmotic-pressure measurement yields the M_n moment of the molecular-weight distribution as

$$\lim_{c \to 0}(\pi_s - \pi_0)/(RTc) = 1/M_n + A_2 c + \cdots,$$

where R is the gas constant, T is the absolute temperature, c is the concentration of polymer, and A_2 is the second virial coefficient. The second virial coefficient measures the interaction between two polymers in dilute solution. To make an accurate extrapolation of the above equation to the limit of zero concentration, one often makes the molecular-weight measurement where A_2 is near zero. The temperature and solvent strength (for a mixed solvent) where A_2 is zero is called the theta point.

Membrane osmometry is one of the molecular-weight methods considered an absolute method. One needs only measure pressure, mass, and volume (for concentration) to obtain a molecular weight. No calibration against polymers of known molecular weight is required.

3.2.2 Vapor-Phase Osmometry Vapor-pressure osmometry is a molecular-weight method using the change in the vapor pressure between the polymer solution and the solvent. This could be an absolute method but to get adequate sensitivity, a droplet of solution is placed on a thermistor (a temperature-measuring device) and a droplet of solvent on another temperature-measuring device. The cooling-rate difference between them is then measured. The instrument has to be calibrated with polymers of known molecular weight. One again measures M_n. Because of the lack of sensitivity of the method, the measurement is limited to polymers of low molecular weights.

3.2.3 Light Scattering Light scattered from a solution arises from two sources, scattering from density fluctuations in the liquid or scattering from refractive-index differences arising from concentration fluctuations of solutes in the solvent. The density fluctuations can be shown to arise from the isothermal compressibility $RT(\delta\rho/\delta p)$ where p is the pressure and ρ is the solution density. The concentration fluctuations arise from the osmotic compressibility $RT(\delta c/\delta\pi_s)$ where π_s is the osmotic pressure of the polymer solution and c is the concentration. For dilute solutions away from the solvent critical point, the density fluctuations are identical to those of the pure solvent. Thus the Rayleigh ratio R_θ is related to the osmotic compressibility through

$$\lim_{\theta \to 0} Kc/R_\theta = (1/RT)(\delta\pi_s/\delta c),$$

where R_θ is the ratio of the intensity difference between solution and solvent at angle θ to the intensity of the primary beam all multiplied by the squared distance to the detector (see schematic in Fig. 5), and

$$K = (16\pi/N_A\lambda_0^4)n_0^2(dn_s/dc)^2,$$

where λ_0 is the wavelength of light, N_A is Avogadro's number, n_0 is the refractive index of the solvent, and dn_s/dc is the refractive-index increment of the polymer solution.

For molecules much smaller than $\lambda_0/20$, the angular dependence of R_θ is related to the change in scattering volume with angle. For larger molecules, light scattered from one region of the molecule interferes with light scattered from another region of the molecule causing the destruction of scattering intensity. This angular dependence is sensitive to the size and shape of the molecule. At low concentrations of the polymer, an expansion in concentration of R_θ is given by

$$\begin{aligned} Kc/R_\theta &= 1/M_w + 2A_2c \\ &\quad + 16\pi^2R_g^2/(3\lambda_0^2)\sin^2(\theta/2) + \cdots, \end{aligned}$$

where A_2 is, as before, the second virial coefficient and R_g is the radius of gyration. The term R_g is defined for homopolymers by

$$R_g^2 = \sum \langle r_{ij}^2\rangle/n^2,$$

where r_{ij} is the distance between scattering center i and scattering center j and $\langle\ \rangle$ is a configurational average. It is a measure of the size of the molecule. Light-scattering data are normally represented by a Zimm plot (Zimm, 1948) (see Fig. 6) where the molecular weight is obtained by a double extrapolation to zero concentration and zero angle.

In the measurement of molecular weight, it is often useful to use a solvent in which A_2 is near zero to facilitate extrapolation of the molecular-weight measurement to the zero-concentration limit.

Light scattering is most easily done on homopolymers. To obtain the M_w of a copolymer by light scattering requires the measurement of the light scattering in at least two solvents with considerably different refractive indexes.

Light scattering is another molecular-weight method which is absolute. No calibration against a polymer of known molecular weight is needed to obtain the molecular weight of a homopolymer.

3.2.4 End-Group Analysis The end groups of a polymer are chemically different from any interior group. The molecular weight of a homopolymer can be obtained by using any measurement technique that will count the number of end groups per mass of the polymer. Besides the spectroscopic methods to distinguish end groups, like IR and NMR described in earlier sections, chemical methods are often available. For example, polyamides (nylons) can be synthesized with amine or carboxylic acid

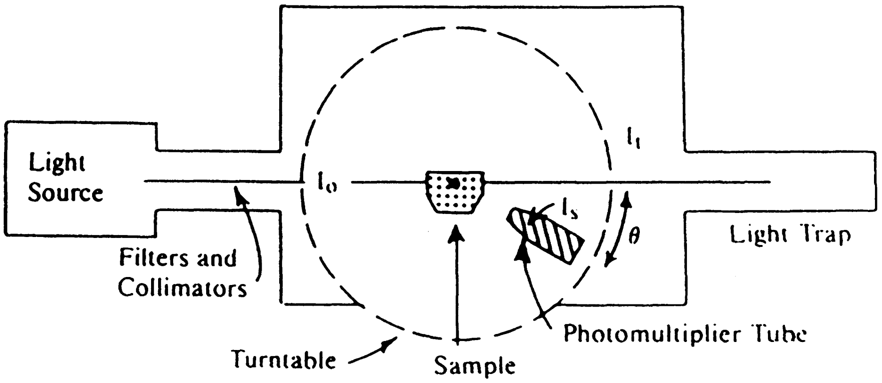

FIG. 5. Schematic of light-scattering instrument. I_0 is the intensity of the source, $I_s(\theta)$ is the scattered light from either the solvent, $I_{\text{solv}}(\theta)$, or the solution, $I_{\text{soln}}(\theta)$, at an angle θ, θ is the angle between the axis of the light source and axis of the detector, and

$$R_\theta = (I_{\text{soln}}(\theta) - I_{\text{solv}}(\theta))r^2/I_0,$$

where r is the distance from the center of the sample to the detector (from Hiemenz, 1984, p. 691).

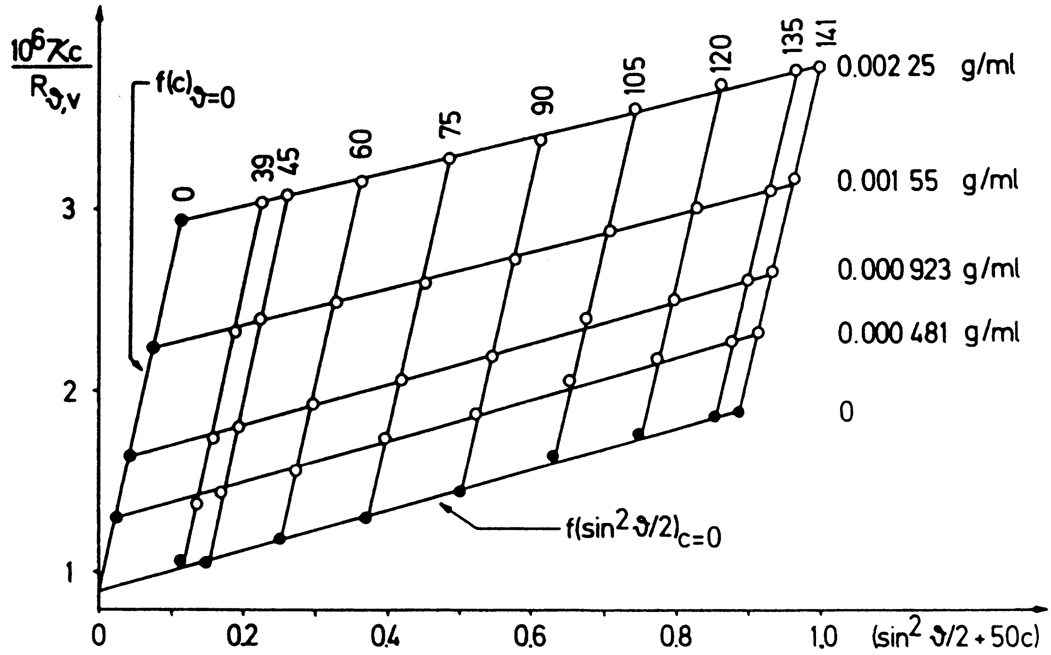

FIG. 6. Zimm plot of reciprocal intensity for poly(vinyl acetate) in butanone at 25 °C. The molecular weight is computed from the intercept (from Elias, 1977, p. 323).

end groups. These can then be counted by normal analytical methods. Assuming the method counts all end groups and the polymer is not branched, then the method yields M_n. The method is absolute under these conditions.

These conditions are seldom met unless special care is taken in the polymerization process. In many commercial processes, the initiation and termination chemical reactions that produce a polymer are often not the same, and so the same chemical groups are not on each end. Impurities often terminate the chemical reaction so that unknown groups could be on at least one end.

The sensitivity of measuring a small number of end groups in the presence of a large number of other groups is constant, independent of the polymer molecular weight. Thus, the method is limited to the determination of polymers of low molecular weight. Under the best of circumstances, the molecular weights of polymers of less than 20 000 g/mole can be measured with this method.

3.2.5 Ultracentrifugation This method is mainly used in molecular-weight studies of biological macromolecules, although it has often been used to determine the molecular weight of synthetic polymers. The equilibrium sedimentation methods of ultracentrifugation weigh the polymer molecules by obtaining an equilibrium concentration gradient within a solution sample. The gradient is a result of a balance between the force of the controlled centrifugal field on the masses of the molecules and the opposing force of the chemical potential of the molecules to redistribute uniformly in the solution (the diffusion potential). In the gradient, the lower–molecular-weight molecules move toward the centrifugal top (the meniscus) and the heavier molecules move toward the centrifugal bottom. Since this technique measures the weight of the polymer molecules, ultracentrifugation determines most accurately the first moment of the mass distribution or M_w of the polymer.

The equilibrium continuous partial fractionation of the polymer between the solution boundaries offers the opportunity to analyze the polymer molecular-weight distribution. Few successful efforts have been made to analyze molecular-weight distribution using this technique. However, the moments of the distribution curve higher than

M_w, i.e., M_z, M_{z+1}, etc., can be measured. In addition, the M_n can also be determined by an equilibrium sedimentation experiment conducted under conditions in which the equilibrium polymer concentration becomes approximately zero in the meniscus region of the solution sample. The uncertainty in M_n and M_z is much greater than the uncertainty in M_w determined by this experimental procedure.

Like light scattering and osmometry, equilibrium sedimentation is an absolute method. In addition to it being an absolute method, the other major advantage of the equilibrium sedimentation procedure is that it determines the M_w more precisely than any other method. Furthermore, practically useful values for M_n, M_z, and M_{z+1} can also be determined in the same single experiment. The singular major problem with the equilibrium sedimentation method is the time, often a week, required to achieve equilibrium.

3.2.6 Intrinsic Viscosity The viscosity of a dilute solution of a polymer is greater than that of the solvent. Usually a small concentration of a high-molecular-weight polymer will increase the viscosity of the solution greatly. The greater the size of the polymer, the more greatly the viscosity increases. Thus before other methods were available to measure the molecular weight of the polymer, viscosity–molecular-weight relations were developed.

The intrinsic viscosity is defined as the limiting slope of the viscosity concentration function. Thus

$$[\eta] = \lim_{c \to 0}(\eta_s - \eta_0)/c,$$

where η_s is the viscosity of the solute at the concentration c in the solution, and η_0 is the viscosity of the solvent. The relationship of intrinsic viscosity to molecular weight is called the Mark–Kuhn–Houwink–Sakurada relationship and is experimentally

$$[\eta] = K_\eta M^a,$$

where the value of K_η depends on the polymer and the solvent and the value of a depends on the solvent quality only. The value of a varies from 0.5 for a chain near its theta point to 0.8 or so for a chain in a good solvent. The Mark–Kuhn–Houwink–Sakurada equation is valid for higher molecular weights. For example, the equation holds above a molecular weight of 10 000 g/mole for polystyrene in tetrahydrofuran, a common polymer solvent for size-exclusion chromatography.

3.3 Methods to Determine Molecular-Weight Distributions

3.3.1 Size-Exclusion Chromatography Size-exclusion chromatography (SEC) is one form of high-performance liquid chromatography (see CHROMATOGRAPHY). SEC is often called gel permeation chromatography (GPC) or gel filtration chromatography. The column packings for nonaqueous SEC are usually porous gel beads of styrene divinyl-benzene or porous glass beads.

In any liquid chromatographic process using a porous medium as the chromatographic bed, the average elution volume in chromatography reflects the partitioning of the polymer between the flowing "mobile phase" and the "stationary phase." In the stationary phase, the polymer is localized in the bead pore. In the simplest quasiequilibrium model of chromatography, the average elution volume V_e is given by

$$V_e = V_m + K_D V_p,$$

where V_m is the mobile phase volume, V_p is the pore volume, and K_D is the partition coefficient. For size-exclusion chromatography, K_D is less than 1.

In size-exclusion chromatography, the polymer has no interaction with the pore wall except to be excluded by it. The polymers that are largest are excluded from the pore (they cannot get in) while the smaller polymers can get into the pores. Thus the largest polymers can only sample the mobile phase V_m. The larger polymers have K_D near zero and the smaller polymers have K_D closer to 1.

Since the separation process is on the basis of molecular size, not molecular weight, the method requires calibration. Furthermore, since the size of a very high–molecular-weight branched polymer can be the same as a much lower–molecular-weight linear polymer, the molecular weight can only be determined by a calibration with polymers of similar repeat units and architecture.

The method called "universal calibration" has alleviated this calibration problem for unknown polymers. In universal calibration, the volume elution from a given column is experimentally found to be a function of the hydrodynamic volume of the polymer independent of polymer architecture and chemical composition (see Fig. 7) (Grubisec *et al.*, 1967). The hydrodynamic volume is the product of the molecular weight and intrinsic viscosity, $[\eta]$. SEC detectors are available that can measure the intrinsic viscosity on line. Using universal calibration, the molecular weight and molecular-weight distribution of any unknown polymer can be measured. There are instances where universal calibration has been shown to fail.

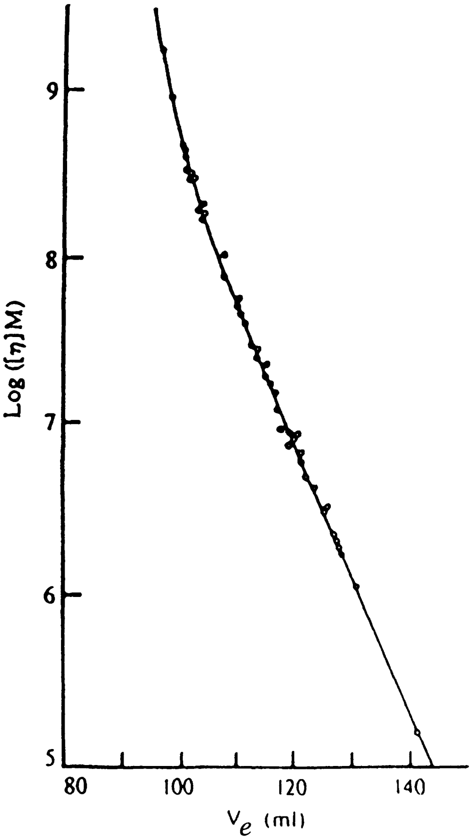

FIG. 7. Plot of $\log([\eta]M)$ vs elution volume for various polymers. The polymers in the figure include linear and branch polystyrene, poly(methyl methacrylate), poly(vinyl chloride), poly(phenyl siloxane), polybutadiene, and branched, block, and graft copolymers of styrene and methyl methacrylate (from Grubisec *et al.*, 1967).

Other detectors, ultraviolet or differential refractive-index detectors, commonly used in SEC, measure concentration of the polymer. When combined with a flow-through light-scattering detector, the molecular weight of a homopolymer at each elution volume can be measured. With this method, the molecular-weight distribution of a homopolymer can be measured.

3.3.2 Mass Spectrometry Generally mass spectrometry has been limited to measuring molecular weights for molecules of masses less than 4000 g/mole. This is due to the difficulty of obtaining the whole, not degraded, molecule in the gas phase. Recently, methods have become available to get whole polymer molecules into the gas phase.

In the most common of these, MALDI (matrix-assisted laser-desorption ionization), the polymer is dissolved in dilute solution of a solid matrix. A laser is used to oblate the matrix. The laser energy is absorbed by the matrix, not the polymer. The polymer is carried into the gas phase by the ablated matrix molecules and ionized by the transfer of charge from the matrix molecules to the polymer. The polymer once in the gas phase can then be analyzed using a variety of methods. For high-molecular-weight polymers, a time-of-flight spectrometer can measure the mass-to-charge ratio of singly or doubly charged large molecules (see, for example, Bahr *et al.*, 1992).

Mass spectrometry is the only available method to hold the possibility of determining the molecular-weight distribution directly. As pointed out earlier, SEC does not separate on the basis of molecular weight. Fractionation methods, to be discussed in the next section, often do not fractionate on the basis of molecular weight only. MALDI time-of-flight mass spectroscopy has the possibility of being an absolute method. The subject is too new to make a final judgment on this.

3.3.3 Fractionation Methods Before the appearance of SEC and mass spectrometry of polymers, most molecular-weight distributions of synthetic polymers were obtained by fractionation of the polymer followed by the measurement of some moment of the molecular weight of each fraction. If the fractionation is quantitative, the molecular-weight distribution can be expected to be quantitative.

We may fractionate a polymer from solution by using a liquid–liquid phase-separation method or a liquid–solid phase-separation method. The phase separation of a polymer solution from a single-phase system to a two-phase liquid system is little different from that which occurs with a small molecule in a solvent. As we go from a good solvent for the solute in which the solute and solvent form a single-phase liquid system to a poorer solvent by changing temperature or adding a poor or nonsolvent to the system, we obtain a two-phase system, one richer in solute than the other. The same occurs in a polymer system. However, for polymers, the temperature or solvent mixture at which the phase separation takes place is strongly molecular-weight dependent. Generally, the higher–molecular-weight species undergo phase separation at higher temperatures or better solvent strengths. Thus, we may separate polymers by molecular weight by selecting one of the two phases.

If the phase separation involves a liquid-to-solid transition, as with the formation of a crystal or precipitate, the higher–molecular-weight species usually solidifies at higher temperature or better solvent strengths.

A solid polymer can be fractionated by extracting the low–molecular-weight species at lower temperatures or poorer solvents. The polymer in its solid phase is often deposited as a film on a packed column as a substrate. Solvent strength is then varied so that each cut comes off as a function of solvent strength.

Size-exclusion chromatography has been used as a method of polymer fractionation. Generally, this technique cannot be used to obtain gram quantities of the polymer since the loading of SEC columns is very limited.

4. DETERMINATION OF CHEMICAL AND CONFORMATIONAL ORDER ALONG THE POLYMER CHAIN

Two of the methods discussed in Sec. 2, NMR and infrared spectroscopies, are utilized in determining chemical and conformational order along the polymer chain. Shielding of the applied magnetic field by neighboring atoms leads to chemical shifts in the NMR spectrum that can be related to chemical order along the polymer chain. As a result of the narrow NMR bands in liquid-state NMR, features attributed to sequences of chemical groups are revealed. Thus, aspects of polymer structure, stereochemical configuration, branching, copolymer sequences, and molecular dynamics are elucidated. An example is illustrated in Fig. 1 where ^{13}C NMR is used for analyzing the stereochemistry of poly(vinyl chloride) and poly(vinyl bromide). Besides the prevalent head-to-tail arrangement (–CH_2CHx-CH_2CHx–) (x refers to either Cl or Br), head-to-head (–$CH_2CHxCHxCH_2$–) and tail-to-tail (–$CHxCH_2CH_2CHx$–) configurations may occur as well. In addition, the halogen atoms can occupy positions that are meso (m) or racemic (r); these arrangements refer to the stereoregularity (isotactic, syndiotactic, and atactic). Sequence lengths of up to pentamers exhibit distinct chemical shifts.

Another application of ^{13}C NMR is determination of branch types, distributions, and concentrations. An example of quantitative information that can be obtained is illustrated in Fig. 2 for a low-density polyethylene. In this figure, the assignments of chemical shifts to the different kinds of branches are given.

IR spectral frequencies and intensities may also be sensitive to chemical order along the polymer chain, including stereochemistry, branching, end groups, and degradation products. The information is generally restricted to order of nearest or next-nearest neighbors of backbone atoms, however, because of the localized nature of most infrared-active vibrations. In addition, the IR spectra of solid polymers provide information on the type and amount of crystalline forms, the degree of crystallinity, orientation of macromolecules, *trans–gauche* bond ratios, and the local environment of constituent chemical groups.

5. EQUILIBRIUM DIMENSIONS AND CONFORMATION OF SINGLE CHAINS IN SOLUTION

5.1 Models without Long-Range Interactions

There are a variety of models for single-polymer chains. The simplest model, the closest model to the ideal-gas model of a gas, is the random-walk model of a polymer chain. In the simplest of these models, only the connectedness of the chain is considered. Each step in the random walk can itself be random both in length and in direction with respect to the earlier step. Thus, each step is viewed as many repeat units that may themselves have a fixed or nearly fixed bond length and perhaps have only a few rotation angles allowed. When many of these repeat units are viewed together, they appear as a random walker with random step size and random angles. This model is called the Gaussian model.

Like other forms of the random walk, only a few modifications of these models are needed to add local structure. In the freely jointed chain model, all the bonds or steps have the same length. The angle between adjacent bonds can take on any value as can the angle of rotation. In the freely rotating chain model, the bond length and the angle between successive bonds are fixed but the rotation around the bond is free.

In the most realistic of these models, the rotational isomeric state model (RIS), each step of the walk represents a repeat unit. The bond distance is fixed as is the bond angle. Only a few rotation angles are allowed. The choice of an allowed angle depends on the angle allowed in the previous few steps. Thus, the RIS describes many details of the local structure of the chain.

Equilibrium properties measured by these models include the free energy f, the average end-to-end distance squared (the average distance between the first and last segments on a linear chain), R_e^2, and the average squared radius of gyration, R_g^2. The radius of gyration, defined previously, can be measured by a light or neutron-scattering experiments.

The end-to-end distance is defined as

$$R_e^2 = \langle r_{n0}^2 \rangle,$$

where r_{n0} is the distance between the first and last beads on the chain and $\langle\ \rangle$ is the configurational average. For a long linear chain in the random walk, any squared distance measure like the end-to-end distance squared or the radius of gyration squared depends linearly on the number of steps, n. For any of the random-walk models of the polymer chain, the radius of gyration and the end-to-end distance are related as

$$R_g^2 = R_e^2/6.$$

For chains in the random-walk approximation, we find

$$R_e^2 = C_n n l^2,$$

where n is the number of monomers or repeat units in the chain, l is the bond length, often in synthetic polymers the carbon–carbon bond length, and C_n is the so-called characteristic ratio. For chains greater than 100 repeat units, C_n is independent of n.

The configurational free energy of such models, f, is for long enough chains

$$f = -kT(n - 1)\ln(z),$$

where z is the partition function per step. For the simplest lattice model of a polymer chain, $z + 1$ is the coordination number of the lattice.

5.2 Models with Long-Range Interactions

None of the above models included any interactions of chain segments separated by large numbers of other segments along the chain. These interactions are deemed long-range interactions. In three dimensions and fewer (actually in fewer than four dimensions), these interactions are important and affect the size parameters' dependence on number of segments and the functional form of the free energy.

When we include long-range interactions, the squared end-to-end distance and the radius of gyration squared in the limit of many segments have the functional form

$$R_e^2 = A_e n^{2\gamma},$$

$$R_g^2 = A_g n^{2\gamma}.$$

The value of γ depends on the nature of the long-range interactions. As with all other molecular interactions, polymer-segment interactions have two components, a repulsive core and an attractive interaction between segments. The repulsive core is usually viewed as a hard-core exclusion between polymer segments. The attractive interaction energy in solution, ϵ, is a competition between terms including polymer-segment–

polymer-segment interactions (ϵ_{pp}), polymer–solvent interactions (ϵ_{ps}), and solvent–solvent interactions (ϵ_{ss}). In lattice models, ϵ has the form

$$\epsilon = \epsilon_{ps} - (\epsilon_{ss} + \epsilon_{pp})/2.$$

In the good-solvent limit, the $\epsilon = 0$, i.e., there is no overall attractive interaction. Under these conditions, the polymer–polymer exclusion dominates and in three dimensions $\gamma = 0.588$–0.6 depending on the character of the model used. Values near $\gamma = 0.588$ are most likely correct although it is unlikely the difference can be observed experimentally from dilute-solution measurements.

(The reader should recall that in one dimension long-range interactions and short-range interactions are quite indistinguishable. In one dimension, the inclusion of local structure so that the chain cannot walk back on itself requires that the chain has $R_e^2 = A_e n^2$. That is, the chain behaves as a rod.)

In a poorer solvent where the polymer–polymer attraction is favored over polymer–solvent attraction, the polymer changes size. At the theta point, a balancing of the attraction and repulsion takes place and $\gamma = 0.5$. The competition between attraction and repulsion in the polymer makes the polymer look like a random walk. In mean field theory of Flory at this solvent strength, A_2, the second virial, vanishes. Experimental evidence supports this view in dilute solutions.

As the attraction increases, the chain collapses. The term γ takes on the value of $\frac{1}{3}$. At chain collapse of a polymer in solution, the chain is not a dense globule, but rather an open structure much larger than the condensed chain. There are a considerable number of theories and simulations that discuss chain collapse, but few experiments. The experimental nature of the transition to collapsed chain is not fully understood at this time.

Since the overall attractive energy ϵ always appears in statistical mechanics as ϵ/kT, where k is Boltzmann's constant and T is temperature, then variations in the solvent strength discussed above may be obtained by varying temperature. Another method to vary solvent strength is to use a mixed solvent. In this case, a varying solvent strength is obtained by varying concentration of good and poor solvents for the polymer. For example, cyclohexane is a poor solvent for polystyrene at room temperature with its theta point being at 34.5 °C. At higher temperature, its solvent quality improves. Benzene is a good solvent for atactic polystyrene at 34 °C. However, the mixture 74% benzene and 26% methanol, a nonsolvent for polystyrene, is a theta solvent for polystyrene at 34 °C.

The use of mixed solvents is not without problems. Often one solvent favors the polymer more than the other solvent. In dilute solution, the good solvent for the polymer may have a concentration in the vicinity of the polymer that differs from the mean solvent concentration. This situation is called preferred adsorption or solvation in polymer science. The occurrence of such preferred adsorption changes the properties of the polymer in solution.

GLOSSARY

Atactic Polymer: A polymer made from repeat units that contain an *asymmetric* carbon atom, in which the stereo arrangements of groups about the asymmetric carbons are random. Atactic polymers tend not to be able to crystallize; rather, they form glasses.

Copolymer: A polymer having a fixed number of chemical constituents or repeat units that are repeated. Diblock copolymers are of the form A–A–A–A–A–A–B–B–B–B–B, and triblock polymers are of the form A–A–A–A–B–B–B–B–C–C–C–C or, more commonly, A–A–B–B–B–B–A–A–A–A. Alternating copolymers are of the form A–B–A–B–A–B–A. These copolymers may also be considered as homopolymers of A–B repeat units. Random copolymers have at least two chemical groups repeating in random order.

End-to-End Distance, R_e: The mean square distance defined by

$$R_e^2 = \langle r_{n0}^2 \rangle,$$

where r_{n0} is the distance between the first and last beads on the chain and angular brackets denote the configurational average. For long, linear chains whose conformations are represented by random walks, the squares of the distance measures, like the end-to-end distance squared or the radius of gyration squared, depend linearly on the number of steps, n. Generally, the end-to-end distance is not directly measured; however, for linear polymers, it is related to the square of the radius of gyration according to $R_g^2 = rR_e^2$. At the theta point and for a random chain, r = $\frac{1}{6}$, independent of the number of repeat units and of the chain structure for long polymers. The constant r is about $\frac{1}{7}$ at the exclusion point. The term R_g commonly appears in theories of elasticity and of other polymer properties.

Homopolymer: A polymer having the same chemical constituent repeated many times and represented by A–A–A–A–A–A–A–A, where A denotes the chemical constituent or repeat unit.

Isotactic Polymer: A polymer made from repeat units that contain an *asymmetric* carbon atom, in which the arrangement of groups about each asymmetric carbon is identical. Isotactic polymers can crystallize.

Monomer: The chemical used in the chemical reaction to produce the polymer. For example, styrene is the monomer for homopolymer polystyrene.

Number Molecular-Weight Distribution: The fraction f_i of molecules with a mass per mole of the molecules m_i. In terms of definitions in the text,

$$f_i = n_i \Big/ \sum n_i$$

Number Average Molecular Weight, M_n: The first mass moment of the number molecular-weight distribution,

$$M_n = \sum f_i m_i,$$

where M_n is obtained from measurements of osmotic pressure, end-group analysis, or vapor-pressure osmometry on dilute solutions or from size-exclusion chromatography.

Polydispersity Index: The ratio of weight average molecular weight to number average molecular weight, M_w/M_n. It is used as a measure of the width of the molecular weight distribution and is always greater than unity.

Radius of Gyration, R_g: The mean square of the radius of gyration for a homopolymer is defined as

$$R_g^2 = \sum \langle r_{ij} \rangle / n^2,$$

where r_{ij} is the distance between repeat units i and j, the summation is over all pairs i,j, and the angular brackets denote configurational average; R_g is a measure of the size of the molecule. It is an observable directly measured by light scattering, neutron scattering, or x-ray scattering for polymers.

Second Virial Coefficient, A_2: The coefficient of the second term in the concentration expansion of the light-scattering equation or the osmotic-pressure equation. The second virial coefficient reflects the interaction between two polymers in dilute solution. The temperature or solvent strength at which $A_2 = 0$ is called the theta point.

Syndiotactic Polymer: A polymer made from repeat units that contain an *asymmetric* carbon atom, in which the arrangements of groups about successive asymmetric carbon atoms alternate. Syndiotactic polymers are known to crystallize.

Telechelic Polymer: A polymer with a chemically active end group to be used in a subsequent chemical reaction.

Thermoplastic Polymer: A polymer formed into its final product by solidification when cooled from the melt. The solidification is the result of crystallization or the supercooling from the liquid to form a glass. Common thermoplastic polymers are polystyrene, polyethylene, and poly(ethylene terephthalate). A thermoplastic polymer is susceptible to heat deformation.

Thermoset Polymer: A polymer in which chemical reactions occur during the process of forming the final product. The chemical reactions often cause the polymer to cross-link. Telechelic polymers are often used as starting materials for thermoset polymers. Thermoset polymers often cannot be reprocessed. Examples of thermoset polymers are polyurethanes and epoxies.

Theta Point: The polymer-solvent compensation point in dilute polymer solutions where the second viral coefficient A_2 is zero. At the theta point, the dimension properties have random-walk behavior.

Weight Average Molecular Weight, M_w: The ratio of the second mass moment to the first mass moment of the number molecular-weight distribution,

$$M_w = \sum m_i g_i.$$

where M_w is usually obtained from measurements of light scattering and equilibrium ultracentrifugation. The quantity g_i is defined under **Weight Molecular-Weight Distribution.**

Weight Molecular-Weight Distribution: The fraction g_i of the total mass of molecules with a mass per mole of the molecules of m_i. In terms of definitions in the text,

$$g_i = w_i \Big/ \sum w_i.$$

INTRODUCTION

Polymers are a ubiquitous class of materials in our daily life. These macromolecules—either in solution, as melts, liquid crystals, or glasses, or in the crystalline state—play a central role also in many modern technologies. This is due to a wide range of attractive properties, e.g., mechanical, rheological, electrical, etc. As far as their optical properties are concerned, however, only polymers in the glassy state and, to a lesser extent, liquid-crystalline phases are important and optimized for various applications.

A description of these optical properties includes, but cannot be limited to, the presentation of those phenomena and properties that describe their intrinsic response to (visible) light. A rough classification of these properties could start, e.g., with transparency and birefringence, which determine the intensity decrease and change of polarization, respectively, of light being transmitted through the sample or the device. The response to external fields is also such an intrinsic property, e.g., the change of the optical properties by applying (strong) magnetic fields described by magneto-optical effects.

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

In cases, however, where the lateral dimensions of the sample are in the micrometer range, i.e., approach or are comparable to the wavelength of light, the optical properties cannot be characterized by bulk features any more but need to take into account the complex sample configuration. Here the three-dimensional arrangement of the (different) polymeric materials is intimately linked to the optical properties of the system. Channel waveguides or whole opto-boards in integrated optics are examples of this.

Another important aspect of the optical properties of polymers concerns not their purely intrinsic features but the nearly unlimited possibilities for a specific functionalization. Here the polymer serves as a matrix into which the functional optical units are incorporated—either by mixing or by covalent attachment. The optical properties of these materials are given by the interaction of the whole system with light.

Some of these functionalizations are designed so as to guarantee a strong interaction with light through specific electronic excitations giving rise to a broad range of phenomena: spectral changes due to the resonance character of absorption, or secondary processes (following the excitation) like luminescence phenomena (fluorescence, phosphorescence, etc.), are examples. Many systems show changes in other properties when photoexcited—e.g., they become photoconductive. The general term photoresponsive was coined to summarize the long list of property changes that can be induced by a purposeful design of the material, typically by the proper functionalization: this list includes photoisomerization and photochemical reactions resulting in a change of optical, mechanical, structural, morphological, rheological, solubility, or (meso-)phase properties. Finally, nonlinear optical properties, relevant for the description of the response of the material to ultrastrong optical fields, i.e., to a giant laser pulse, define the most active field of research in recent years related to optical properties of polymers.

In what follows, we are able to cover only a few selected examples in trying to highlight some of the improvements that have been achieved by extensive research and development that was focused in two nearly opposite directions: One goal was to *minimize* the interaction with light, e.g., to reduce the losses in a polymer optical fiber (POF) used in (local) data communication networks or to decrease the noise in optical recording and reading for information storage on optical disks. The other strong effort was to *enhance* the interaction with light, e.g., to increase the light-intensity–dependent refractive-index change n_2 in selected polymers needed to switch "light by light" in a future photonics device application.

In Sec. 1 we concentrate on some "passive" bulk material properties related, e.g., to their transparency or their dispersion properties. Section 2 is called "polymers in special configurations" and describes polymers in ultrathin films from monomolecular layers to multilayer assemblies, integrated optics with planar- and channel-waveguide structures, and fibers. Section 3, finally, is devoted to nonlinear materials and device concepts based on second- ($\chi^{(2)}$) and third-($\chi^{(3)}$) order nonlinear optical effects.

1. POLYMERS WITH SPECIFICALLY TUNED BULK OPTICAL PROPERTIES

In this section, we concentrate on the discussion of the remarkable progress that has been made in recent years in the development of polymeric materials with specific, tailor-made property profiles. Depending on the various applications, these synthesis and processing optimizations were in some cases aimed at reducing as much as possible any interaction with light so as to not change its intensity, state of polarization, etc. Clearly, these are the applications where polymers are to replace inorganic glasses as windows, shields, eyeglasses, substrates, etc. A more recent example is the use of polymers as substrate materials for optical storage disks or highly transparent materials for polymer optical fibers.

Another important optical property of polymers is their dispersion behavior: The isotropic or anisotropic refractive index and its dependence on the wavelength of light are key parameters that need to be tunable to certain values in all areas of polymers for integrated optics. As an example, solid polyelectrolytes with a broad range of refractive-index values and dispersion characteristics are briefly discussed below.

After a short introduction to some recent developments of magneto-optical applications of polymers, we turn to probably the most important application of polymers in microelectronics: as resist materials that are optimized with respect to their absorption of photons (and, of course, with respect to other property changes like solubility following excitation by the exposure to light).

1.1 Polymers as Transparent Substrates for Optical Disks

The availability of low-cost lasers made optical information storage an attractive alternative to existing mass-storage concepts. The largest volume use of polymers for optical recording, however, is still in disk substrates. The material used for compact disks (CD), CD-ROMs (read-only memory), and video disks has to fulfill extreme requirements (Kämpf, 1985):

1. optical homogeneity (low birefringence);
2. high transparency in the visible, in some cases also in the UV (λ = 280–380 nm);
3. high shape stability (low thermal expansion, water uptake ≤0.3%);
4. isotropic expansion upon temperature or humidity increase;
5. good mechanical properties;
6. constant thickness, planarity; and
7. constant rheological properties for the molding process of the "pits".

Currently, mostly poly(methylmethacrylate) (PMMA) and poly(4-methyl-1-pentene) as well as bisdiallylpolycarbonates (PC) are used for the fabrication of substrate disks. These polymers offer the optical quality of glass. Some selected physical properties of PMMA and PC are summarized in Table 1 (after Pearson, 1988).

Table 1. Selected physical properties of PMMA and PC substrates.

	PC	PMMA
Transmittance (%) at 830 nm	90	92–93
Refractive index at 830 nm	1.58	1.49
Birefringence (nm) at 830 nm	20–30	<20
T_g (°C)	150	100
Thermal-expansion coefficient [(°C)$^{-1}$]	(6–7) × 10^{-5}	7.6 × 10^{-5}
Rockwell hardness (M scale)	75	90
Izod impact strength (kg cm/cm)	1–2	1.6
H_2O absorption (%)	0.25	0.54

1.2 Solid Polyelectrolytes as Glassy Polymers with Tunable Refractive Indices and Dispersion Characteristics

The various available polymers can have very different refractive indices and dispersion properties. However, Fig. 1 shows that these materials exhibit typically much lower refractive indices than inorganic glasses as a result of the absence of highly polarizable units like, e.g., the heavy metals with their many electrons in flint glasses. One extreme case, e.g., is poly(tetrafluorethylene) with n_D = 1.345 (data point A in Fig. 1). A material with a substantially higher refractive index like poly(N-vinylcarbazole) with n_D = 1.685 has a very high dispersion ν_D (the Abbe number ν_D is defined by $\nu_D = (n_D - 1)/(n_F - n_C)$, with n_D, n_F, and n_C being the refractive indices at three standard wavelengths: blue, λ = 486.1 nm; yellow, 589.2 nm; red, 656.3 nm, respectively).

One successful attempt to expand the available polymeric materials toward higher refractive indices was recently reported for solid polyelectrolytes, also called ionenes

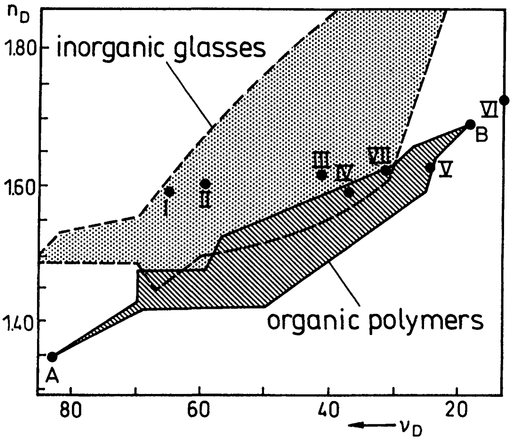

FIG. 1. Refractive indices n_D and optical dispersion ν_D of inorganic glasses (dotted area), organic polymers (dashed area), and a series of selected ionenes (numbered I–VII according to Table 2). A, poly (tetrafluorethylene); B, poly(N-vinylcarbazole).

(Simmrock *et al.*, 1989). Given their general structure

$$[R^1 - N^{\oplus}(R^3)_2 - R^2 - N^{\oplus}(R^4)_2]X^{\ominus\ominus}, \qquad (1)$$

with the main-chain segments R^1 and R^2, and R^3 and R^4 being organic moieties, e.g., aliphatic groups, there is an almost unlimited range for tuning their solid-state properties, e.g., their crystallinity or their ability to solidify as glasses, while on the other hand their optical properties can be largely varied by the introduction of suitable counterions, both monovalent and divalent. In particular, by the introduction of structural irregularity into the main chain ($R^1 \neq R^2$), glassy materials with very different polymeric properties like the glass-transition temperature could be synthesized. Table 2 indicates the progress in extending the selection of polymers toward higher refractive indices with a wide range of Abbe numbers (cf. Fig. 1).

The interrelation between high refractive index and high dispersion is demonstrated in Fig. 2 for two different ionenes (Mathy *et al.*, 1991). The first one, polyelectrolyte I (cf. Table 2), with $ZnBr_4$ as counterions, has its strongest absorption in the deep ultraviolet (DUV) range not exceeding $\lambda = 220$ nm [see Fig. 2(a)]. The Kramers–Kronig analysis with a background refractive index of $n_0 = 1.516$ shows that as a result the dispersion in the visible is very low despite a relatively high refractive index [Fig. 2(b)]. On the other hand, the introduction of HgI_4 ions into the polyelectrolyte VI extends the absorption of the material into the near-uv range [Fig. 2(c)] with a consequently much higher (resonance enhanced) refractive index but also with a very strong wavelength dependence, i.e., low Abbe number [Fig. 2(d)].

It is clear that this flexibility for tuning the linear optical properties of polymeric materials is a very promising feature for future device configurations, e.g., in integrated optics. We should also mention that the introduced counterions, of course, may also have high nonlinear polarizabilities, allowing for the preparation of highly functionalized materials, e.g., for $\chi^{(2)}$ (Weiss *et al.*, 1995) or $\chi^{(3)}$ applications (Meyer *et al.*, 1991).

1.3 Magneto-optical Polymers

Certain materials act naturally as polarization rotators, a property known as optical activity: waves with right- and left-circular polarization travel with different velocities. This property is found in media in which the molecular units have an inherently helical character (quartz, selenium, tellurium, but also many organic/polymeric materials). Materials that have different absorption coefficients for right and left circularly polarized light are said to exhibit circular dichroism.

An effect related to this, the Faraday effect, describes the polarization rotation of light passing through a material placed in a static magnetic field. The Faraday rotation angle ξ is given by

$$\xi = VBl, \qquad (2)$$

where B is the magnetic induction in the direction of the light-wave propagation, l is the length of the sample, and V is a material parameter, called the Verdet constant. This

constant can be relatively high in polymers containing phenyl groups [e.g., $V \approx 0.1$ min/(Oe cm) for polystyrene; Muto and Ito, 1992]. In a Faraday rotator, the sense of the rotation is governed by the direction of the magnetic field and, therefore, does not change with the reversal of the direction of propagation of the wave. This is the basic concept for optical isolators based on this phenomenon. Its principle is outlined in Fig. 3: A linearly polarized wave passing the Faraday rotator may experience a polarization rotation of, say, 45°. It passes another polarizer B tuned to this angle. After reflection it again can go through the polarizer, but is then rotated by the rotator by another 45° in the same direction. This wave is now orthogonal to the incident polarizer A and hence is blocked. Muto and co-workers (1991) have used a poly(α-methylstyrene) rod of $l = 19$ mm to construct a 45° rotator for $\lambda = 488$ nm light at 4 kOe magnetic field. Its transmission characteristic is shown in Fig. 4. Inserting the isolator into the laser beam

causes a loss of ca. 5 dB, but the isolation obtained is ca. 15 dB. Further improvements of the device performance are expected for materials with lower birefringence.

1.4 Photoresists

The basic lithographic processing steps are schematically depicted in Fig. 5. Onto the oxidized silicon wafer (a), a thin photoresist polymer is deposited typically by spin-coating (b). Either by use of a photomask (c1), which allows for a structured parallel exposure of the photoresponsive material, or by a setup that scans a focused beam (e.g., an electron beam) for a serial exposure across the polymer layer (c2), a latent image is stored in the resist material. By a developing process, this image is converted into a surface-relief structure (d). Depending on the chemical nature of the resist material, the exposed areas may be rendered more soluble to the developer than the unexposed areas, thereby producing a positive-tone image of the mask, or these areas are made less soluble, in which case a negative-tone image

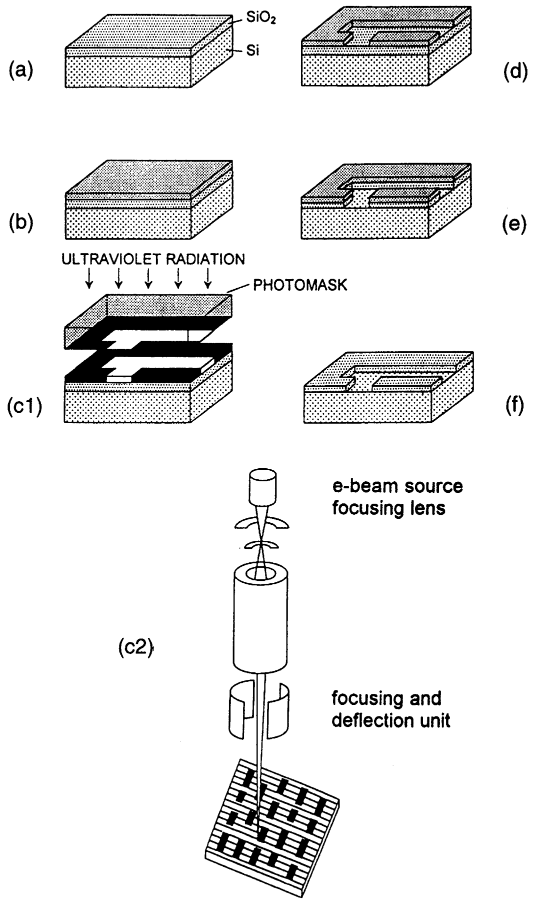

FIG. 5. Basic processing steps in lithography: (a) The oxidized wafer is (b) (spin-)coated by a thin photoresist layer. This is irradiated to form a latent image either (c1) by a photomask in a parallel exposure, or (c2) by an electron beam in a serial process. Developing leads to (d) a relief structure that allows for (e) a patterned etching of the oxide layer. (f) After stripping off the polymer the structure is ready for the next cycle. (After Bowden and Turner, 1988.)

is obtained. In either case, the development produces uncovered areas on the wafer (e) that allow for a structured etching or diffusion processing of the substrate. After the removal of the resist [the stripping (f)], the final three-dimensional replication of the two-dimensional mask pattern in the wafer surface is obtained.

This scheme of the processing steps is sufficient to appreciate some of the basic unique properties that are required of a resist material (Bowden, 1988):

1. It must be capable of being uniformly deposited as a thin (0.5–2 μm) film across the wafer of up to 8 in. (20.3 cm) in diameter.
2. It must be sensitive to different types of radiation (uv, DUV, x-ray, electron beam) and must, upon exposure, undergo a chemical change inducing a change in some physical property of the materials, e.g., a solubility change, that enables exposed and unexposed areas to be differentiated by an appropriate developing scheme.
3. It must adhere to a variety of substrates and withstand the various etching environments encountered in integrated-circuit (IC) processing, including high temperatures, corrosive etching chemicals, etc.
4. A most important requirement is the high resist resolution. The current IC mass production uses 0.8-μm lines, 0.5 μm are in the development stage, and the 64-Mb (megabit) DRAM (dynamic random-access memories), scheduled for 1995, require 0.35-μm structures to be fabricated.

The basic physical/optical limitations encountered in the image-generation process during exposure are related to the diffraction limit of the projection tools used in photolithography [or to image degradation by (secondary) scattering processes in the resist in electron-beam lithography]. This has led to the development of polymeric resist materials for the use of shorter wavelengths in DUV lithography or even synchrotron radiation in x-ray lithography. On the materials side, this has far-reaching consequences as to the strategies for converting the latent image into a surface-relief structure by the development step. In cases where the exposing radiation has not enough energy to rupture bonds directly (e.g., at the wavelengths encountered in traditional lithography: e.g., with the so-called *g* line at $\lambda = 436$ nm and the *i* line at $\lambda = 365$ nm), differential solubility schemes based on polarity changes in the matrix resulting from polarity changes of the sensitizer have been developed. This principle is used in the NOVOLAC-based photoresists. For lithography with radiation that has sufficient energy to break bonds, the mere change in molecular weight of the polymer matrix could be enough for a solubility differentiation.

1.4.1 The NOVOLAC/Diazonaphthoquinone Resist Today, all submicron imaging in photolithography is done with positive photoresist. These materials are two-component systems based on diazonaphthoquinone-sensitized NOVOLAC resins. The dissolution changes are caused by chemical modifications in the sensitizer that cause polarity changes in the irradiated matrix rendering the NOVOLAC soluble in aqueous base. This scheme is shown in Fig. 6. The system contains a cresol-formaldehyde NOVOLAC resin as the matrix material. Photosensitivity is given to the polymer by addition of diazonaphthoquinone, which undergoes photolysis to produce a ketene intermediate that rapidly reacts with the water in the resin to yield an indenecarboxylic acid. While the pristine lipophilic diazonaphthoquinone serves as a dissolution inhibitor reducing the solubility of NOVOLAC films in aqueous base, the final acidic photoproduct renders the film soluble. Hence, this system functions as a positive resist. Because the polarity of the unexposed resist is unchanged, resolution of the pattern is not limited by swelling of the unexposed areas as was the case for the older resists based on bisazide–rubber formulations. Many modifications to this basic mechanism have been developed to improve the resist performance further: These include image reversal, contrast enhancement by bilayer or multilayer resist preparations, etc. (Willson and Bowden, 1988).

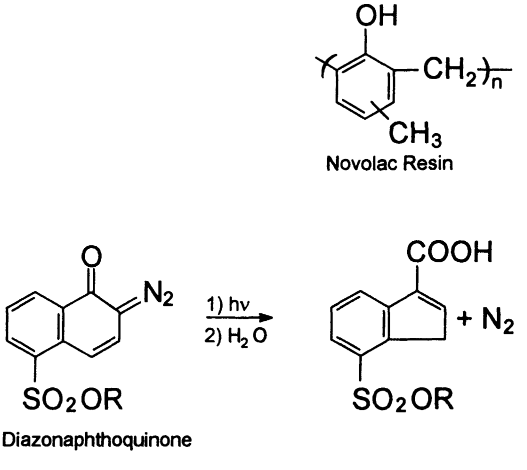

FIG. 6. The two-component photoresist based on a NOVOLAC matrix and a diazonaphtoquinone sensitizer.

1.4.2 Deep-UV Resists The usual exposure wavelength for diazonaphthoquinone systems is λ = 405–436 nm. Materials designed for an effective exposure in the mid-uv (300–350 nm)—e.g., polysilanes—have proven to increase the resolution needed for the continuous trend toward higher device integration. A selection of DUV materials is listed in Table 3. Only positive-tone resists are given. Another important feature of these systems is their organosilicon content. In an oxygen plasma used for reactive ion etching (RIE), these silicon moieties are converted to silicon dioxide at the surface of the resist, acting there as a passivation layer that protects the underlying polymer against further erosion.

Another system recently reported by Przybilla and co-workers (1992) for use in DUV lithography with KrF eximer lasers at λ = 248 nm is given in Fig. 7. Based on a partial replacement of hydroxystyrene with 2-hydroxy-hexafluoroisopropylstyrene, a resist material is obtained that is highly transparent, dry-etch resistant, and alkali soluble. By the addition of photoreactive inhibitors, a photolithographic polymer is obtained that allows for the fabrication of narrow lines of sizes far into the submicron range. An example is given in Fig. 8.

1.4.3 X-ray (Synchrotron) Resists Synchrotron radiation, i.e., the relativistic emission of light from electrons that propagate in a storage ring nearly with the speed of light, is the ultimate light source also for lithographic applications (Heuberger, 1988). Consequently, active research is conducted worldwide on materials that could be used for x-ray lithography in the wavelength range of 0.1 to 5 nm. The 1:1 projection technique with a mask–wafer separation of typically 50 μm allows for the fabrication of structures with less than 0.1-μm linewidths. Exposure times of only a few seconds have been shown to be enough to produce structures with aspect ratios >20:1 (height:width), not limited by diffraction, interference, or focal depth and independent of substrate layers or wafer topography.

2. POLYMERS IN SPECIAL CONFIGURATIONS

The foregoing discussion was focused on polymers where the bulk optical properties were of interest, specifically tailored for se-

lected applications. In this section, we concentrate on optical properties of polymers prepared in a very special configuration, where this configuration and the fabrication protocol are integral aspects of their optical properties.

2.1 Ultrathin Films

Ultrathin polymer films, in the extreme case only one molecular layer thick, are of special interest from an applied point of view for all kinds of surface modifications, be it for lubrication, isolation, adhesion, or any other possible purpose, and provide a special challenge for the experimentalist who has to develop methods that are sensitive enough to allow for an optical characterization of coatings only a few nanometers in thickness.

One example is provided by so-called Langmuir monolayers (Langmuir, 1917). Molecules like soaps, lipids, etc., can be prepared as monomolecular films at a water–air interface. Driven by the reduction of the surface free energy of water, these molecules spread across the surface when applied, e.g., from a volatile solvent. After compression these monolayers can be transferred to a solid support by dipping and withdrawing a suitable substrate through this highly organized film at the water–air interface. Thus, multilayer assemblies with a precise control of their thickness can be obtained, as is schematically sketched in Fig. 9. First reported by Blodgett (1935), this technique has

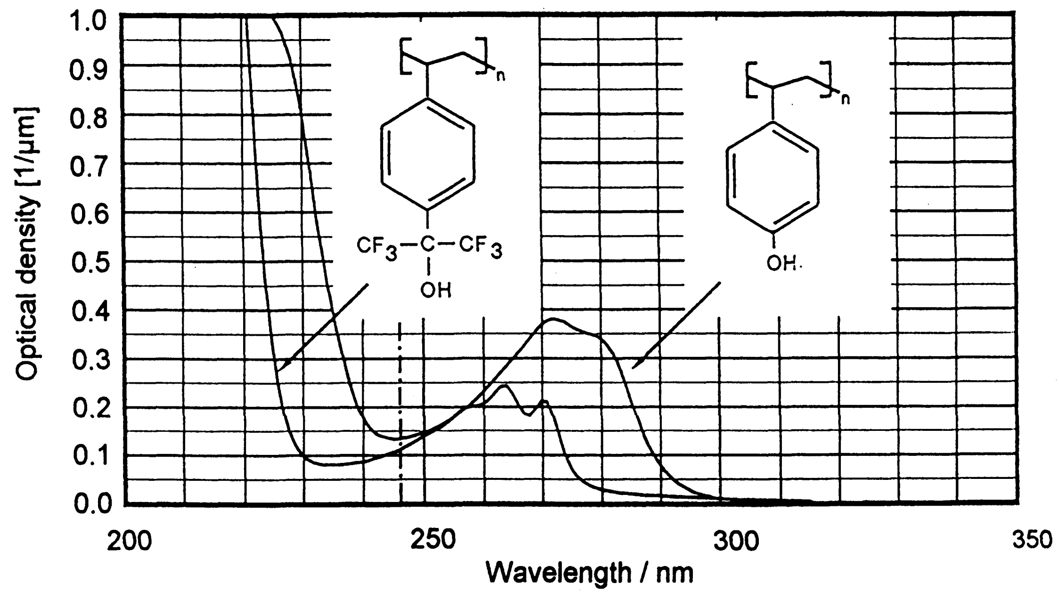

FIG. 7. Comparison of UV spectra of poly[4-(2-hydroxy-hexafluoroisopropyl)styrene] and poly(4-hydroxystyrene). Film thickness 1 mm on a quartz wafer. (After Przybilla *et al.*, 1992.)

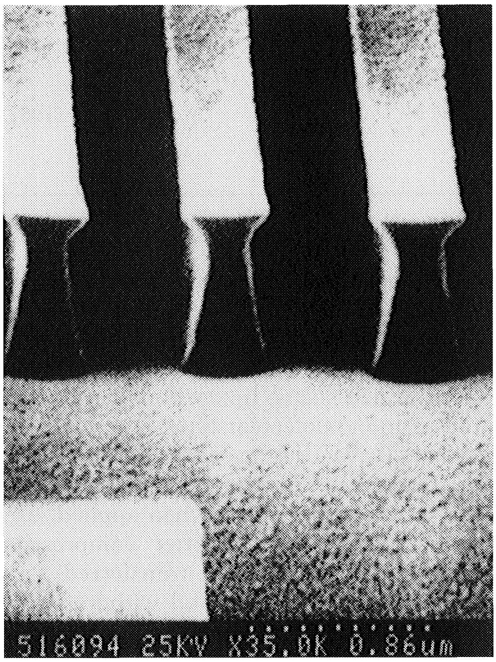

FIG. 8. 0.5-μm line and space structures obtained with dissolution-inhibition type photoresist material based on a modified polystyrene (cf. Fig. 7). Exposure at λ = 248 nm. (After Przybilla *et al.*, 1992.)

regained a worldwide interest as an excellent tool for the buildup of supramolecular architectures (Roberts, 1990) with tailor-made molecules ever since the pioneering work of Kuhn and co-workers (1972). These systems are therefore called Langmuir–Blodgett–Kuhn (LBK) layers.

Various techniques have been developed in recent years sensitive enough to allow for

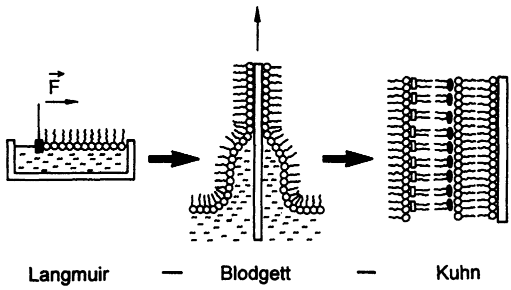

FIG. 9. Schematic representation of the Langmuir–Blodgett–Kuhn technique: The Langmuir monolayer prepared at the water–air interface at a selected surface pressure is transferred during the withdrawal of the solid substrate. Supramolecular architectures can be built up by choosing different functional units in the individual layers.

a quantitative evaluation of the optical properties of these ultrathin coatings (Swalen, 1986). One group of techniques uses evanescent waves and, in particular, surface plasmons as highly specific and sensitive interfacial light probes (Knoll, 1991a, b).

One way of introducing surface plasmons [plasmon-surface polaritons (Burstein *et al.*, 1974; Raether, 1977) or PSPs], especially in the experimental setup called the Kretschmann configuration (Kretschmann, 1972) (see Fig. 10, top), is to note that the nearly free-electron gas in the thin (≈50 nm) metal film evaporated onto the base of the prism acts as an oscillator that can be driven by the electromagnetic wave impinging upon that interface at total internal reflection conditions. Therefore, we are dealing with the resonant excitation of a coupled state between the plasma oscillations and the photons, i.e., the "plasmon–surface polaritons" (Raether, 1988). This resonance phenomenon can be clearly seen in the ATR scan (attenuated total reflection; see bottom half of Fig. 10): Below θ_c the reflectivity is very high because the metal film acts as a mirror with little transmission. Above θ_c for total internal reflection, however, a relatively narrow dip in the reflectivity curve at θ_0 indicates the resonant excitation of such a PSP wave at the metal–air interface. The coupling angle is given by the energy- and momentum-matching condition between photons and surface plasmons:

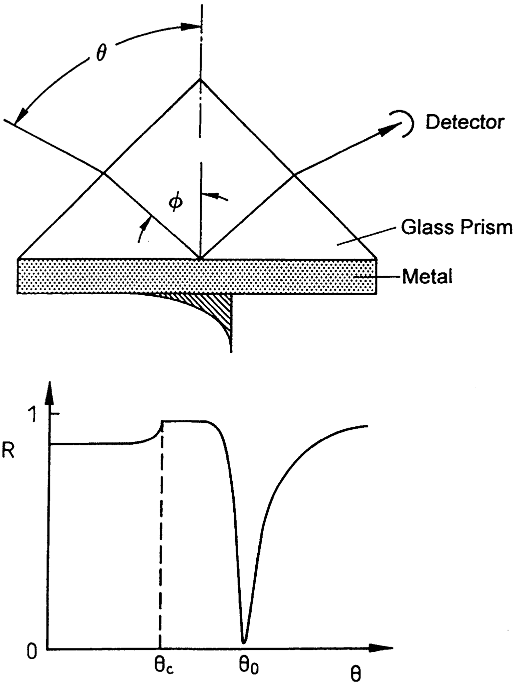

FIG. 10. ATR setup for the excitation of surface plasmons (PSPs) in Kretschmann geometry: (Top) A thin metal film ($d \sim 50$ nm) is evaporated onto the base of the prism and acts as a resonator driven by the photon field. (Bottom) The reflectivity R is recorded by a detector as a function of the angle of incidence and shows the increase to unity at θ_c, the critical angle for total reflection. The resonant excitation of the PSP wave is seen in the reflectivity curve as a sharp dip at coupling angle θ_0.

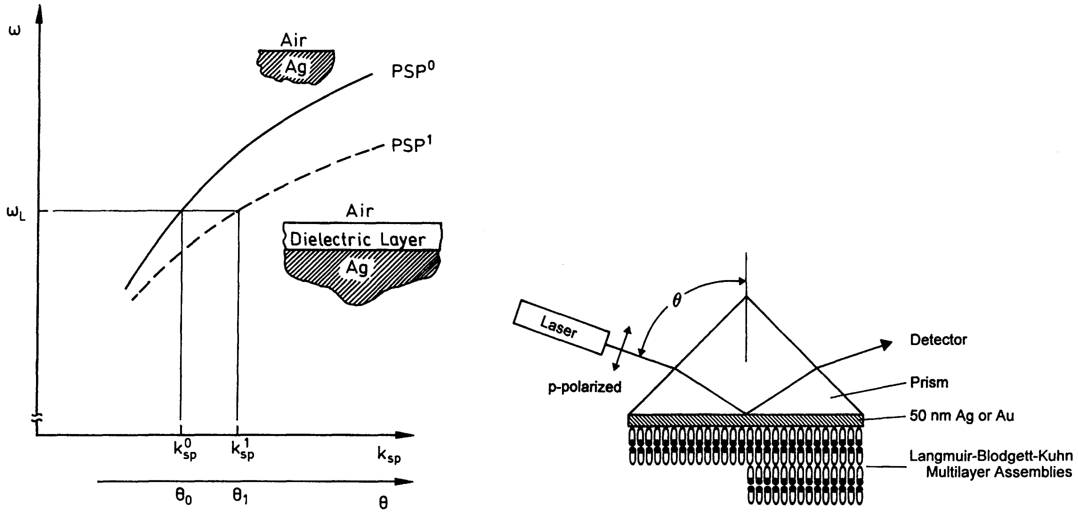
$$k_{sp}^0 = k_{ph}^0 = n_1(\omega/c)\sin\phi_0, \tag{3}$$

with k_{ph}^0 being the parallel component of the photon wave vector, ω the photon energy, c the speed of light, and ϕ_0 the (internal) coupling angle (see Fig. 10). Since we are dealing with an evanescent wave propagating along the interface, the penetration depth into air is only of the order of the wavelength. The resonance character of this excitation gives rise to an enhancement of the field E at the interface by more than a factor of 10, which is the origin of the remarkable sensitivity enhancements obtainable, e.g., in Raman spectroscopy when working with PSP light (Ushioda and Sasaki, 1983; Knobloch *et al.*, 1989). These modes obey a known dispersion relation, ω vs k_{sp}, so that each photon of energy $\hbar\omega_L$ allows for the excitation of exactly one PSP mode. This is schematically depicted in Fig. 11(a). The solid curve represents the dispersion of the surface plasmons at a metal [e.g., Ag—air interface (PSP^0)]. The horizontal line at ω_L intersects the dispersion curve at k_{sp}^0 and thus defines the coupling angle θ_0. The typical experimental setup is schematically given in Fig. 11(b). *P*-polarized photons from a laser excite PSP at the base of the prism, which is first covered with the thin metal layer by evaporation and then coated, e.g., by LBK layers of increasing thickness. The reflected intensity is monitored as a function of the angle of incidence by a photodiode. The thin dielectric coating causes a shift of the dispersion curve (PSP) to higher momentum:

$$k_{sp}^1 = k_{sp}^0 + \Delta k_{sp}, \tag{4}$$

which, according to Eq. (3), shifts the reso-



(a) (b)

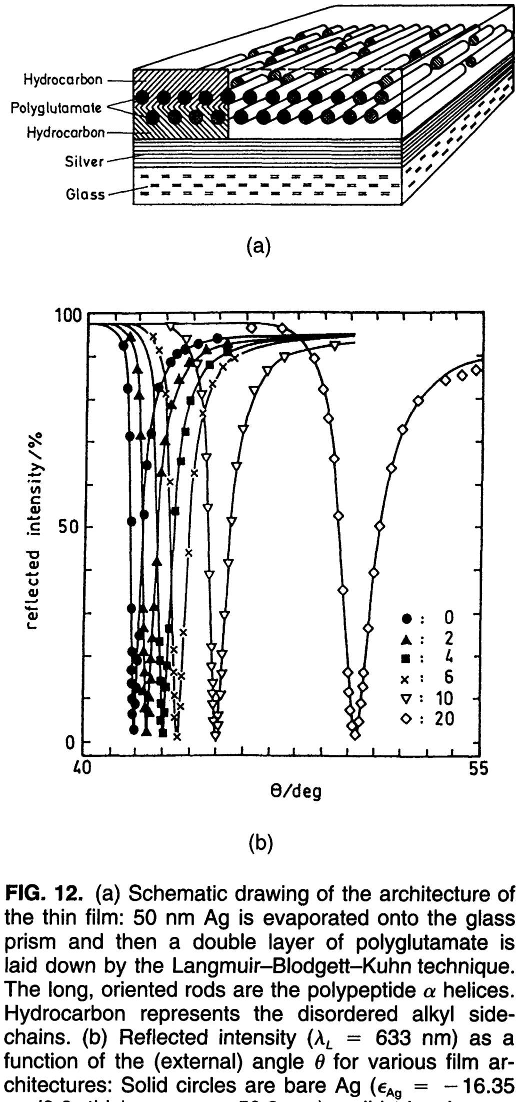
FIG. 11. (a) Dispersion relation, ω vs k_{sp}, of plasmon–surface polaritons at a Ag–air (PSP^0, solid line) and at a Ag–dielectric coating–air interface (PSP^1, broken line), respectively. Laser light of energy ω_L couples at angles θ_0 and θ_1, respectively, given by the energy- and momentum-matching condition (see the intersection of the horizontal line at ω_L with the two dispersion curves). (b) Schematic of the experimental setup for surface-plasmon spectroscopy.

nance to a higher angle θ_1. From this shift and Fresnel's equations, one can calculate the optical thickness of the coating (Gordon and Swalen, 1977). This is demonstrated quantitatively for LBK multilayer assemblies prepared from polyglutamate monolayers. A schematic drawing of a transferred double layer is presented in Fig. 12(a). It shows the quasi two-dimensional nematic structure of these "hairy rods"—stiff polyglutamate helices with long, flexible alkyl side chains (Duda *et al.*, 1988).

Figure 12(b) gives the results of ATR scans obtained from the bare metal and 2, 4, 6, 10, and 20 layers of polyglutamate, respectively (Hickel *et al.*, 1990). The symbols are the experimental data points, the solid lines Fresnel calculations. All these layer preparations can be described by a constant index of refraction $n_z = 1.486$, and the multiple of a constant thickness per monolayer of $d_0 = 1.75$ nm.

The sensitivity of this technique to extremely small refractive-index changes is demonstrated in Fig. 13(a). Given is the angular scan (full circles) of the PSP resonance found for a sample consisting of Ag, 8 layers of polyglutamate, and 6 layers of an azobenzene-derivatized (and hence photoreactive) liquid-crystalline polyacrylate (structural formula is given in the inset) that could be processed by the LBK technique (Sawodny *et al.*, 1992). The spacer layers were necessary in order to decouple (electronically) the azobenzene chromophores from the metallic acceptor states in the substrate. Illuminating the sample with uv light ($\lambda = 360 \pm 30$ nm) shifts the dark-adapted all-*trans* chromophores through *trans–cis* isomerization to a new photostationary equilibrium with a high *cis*-isomer content. As a result, the optical refractive-index anisotropy is changed and the index normal to the layers is reduced. This shifts the surface-plasmon resonance to smaller angles—the LBK multilayer is now optically thinner [open triangles in Fig. 13(a)].

If this change of the optical thickness is followed on line (during illumination) by recording the reflected intensity at a fixed angle of incidence [e.g., $\theta = 47.2°$, cf. Fig. 13(a)], a kinetic analysis of the refractive-index changes can give information as to the reaction rates, the equilibrium changes, the reversibility, etc. The latter important aspect is shown in Fig. 13(b). The first rapid decrease of n_z upon uv illumination can be partly restored by switching to visible light (λ = 450



(a)

(b)

FIG. 12. (a) Schematic drawing of the architecture of the thin film: 50 nm Ag is evaporated onto the glass prism and then a double layer of polyglutamate is laid down by the Langmuir–Blodgett–Kuhn technique. The long, oriented rods are the polypeptide α helices. Hydrocarbon represents the disordered alkyl side-chains. (b) Reflected intensity (λ_L = 633 nm) as a function of the (external) angle θ for various film architectures: Solid circles are bare Ag ($\epsilon_{Ag} = -16.35 + i0.6$, thickness s = 50.8 nm); solid triangles are two layers of polyglutamate on top; solid squares = 4; crosses = 6; open triangles = 10; and diamonds = 20 layers. Solid lines are Fresnel calculations.

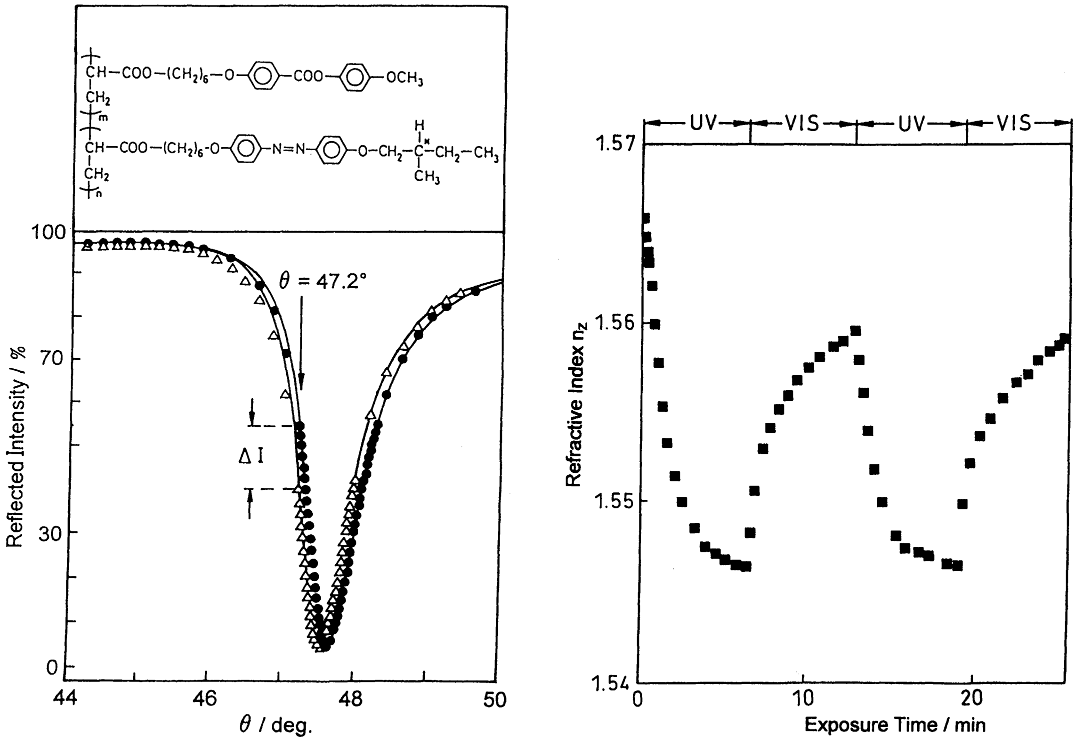
± 30 nm), which isomerizes the azobenzenes back into the *trans* state. These reaction cycles can be conducted many times. It is important to note that, given the signal-to-noise level of these data, index changes as small as Δn_z = 0.0001 can be monitored in reactive layers that are only 15 nm thick!

2.2 Integrated Optics

Since the concept of "integrated optics" emerged in the late 1960s, a significant growth of the areas of optical communication, signal processing, etc. has stimulated a major research and development effort in the field of organic and polymeric materials aimed at optimizing their functional properties by molecular design and synthesis (Stegeman *et al.*, 1987; Prasad and Williams, 1991; Messier *et al.*, 1989). This concerns not only their nonlinear optical properties [i.e., primarily their second- and third-order hyperpolarizabilities (see Sec. 3)] but also their linear optical response to light and, equally important, also other chemical and physical properties of the material and processing parameters like stability (against chemical attack, temperature, light, aging, delamination, etc.), ease of preparation (compatible with technologies developed for microelectronic device fabrication), cost effectiveness, and others.

One very crucial requirement of a material for the envisaged integrated-optics application is that it can be prepared as a structure capable of guiding light waves with acceptable losses. The three corresponding basic configurations (Lee, 1986; Chang, 1991) are schematically depicted in Fig. 14: 14(a), the planar-waveguide structure given in the so-called asymmetric-slab configuration with a solid substrate and air as superstrate; 14(b), the various channel waveguides (strip, embedded strip, and buried strip, from top to bottom) prepared by starting in some cases with a planar waveguide and then further structuring and etching the sample; and 14(c), the optical fiber with a high-index core and a lower-index cladding. Such waveguide structures are discussed in the literature not only with respect to their role as passive interconnects between different integrated optical-circuit (IOC) components but also in the context of various design concepts for active IOC modules like directional couplers, phase and amplitude modulators, second-harmonic generators for laser diodes, etc. (Stegeman and Stolen, 1989).

In this section, we limit the discussion to the case of a planar waveguide structure, but the general ideas allow for a straightforward extrapolation to more complicated designs. After a short presentation of various schemes for coupling plane electromagnetic waves (e.g., photons from a laser) into such structures, we give a few examples for waveguides fabricated from novel polymeric materials



(a) (b)

FIG. 13. (a) Reflected intensity as a function of the angle of incidence for a sample consisting of Ag–8 layers polyglutamate–6 layers of the photoreactive liquid-crystalline polymer given in the inset; full circles, layers as prepared (in the dark-adapted *trans* state); open triangles, after illumination of the layers with UV light (λ = 360 nm) for 10 min. Full curves are Fresnel-fit calculations. (b) Refractive-index change as obtained by recording the intensity reflected from the same sample at a fixed angle of incidence [θ = 47.2°, cf. (a)] while first illuminating with uv light, then after 6 min switching to visible light (VIS), and so on.

with promising optical properties that can be tailored to some extent for future device applications.

2.2.1 Planar Waveguide Structures

We consider the asymmetric-slab configuration. Within Maxwell's theory it is then rather straightforward to arrive for the nonabsorbing case considered here at the well-known eigenvalue equation for waveguide modes of order m (Tien, 1969):

$$k_{2z}d = \tan^{-1}\beta_{21} + \tan^{-1}\beta_{23} + m\pi, \quad (5)$$

with k_{2z} being the wave vector of the mode of order m, d the thickness of the waveguide structure, and $2\beta_{ij} = r''_{ij}/r'_{ij}$ with $r_{ij} = r'_{ij} + ir''_{ij}$ the complex reflection coefficient at the interface between media i and j. For a given set of materials and hence combination of refractive indices (which determines $\tan^{-1}\beta_{21}$ and $\tan^{-1}\beta_{23}$ for a fixed frequency), the number of eigenmodes depends only on the thickness of the waveguide layer.

The detailed analysis of Maxwell's equations can yield the optical-field distribution for each eigenmode (Tamir, 1979). Figure 15 shows the optical-field distributions for the first three modes (with their electric field being parallel to the film along the y axis) calculated with the following indices of refraction: substrate n_3 = 1.46, waveguide film n_2 = 1.55, cladding (air) n_1 = 1. Note that the optical field extends as an evanescent wave into both the cladding and the substrate, where it decays exponentially as a function of distance from the interface, though for this asymmetric slab in an asymmetric way.

The three most important techniques for coupling light into this waveguide are sche-

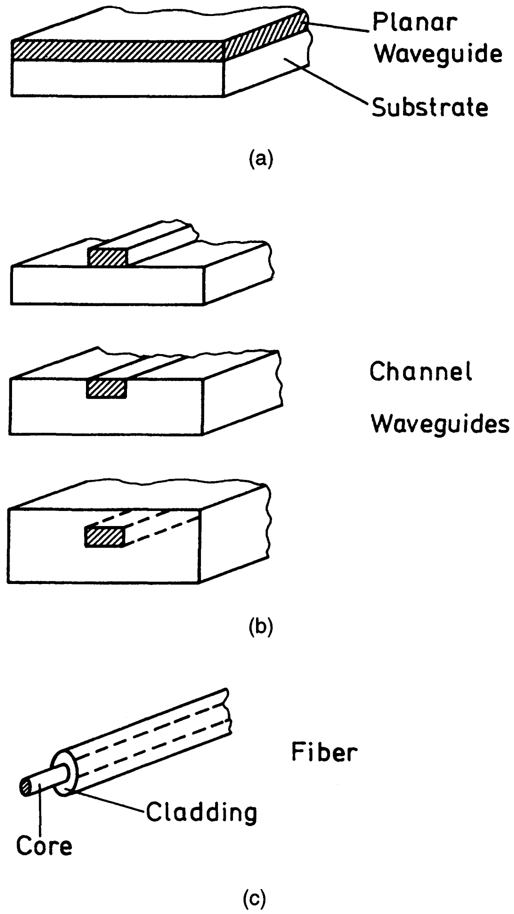


FIG. 14. Basic waveguide structures. (a) Planar waveguide (shaded) on a substrate. (b) Channel waveguides: (top to bottom) strip, embedded strip, buried strip. (c) Optical fiber with the core and the cladding of lower refractive index.

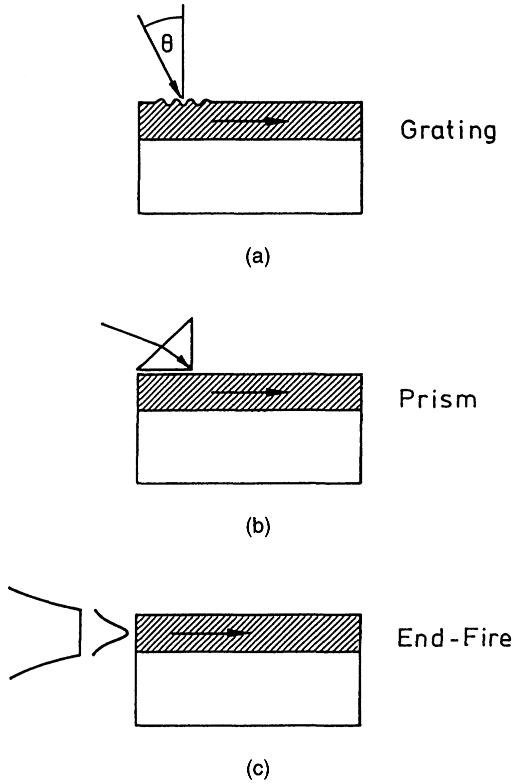

FIG. 16. The three basic coupling geometries. (a) Grating coupling, (b) prism coupling, both of which require the tuning of the angle of incidence, θ; (c) end-fire coupling, e.g., by a microscope objective.

matically sketched in Fig. 16. The grating [16(a)] and prism coupling methods [16(b)] are commonly used for planar waveguides. Efficient coupling can be achieved only under wave-vector matching conditions. For grating coupling, this requires that the photon wave-vector component parallel to the surface plus or minus a multiple of the grating vector $G = 2\pi/\Lambda$, with Λ the groove spacing of the grating, matches the waveguide propagation vector:

$$k_x^m = k_0 n_1 \sin\theta \pm mG. \tag{6}$$

In the case of prism coupling, the projection of the photon wave vector at the base of the prism must be equal to the guided wave vector:

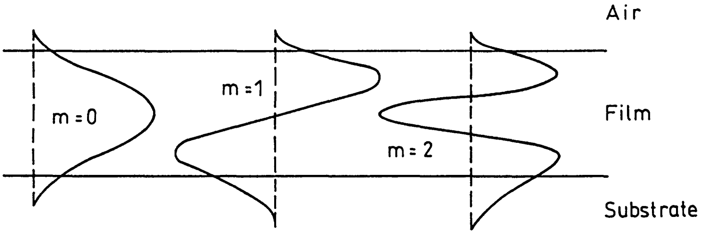

FIG. 15. Optical-field distribution in a planar waveguide structure of substrate–film–air configuration for the first three *s*-polarized modes ($m = 0,1,2$). The higher index of the substrate ($n_3 = 1.46$) compared with the superstrate (air, $n_1 = 1.0$) is the reason for the much stronger evanescent field penetrating into the substrate material.

$$k_x^m = k_0 n_p \sin\theta, \tag{7}$$

with n_p = index of refraction of the prism. This requires a prism with an index higher than the waveguide material.

The end-fire coupling (e.g., from a microscope objective to a channel waveguide) matches the incident-field spatial distribution to that of the guided wave [Fig. 16(c)].

2.2.2 Waveguides from Novel Polymeric Materials For the examples presented in the following, a modified prism-coupling technique as schematically depicted in Fig. 17(a) was used. The waveguide modes were launched with the help of a high-index prism by coupling through a metal (Au or Ag) gap of 50 nm thickness excited with p-polarized light. In this geometry, the $m = 0$ mode is the surface plasmon. Its optical intensity peaks at the metal–waveguide interface and decays (for films of typical waveguide thicknesses of ca. 1 μm or more) completely within the film. Its polarization is predominantly parallel to the film normal. Its angular position, therefore, depends only on n_z but not on the waveguide thickness. The other waveguide modes can be excited with either s- or p-polarized light and will, in general, depend on all three indices, i.e., n_x, n_y, and n_z, as well as on the film thickness [cf. Eq. (5)]. Figure 17(b) shows a series of waveguide modes obtained with p-polarized excitation of $\lambda = 633$ nm in a spin-cast film of a solid polyelectrolyte the structure formula of which is given in the inset. The various modes were measured in reflection. The broad dip in the reflected intensity at the high-angle side ($\theta \simeq 73°$) marks the surface plasmon. The crosses are the experimental data points; the full line (for better clarity somewhat shifted) is a theoretical fit based on a Fesnel calculation (Wolter, 1956). From this one obtains the thickness of the waveguide film $d = 1.85$ μm as well as its (isotropic) index of refraction $n = 1.63$. By recording the reflectivity as a function of the angle of incidence for s-polarized light (not shown), it was found that an isotropic approximation of the refractive index was sufficient in order to characterize the whole waveguide mode pattern.

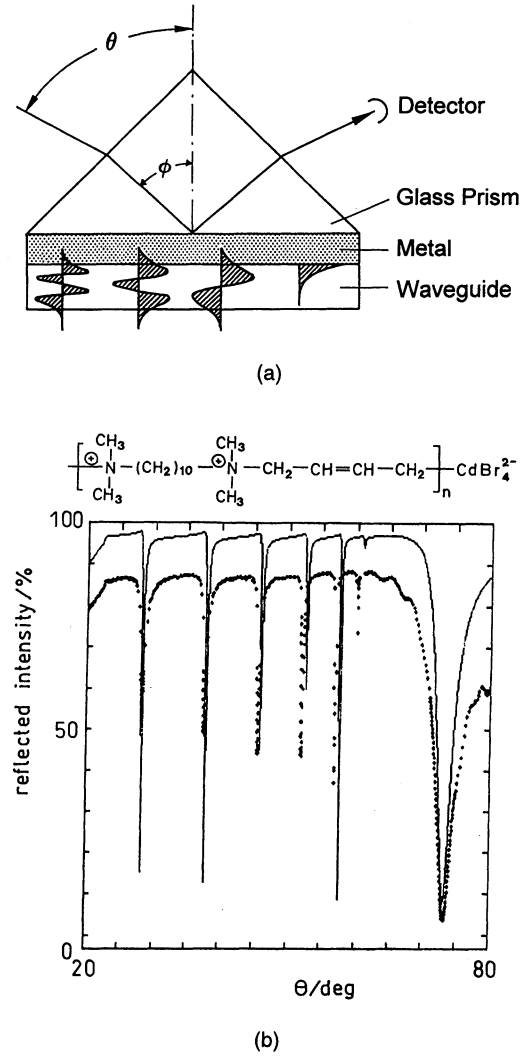

FIG. 17. (a) Attenuated total reflection setup for coupling surface-plasmon as well as waveguide modes into a planar film structure. Coupling is achieved through a thin metal gap at the base of the prism. (b) Reflected intensity recorded as a function of the angle of incidence for a thin film of a solid polyelectrolyte (structure formula given on top) spin-cast onto the Ag-coated (s = 50 nm) base of a high-index prism (SF57) as in (a). The crosses are the experimental data points, the full curve is the theoretical fit. Excitation with p-polarized light from a HeNe laser (λ = 633 nm).

Nevertheless, a closer comparison between the experimental and the theoretical curves of the angular reflectivity shows some distinct differences. First of all, the experimental modes are somewhat broader than calculated with an ideal slab geometry for the waveguiding film. This indicates some thickness and lateral refractive-index heterogeneities within the spin-cast film. In addition, not all calculated angular positions for the various modes fully coincide with the experimental ones. Given the different field-intensity distributions of the different modes (cf. Fig. 15), this discrepancy points to a certain perpendicular refractive-index variation (an index profile) within the waveguide. Both deviations from ideality within the phase and normal to the plane need to be carefully avoided in an IOC structure because such heterogeneities clearly would limit the optimum performance of the device.

2.2.3 Waveguide Loss Measurements

Typically, waveguides are designed to propagate light over long distances. This requires, first of all, the absence of any absorptive losses, either by molecular, electronic, or vibronic transitions or by dissipation, e.g., in metallic materials used as electrodes. Equally important is the control of any scattering losses, which would also result in an enhanced damping of the guided modes. This not only includes the minimization of bulk (volume) fluctuations of the optical density but requires also the ultimate control of surface-scattering processes, e.g., at interfacial roughness caused by processing steps.

One way of characterizing waveguide structures along these lines is to measure the losses of the guided waves directly. Figure 18(a) shows a schematic of an experimental setup designed for loss measurements in planar structures. Laser light is coupled to the waveguide by a grating (or prism). A coherent fiber bundle is used to transmit the light scattered off the guided streak in the planar structure, which is a measure of the local mode intensity. A photomultiplier tube with a slit diaphragm reads this scattered intensity with high spatial resolution and hence allows for the quantitative analysis of the (exponentially) attenuated optical field in the waveguide. A data-acquisition and analysis system gives the loss values typically in dB/cm (1 dB corresponds to an intensity attenuation to 79%).

Figure 18(b) gives the results obtained from a polyelectrolyte thin film prepared by spin-coating onto a low-index glass substrate, measured in air with prism coupling. Data points taken from Mathy *et al.* (1991) were measured with different laser lines and plotted correspondingly as a function of the wavelength employed. Two aspects are noteworthy:

1. For most of the wavelength range investigated, the data seem to follow a λ^{-4} power law [straight line in Fig. 18(b)], which suggests Rayleigh scattering as the predominant attenuation mechanism.
2. For wavelengths $\lambda \geq 650$ nm, losses in the range of 1 dB/cm or less seem to be feasible with these materials, which makes them also technologically interesting.

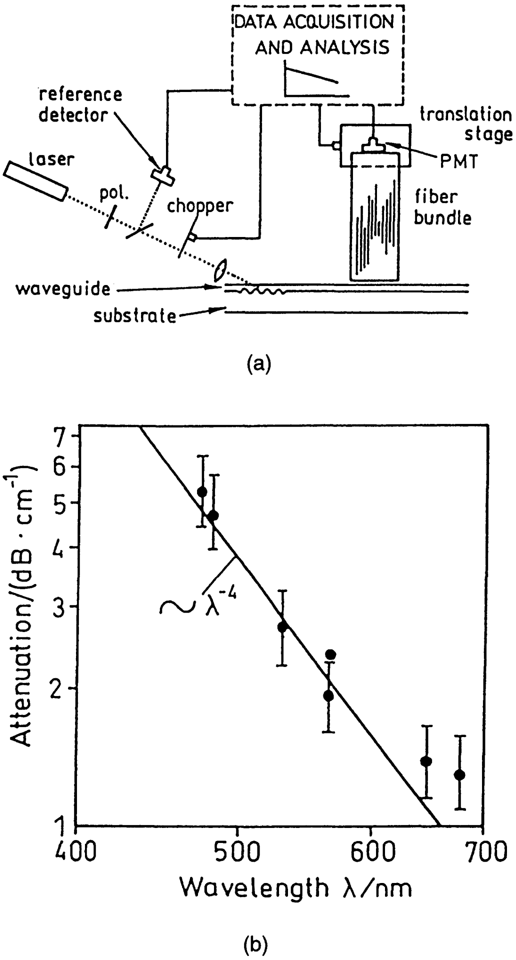

FIG. 18. (a) Schematic of the setup used for the determination of mode losses in waveguide structures. Laser light is coupled to the planar waveguide by means of a grating or prism. A fiber bundle records the local level of stray light, which is a measure of the field intensity along the guided streak. (b) Loss data for *s*-polarized (m = 0) modes (given as attenuation in dB/cm) for various wavelengths as obtained for a planar waveguide structure fabricated by spin-casting a solid polyelectrolyte. The straight line is a λ^{-4} power law. Data from Mathy *et al.* (1991).

2.2.4 Supramolecular Design of Waveguide Films by the Langmuir–Blodgett–Kuhn Technique Finally, we should briefly discuss possibilities for the ultimate control of a planar waveguide structure at the molecular level as is in principle possible by the LBK method. Here, multilayer assemblies capable of carrying guided modes are built up, layer by layer, by dipping and withdrawing a substrate many times through a monomolecular layer prepared at the water–air interface (Swalen *et al.*, 1978). The number of possible molecular structures of the individual layers is nearly infinite, and so are the functionalities that can be tailored into these systems. Even if it is unlikely that the tedious preparation process ever will make it into a large-scale production line, these LBK films nevertheless are extremely helpful as model systems to develop and test molecular structural concepts, functional units (like nonlinear chromophores, etc.), supramolecular assemblies, and device configurations.

As an example for a simple passive planar waveguide structure prepared by this LBK technique, we present in Fig. 19 results obtained with a multilayer assembly of the polyglutamates previously presented. Figure 19 demonstrates the good optical quality of a thick multilayer assembly (150 layers) capable of guiding modes with different polarizations; the upper frame was taken with *p*-polarized light, while the lower frame shows data with *s* polarization. The full circles are experimental points measured with waveguide modes propagating perpendicularly to the dipping direction, the crosses are for parallel propagation. The full lines are Fresnel fits and show the excellent theoretical description of these structures as planar slabs. The optical in-plane anisotropy can be analyzed quantitatively and amounts to only $\Delta n = n_{\parallel} - n_{\perp} = 0.01$. This demonstrates the sensitivity of the coupling conditions to subtle refractive-index variations.

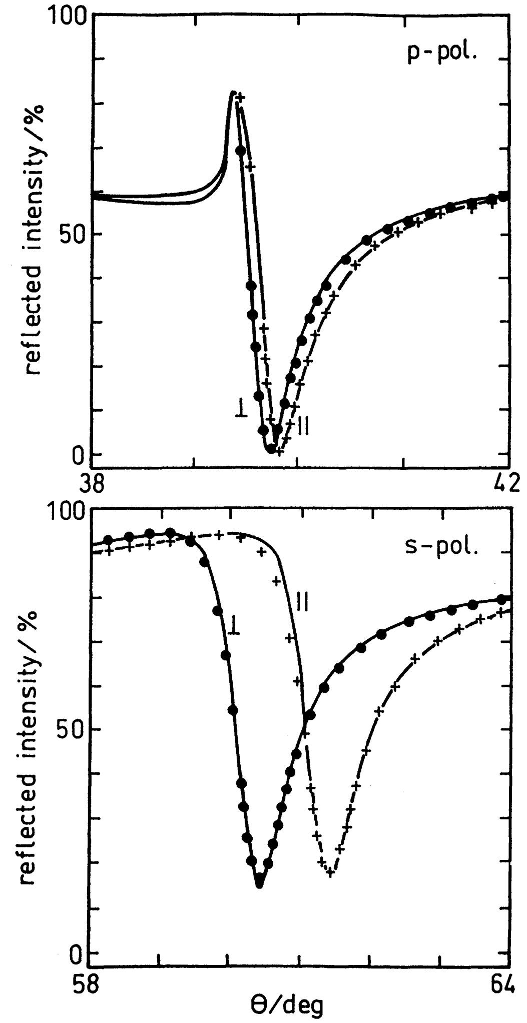

FIG. 19. Waveguide mode pattern as obtained from a polyglutamate multilayer assembly of 150 layers for (upper frame) *p*- and (lower frame) *s*-polarized light. Full circles are obtained for modes propagating perpendicular to the dipping direction, which is the preferred axis of the hairy rods. Crosses are from modes propagating parallel to the rods. The full curves are Fresnel calculations showing the corresponding in-plane anisotropy of the index of refraction.

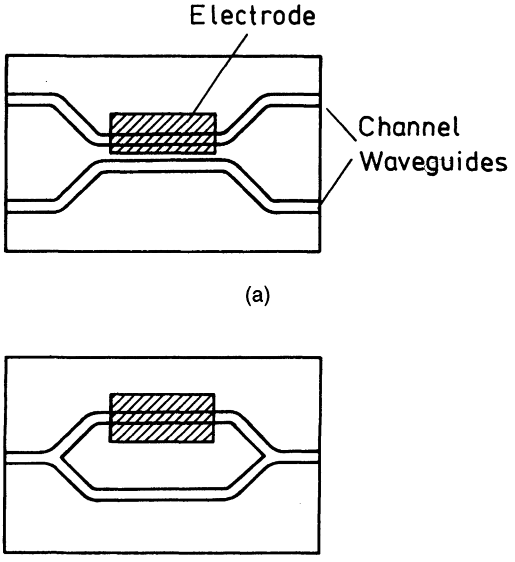
2.2.5 Channel Waveguides The theoretical description of guiding light in a two-dimensional waveguide structure [optical confinement in two dimensions like in the channel waveguides shown in Fig. 14(b)] adds nothing new, and just requires more complex numerical techniques for the calculation of the exact dispersion relation and hence the various modal structures. These channel waveguides are eventually the ultimate structures needed for any IOC. This includes, in particular, active devices based on materials with nonlinear optical effects. Two basic structures are shown in Fig. 20. The (electro-optical) coupler, in which two channel waveguides are sufficiently close that they can interact like two weakly coupled mechanical oscillators, is shown in (a). The



(a)

(b)

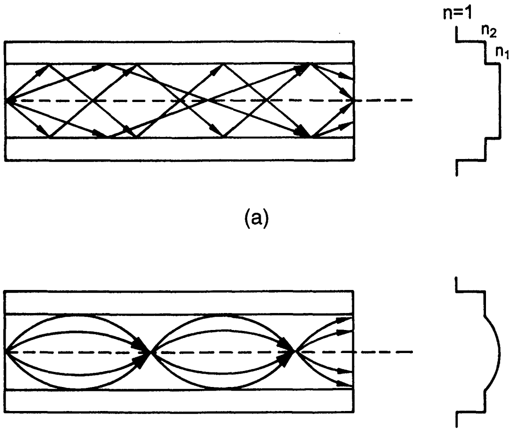
FIG. 20. Basic structures for integrated optical circuits (with special emphasis on electro-optical control): (a) channel waveguide coupler, (b) (integrated) Mach–Zehnder interferometer.

strength of the interaction that determines, e.g., the flow of light intensity from one channel to the other can be controlled by the application of a dc electric field through the Pockels effect provided the polymeric waveguide material has a correspondingly large second-order susceptibility $\chi^{(2)}$. The integrated Mach–Zehnder interferometer shown in (b) allows for a phase shift of the light in one branch relative to that propagating in the other channel. This then leads to constructive or destructive interference at the output. Again, this interaction can be controlled either by $\chi^{(2)}$-active materials through the application of an electrical field [electrodes are shown in Fig. 20(b)] or by a material with an intensity-dependent refractive index n_2 (see below).

2.2.6 Polymer Optical Fibers (POF)

Single-mode glass optical fibers are widely used as long-distance and high-bandwidth communication media because of their excellent transparency. In short-distance networks, however, where many junctions between different fibers are necessary, already slight displacements of two coupling cores each with a diameter of only about 5 μm would cause substantial coupling losses. Polymer optical fibers (POFs) with their considerably larger core diameter (ca. 1 mm) are in this respect much easier to handle. In addition, they offer other advantages like low cost, easy processing, and flexibility. However, all commercially available POFs have been of the step-index (SI) type [Fig. 21(a)]. For these multimode fibers, the different guided waves all travel with the same phase velocity but along different paths within the core, a phenomenon called modal dispersion. This is schematically depicted in Fig. 21(a). As a result of internal mode coupling, even a single input pulse [cf. Fig. 22(a)] is greatly distorted and considerably broadened. An example is given in Fig. 22(b). This means that two consecutive input pulses need to be separated in time in order to be resolved at the output as two individual pulses. The transmission bandwidth is thereby greatly reduced and currently amounts for SI-POF to ca. 5 MHz km.

A solution to this problem is the graded-index (GI) fiber. Here the refractive-index profile with the highest values in the center of the core results in a higher phase velocity of those "rays" traveling in the outer periphery of the core. Their longer pathways are therefore compensated by a faster propagation speed. As a consequence, the input pulse is far less broadened, which results in a higher bandwidth. An example that was re-



(a)

(b)

FIG. 21. Typical optical rays and refractive-index profile of (a) a multimode step-index (SI) fiber, and (b) a graded-index (GI) fiber.

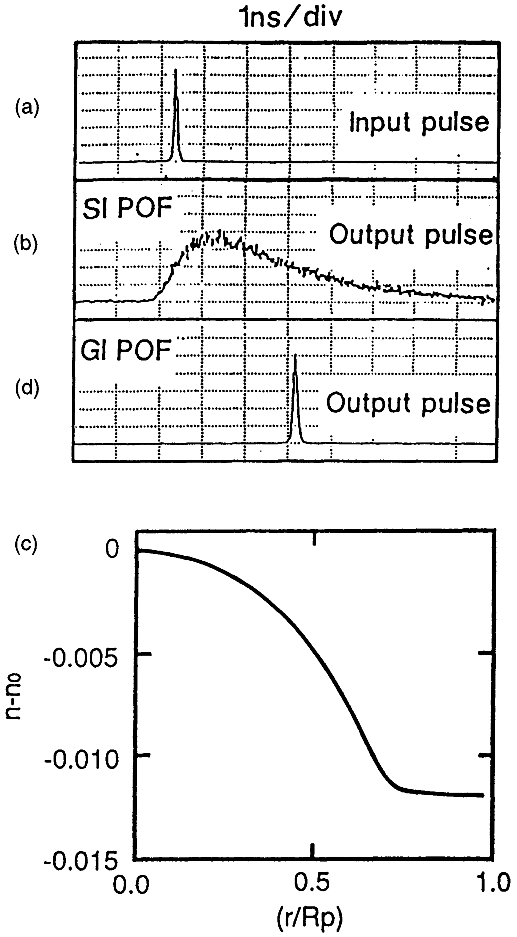


FIG. 22. (a) Short input pulse in a POF; (b) output pulse after traveling through a step-index fiber; (c) index profile of the graded-index fiber that transmits the input pulses nearly unbroadened as shown in (d). (After Ishigure *et al.*, 1992.)

cently reported for Gi-POFs prepared by a special copolymerization process (Koike, 1991) is given in Fig. 22: (c) shows the refractive index profile, (d) compares the input pulse with the output pulse. The bandwidth obtained was shown to be ca. 2 GHz km (Ishigure *et al.*, 1992).

Another improvement in the development of polymer optical fibers concerns the intrinsic losses given by absorption processes. This is indicated in Fig. 23 for a fiber made of poly(methylmethacrylate) (Groh *et al.*, 1989). The higher overtone vibrations of the C–H groups in the material are responsible for attenuation losses at $\lambda \approx 680$ nm of more than ca. 200 dB/km. Perdeuteration results in a substantial reduction of the band strengths but also in a shift of their spectral positions. Both effects reduce the loss in these fibers considerably (Fig. 23). Other attempts to reduce the absorption coefficient at relevant communication wavelengths successfully introduced fluorocarbon moieties in the material with the additional improvement of the maximum operating temperature. This is an important issue, e.g., for the implementation of POFs in automobiles (Groh *et al.*, 1989).

3. NONLINEAR OPTICAL PROPERTIES OF POLYMERS

Polymers with large nonlinear optical susceptibilities are likely to play a major role in the rapidly growing area of photonics. We concentrate in the following on some general fundamental device concepts, on materials design considerations, and on some polymer-specific issues relevant for nonlinear optics.

We first give a few remarks as to the functionalization of polymers for their use in nonlinear optical device configurations (Zyss, 1985). We then focus on some applications related to the second-order nonlinear optical susceptibility $\chi^{(2)}$ and finally summarize some third-order $\chi^{(3)}$ effects and how they could be implemented into future technologies for information processing.

3.1 General Concepts for the Functionalization of Polymers for Nonlinear Optics

The nonlinear optical response of polymers developed for future IOCs needs to be optimized through a suitable functionalization of the matrix by chromophores with correspondingly large second- or third-order susceptibilities. The two processes need, however, different strategies for an optimized material (Kajzar, 1992).

For the second-order processes, the relation between the macroscopic averaged (denoted by angular brackets) nonlinear susceptibility $\chi^{(2)}$ and the molecular nonlinear polarizability β_D is determined by the following equation (Williams, 1987; Singer *et al.*, 1987):

$$\langle \chi^{(2)} \rangle = f\beta_D N_D \langle \cos^3\vartheta \rangle, \qquad (8)$$

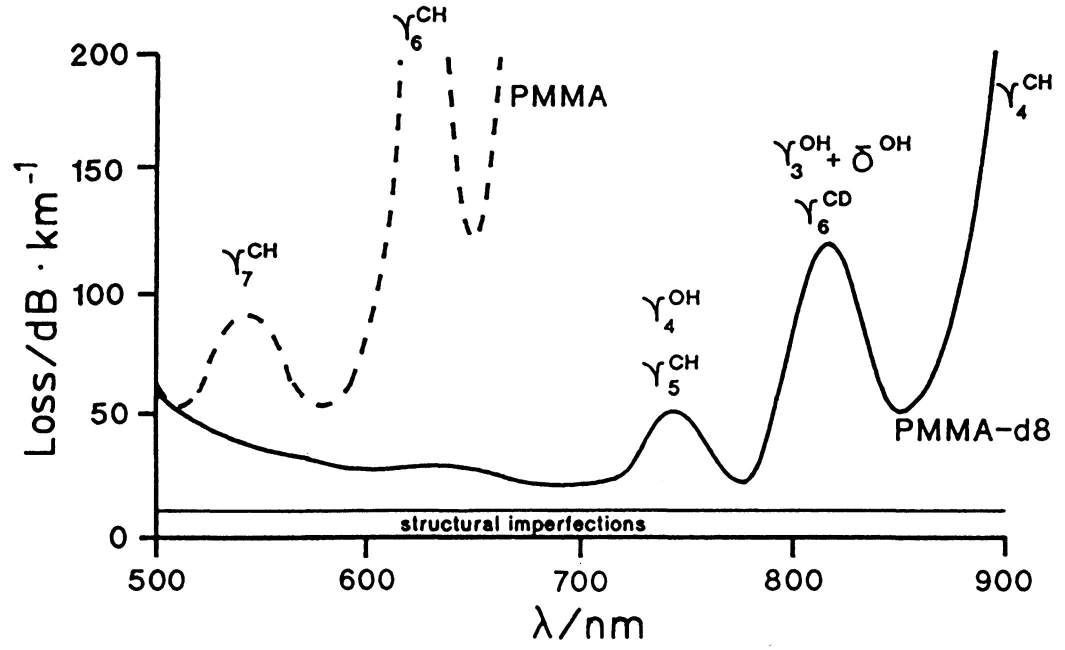

FIG. 23. Spectral-loss data for a regular PMMA POF (dashed curve) and for a fiber made from perdeuterated PMMA (full curve). Some vibrational band assignments are given. (After Groh *et al.*, 1989.)

where N_D is the density of the active molecules, f is a local-field factor of the optical field, and $\langle \cos^3 \vartheta \rangle$ is a measure of the order parameter describing the average orientational distribution of the chromphore's nonlinear optical axis relative to the applied field. Maximum $\chi^{(2)}$ is obtained if all factors in Eq. (8) are optimized.

The first step is the choice of a chromophore system with a large β_D. The most promising candidates are dyes of the charge-transfer type with a strong donor and acceptor group linked together by a conjugated π-electron system (Singer *et al.*, 1989). This leads to a strong and highly asymmetric polarizability and hence to a large nonlinearity. By now, hundreds of different chromophores have been synthesized and tested, some of which are given in Table 4 (cf. also Burland *et al.*, 1991). This compilation demonstrates that by a systematic variation of the donor and acceptor strengths and of the conjugation lengths substantial improvements in β_D can be achieved.

The next step, the maximum level of functionalization, concerns the question of how to dope the polymer matrix. Three strategies have been suggested. The first is the mere mixing of a suitable dye as the functional guest in a polymeric host material. One example of a suitable dye is presented in Fig. 24 (Levenson *et al.*, 1991). The dye's structure formula is shown above Fig. 24. The addition of 15 wt% dye to the PMMA matrix changes the linear optical properties of the polymer: The relatively flat background index of refraction of PMMA [full curve in (a)] shows for the mixture the resonant dispersion behavior (broken curve) of strong chromophores. The corresponding behavior is seen for the extinction coefficient α [Fig. 24(b)]. This material showed (after poling, see next section) decent $\chi^{(2)}$ values and could successfully be implemented into an electro-optic phase modulator.

A major drawback of the host–guest systems is the limited solubility of the dyes in the polymer: typically only 15–20 wt% can be mixed without phase segregation and crystallization. Another problem, in particular in view of device applications, arises from the typically low temporal stability of the noncentrosymmetric orientation distribution induced by the poling process (see below). Depending, of course, on the storage temperature, decay times of a few hours to

days have been reported (Page *et al.,* 1990). However, certain host–guest systems based on polyimide matrices have been demonstrated to exhibit stable $\chi^{(2)}$ values for hours even at temperatures as high as T = 300 °C (Wu *et al.,* 1991).

The aforementioned problems have led to the development of polymers where the chromophores either were an integral part of the main chain (Köhler *et al.,* 1990) or, more widely reported, were attached to the host polymer as functional side chains. A small selection of the many systems presented in the literature is given in Fig. 25; only examples based on acrylates or methacrylate polymers are added. All these attempts were aimed at fabricating a material that can easily be processed, e.g., in the form of a glassy film or channel waveguide, that shows a high β_D value of the employed chromophores, that allows for a high content of nonlinear-optically (NLO) active moieties, and that gives a stable configuration when poled (Man and Yoon, 1992). In fact, these copolymers allowed for a much higher functionalization of the material than for the host–guest systems.

Yet another approach recently reported (Eich *et al.,* 1989; Jungbauer *et al.,* 1991; Swalen *et al.,* 1991; Chen *et al.,* 1991) currently seems to be the ultimate solution for a stable chromophore orientation distribution: the incorporation of the NLO-active moieties into the polymer network as an integral part of the cross-linked matrix. One of the systems is shown in Fig. 26 (Swalen *et al.,* 1992): An epoxy monomer (a) is made to react with electric-field–oriented NLO-active amine monomers (b) to give a highly functionalized cross-linked and hence stable $\chi^{(2)}$ material (c). Very good long-term stabilities have been achieved (see below).

For the third-order nonlinear optical processes, polymeric materials with a high degree of delocalization of the conjugated electron cloud seem to be the most promising candidates. This leads to a large component γ_{xxxx} of the molecular hyperpolarizability tensor γ_D along the polymer chain (conjugation)

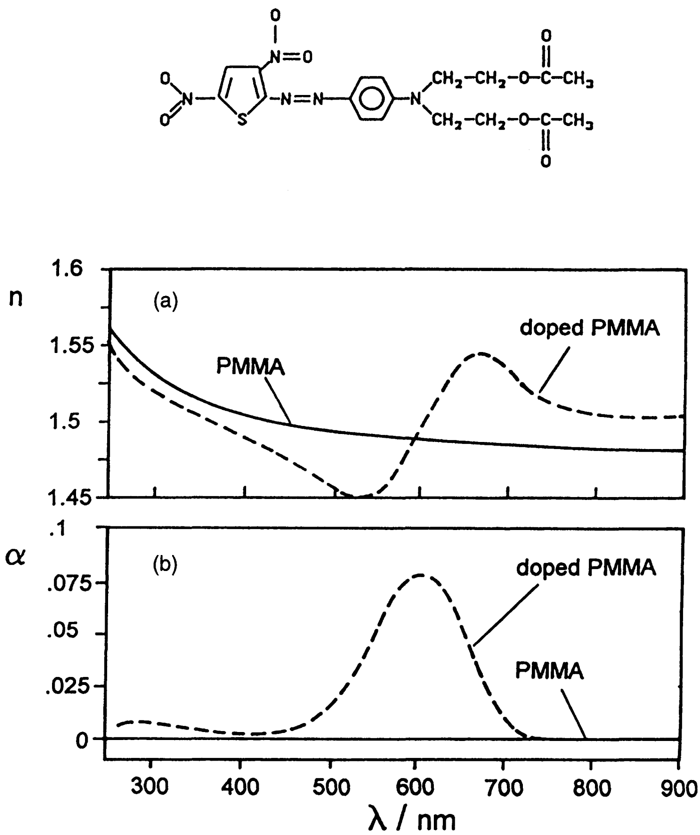

FIG. 24. Example for a host (PMMA)–guest (TP, structure formula given above figure) system. direction. Some examples, currently studied in many laboratories, are given in Fig. 27 (see, e.g., Jenekhe *et al.*, 1992, and references therein). According to

$$\langle\chi^{(3)}\rangle = f\gamma_{xxxx}N_D\langle\cos^4\vartheta\rangle, \tag{9}$$

this is one prerequisite for a high value of the macroscopic nonlinear susceptibility $\chi^{(3)}$. Another important issue also for third-order materials is the orientational order of the chromophores described by $\langle\cos^4\vartheta\rangle$. Although not as crucial as for the $\chi^{(2)}$ devices, which require a noncentrosymmetric arrangement of the NLO-active groups, here, too, the efficiency of the material depends on a good orientation: $\langle\cos^4\vartheta\rangle = 0.2$ for a three-dimensional disorder whereas $\langle\cos^4\vartheta\rangle = 1$ for a system where all the polymer chains are parallel to a given direction. This means that the internal order can be responsible for substantial enhancements of the device performance. The packing density of the chromophores that determines N_D [cf. Eq. (9)] is another factor that needs to be optimized for a large $\chi^{(3)}$ but has to be balanced against other materials and processing parameters. For example, most of the chromophores presented in Fig. 27 are nearly intractable, i.e., they are largely insoluble in most solvents and cannot be prepared, e.g., in thin-film form. This has led to many more or less successful routes to a final product via some soluble and hence processable precursor materials. One example is given in Fig. 27: here, a tetramethylene sulfonium chloride precursor polymer is converted as a spin-cast thin film by a thermal treatment to the final poly(*p*-phenylenevinylene) system (Lenz *et al.*, 1990), which showed decent γ_D values (Bubeck *et al.*, 1989). Another trend in current $\chi^{(3)}$-materials research concerns the incorporation of molecular structures with a two-dimensional π-electron delocalization. Some examples are given in Fig. 28 (Sasabe *et al.*, 1990; Schrader *et al.*, 1991). The ob-

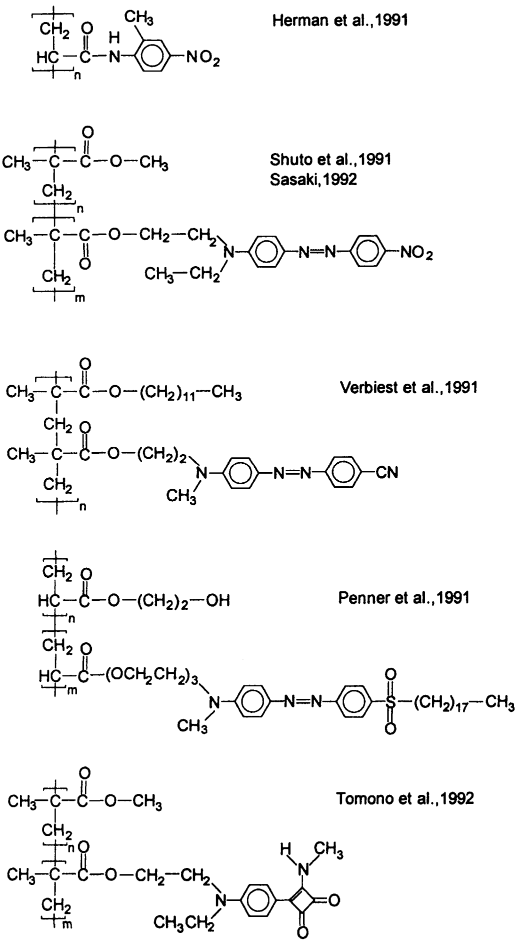

FIG. 25. Examples for different dye-substituted side-chain polymers.

tained nonresonant $\chi^{(3)}$ values, however, are not too promising as yet (Schrader *et al.*, 1991).

3.2 Second-Order Nonlinear Optics with Polymers

Among the numerous device configurations based on $\chi^{(2)}$ processes that have been realized and demonstrated in various laboratories, we focus only on two very basic concepts, i.e., a polymeric waveguide structure designed for second-harmonic generation (SHG) and an electro-optic (EO) modulator that is the key unit for many switching devices. Both modules require that the NLO-active chromophores be highly oriented in a noncentrosymmetric narrow distribution.

3.2.1 Control of Orientational Order For polymeric materials, two strategies have been developed for obtaining oriented samples. The first is based on the LBK technique. For the usual *Y*-type deposition where one monolayer (*A*) is transferred on the downstroke and the other (*B*) on the upstroke, this requires a double-trough arrangement with the $\chi^{(2)}$-active layer being transferred, e.g., only on the upstroke whereas an optically inert material is deposited on the downstroke (Hsiung *et al.* 1991; Penner *et al.*, 1991; Aust *et al.*, 1993). A different approach

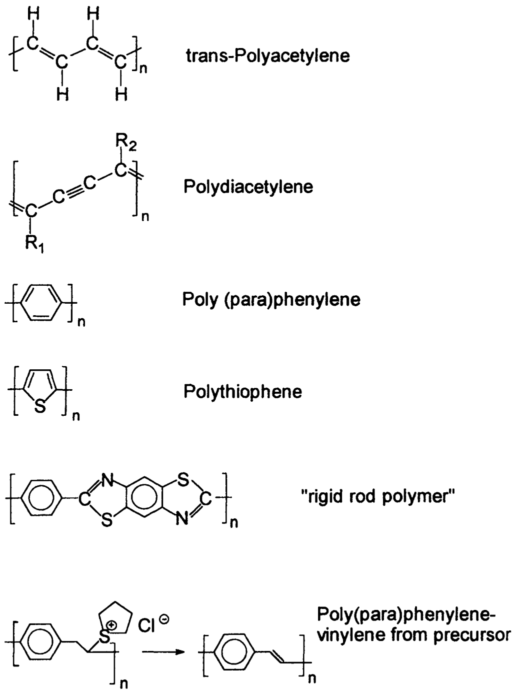

FIG. 27. Structure formulas of some selected $\chi^{(3)}$-active polymers.

to the problem of generating noncentrosymmetric structures by the LBK method has recently been reported for molecular arrangements of 2-docosylamino-5-nitropyridine, the chromophores of which are arranged in a plane parallel to both dipping directions with a net polar orientation giving rise to a large $\chi^{(2)}$ activity (Bosshard *et al.*, 1991). If two different types of chromophores with opposite β_D components are used for the *A* and for the *B* layer, respectively, then it is possible to prepare LBK multilayer assemblies in the *Y* mode with a very high chromophore density (Cresswell *et al.*, 1990). In passing, we should note that self-assembly multilayers with their intrinsically noncentrosymmetric arrangement have also been successfully introduced for $\chi^{(2)}$-active structures (Allan *et al.*, 1991).

All these systems, however, have in common that, in addition to the NLO-active chromophores, highly specialized molecular moieties need to be incorporated in order to tune the molecule's properties to the desired character (to allow for a self-assembly process, e.g.) (Bubeck *et al.*, 1991). From a technical point of view, it is also highly unlikely that such a time-consuming process as the LBK deposition of multilayers will ever make it to a commercially competitive device-fabrication level.

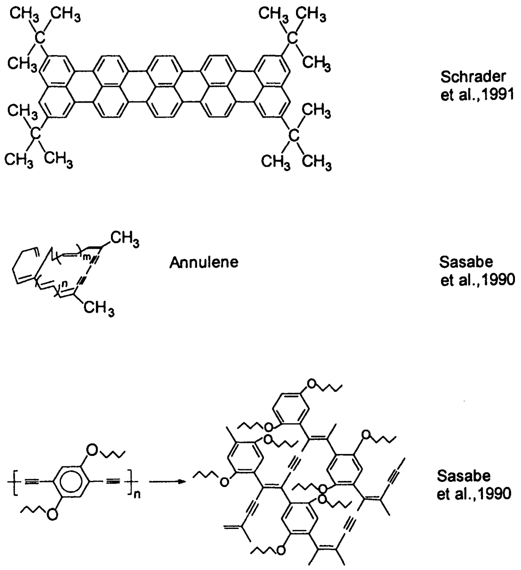

FIG. 28. Some examples for systems with a near two-dimensional π-conjugation.

Therefore, the alternative strategy, i.e., starting from a functionalized polymer with random chromophore orientation spin-cast onto a solid substrate and then subsequently oriented by a poling process, is certainly the more promising and hence more widely applied approach. In the following, we briefly review some aspects of the poling process and its stability.

Two of the basic experimental configurations used for the static electric-field–induced noncentrosymmetric orientational order of the chromophores in functionalized polymer thin films are summarized in Fig. 29. The complete EO-waveguide structure shown in (a) includes, in addition to the NLO-active core, the two buffer layers that isolate the guided mode from any absorptive losses in the (metallic) electrodes. The latter will be used in the final device as the control electrodes but can also be used to apply a dc field of the order of some 10 MV/cm during the poling process at elevated temperatures (see below). The top electrode-free poling process based on a corona discharge setup is sketched in Fig. 29(b). At present, it is not yet clear which approach—electrode or co-

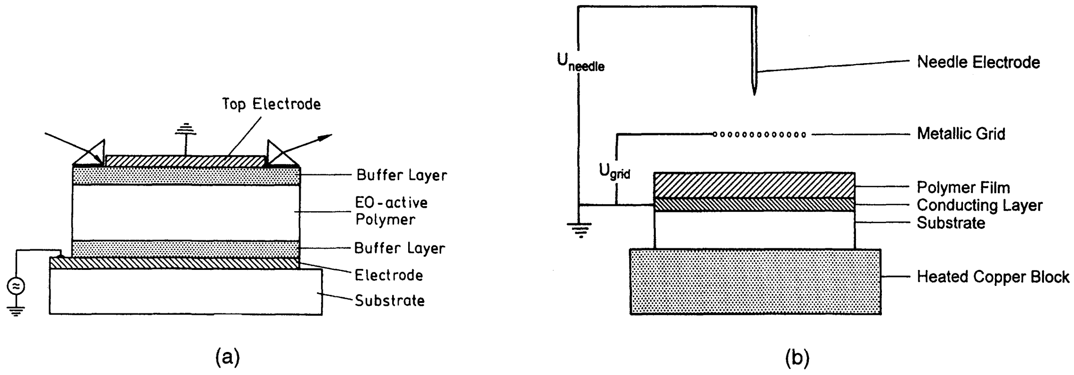

FIG. 29. (a) Schematic cross section of a polymer layer with electro-optic activity sandwiched between two buffer layers and two electrodes. This configuration can be used for (out-of-plane) poling and for (simultaneous) waveguide spectroscopy. (b) Schematic of a setup used for corona (discharge) poling.

rona poling—will yield the better results, i.e., produce a higher degree of orientation, better homogeneity, tolerance against defects, etc. (Herminghaus *et al.*, 1991).

In any case, the poling process requires an orientational (rotational) flexibility of the chromophores in the polymer matrix. This is achieved by heating the sample to a temperature close to the glass-transition temperature T_g of the material. Details of the actual temperature–electric field (applied voltage) protocol differ from laboratory to laboratory but certainly depend also on whether one is dealing with a host–guest, main-chain, or side-chain polymer or a cross-linkable system that can be cured by a thermal process. For the last case, a typical protocol is given in Fig. 30 (Swalen *et al.*, 1991). Without any voltage applied, the system is heated to a temperature where cross-linking is initiated, leading to a slight increase of T_g. This precuring period is followed by the actual poling process, which in the presence of the orienting field further cross-links the polymer–chromophore network with a concomitant increase of the glass-transition temperature.

The poling process can be followed on line by recording either the second-harmonic generation or electro-optic efficiency or, very simply, by monitoring the linear absorption data. Once the polymer sample is cooled down again to room temperature, this polar anisotropy and hence the noncentrosymmetric $\chi^{(2)}$ activity is frozen in—however, not completely, depending on the system. For device purposes this is, of course, an issue of utmost importance and hence has been the subject of many studies. With some exceptions (discussed already above), the general behavior can be classified as shown in Fig. 31: the host–guest systems show the fastest back-relaxation to a more or less isotropic distribution. Much better results are obtained with chromophores covalently attached to the polymer backbone, although clearly this reduced flexibility also may result in a reduced net orientation obtainable through poling. The best stability is found for the cross-linked system.

It should be pointed out that most of these results are obtained, at least to some extent, by a trial-and-error approach. Many of the details are not understood yet, and in many cases only very crude models have been treated. What is certainly missing is a better understanding of the correlation of these linear and nonlinear optical properties with other polymer-specific characteristics given by the structural and dynamical features of these functionalized materials.

3.2.2 Second-Harmonic Generation (SHG)

One of the key device applications of $\chi^{(2)}$-active polymers is the generation of second-harmonic light. The driving force is the search for efficient blue-light sources, in this case through frequency doubling of red laser-diode emission, e.g., for use in optical-storage concepts. The basic configuration is given in Fig. 32(a). Laser light of frequency ω, incident on the sample of thickness d at an angle θ with a fixed polarization, is refracted at the surface of the nonlinear medium and propagates through the film.

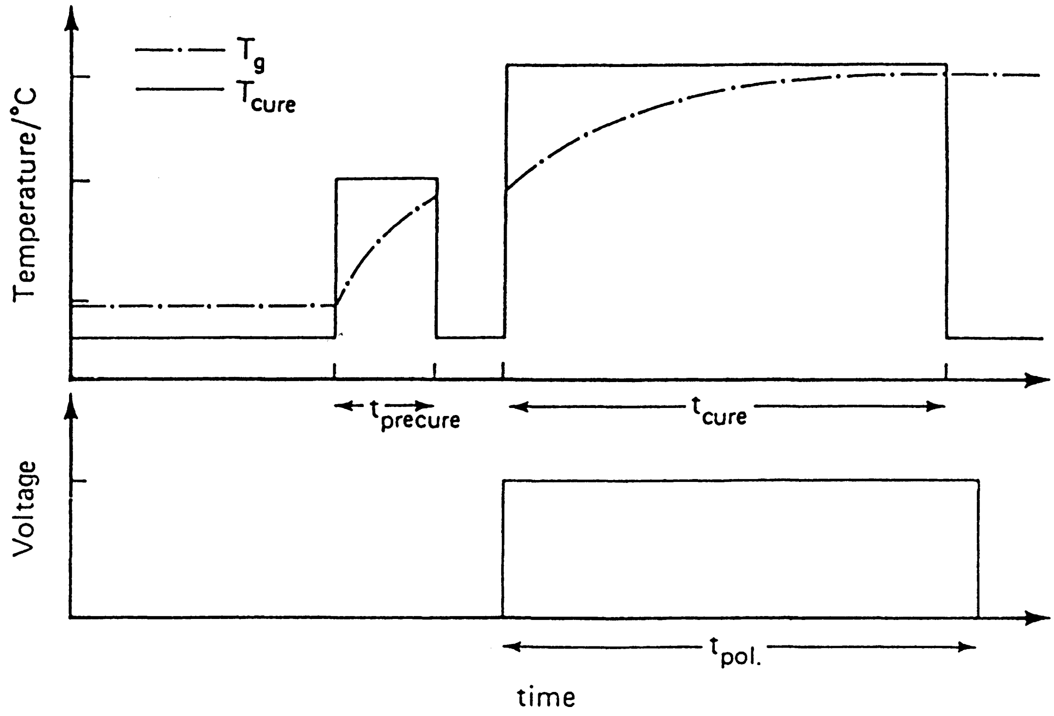

FIG. 30. The temperature–voltage protocol for a dye–polymer system that undergoes a thermally induced cross-linking reaction with a simultaneous increase of the glass-transition temperature T_g. (After Swalen *et al.*, 1991.)

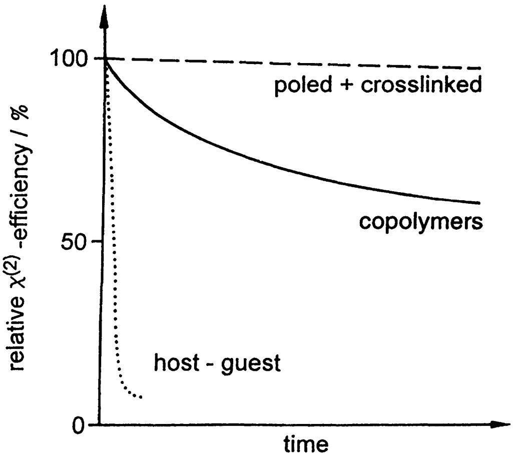

FIG. 31. Qualitative stability behavior of poled polymer films. Typically, the host–guest mixed system randomizes very fast; the copolymer system has a high residual orientation even after long times; the cross-linked system has a long-term stability.

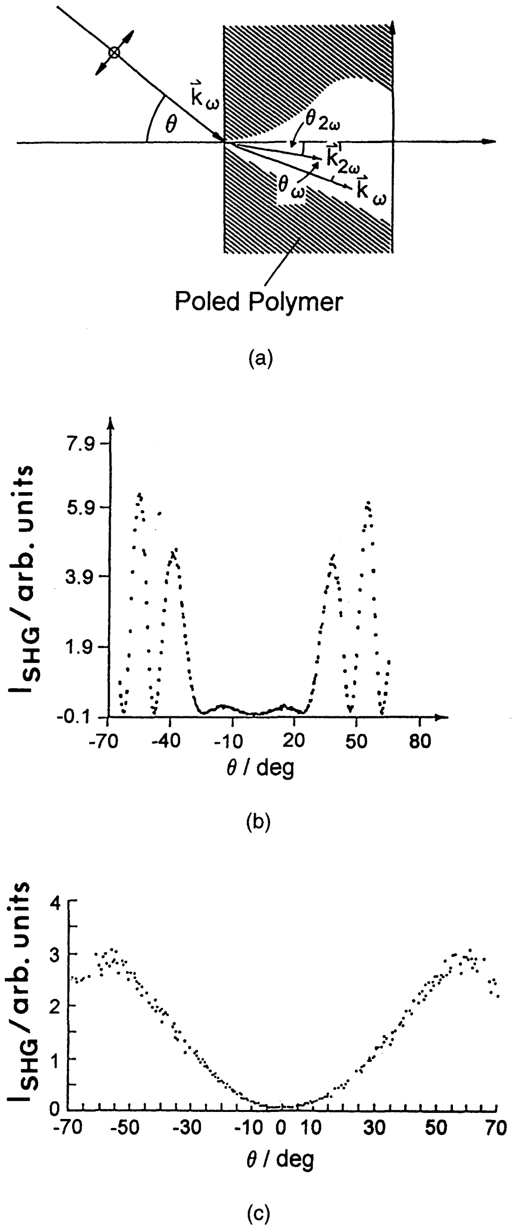
The second-harmonic wave follows the fundamental beam and as such is called the bound wave (Jerphagnon and Kurtz, 1970). In addition, a second-harmonic wave is generated at the surface of the film; it is, however, refracted at a different angle because the refractive index $n(2\omega)$ of the NLO material is different from the value at the fundamental, $n(\omega)$. This wave is called the free wave. The two waves interfere to give the overall SH intensity, with an oscillatory pattern as one rotates the sample called Maker fringes (Ledoux *et al.,* 1987; Verbiest *et al.,* 1991). Depending on the thickness of the sample, several minima and maxima can be observed [Fig. 32(b) for a thick film, 32(c) for a thin film after Swalen *et al.,* 1992].

Now, the required high laser-light intensity for efficient nonlinear conversion is best realized in a waveguide configuration with



(a)

(b)

(c)

FIG. 32. (a) Schematic representation of the propagation vectors whose interference leads to the Maker fringe pattern; (b) Maker fringes for a thick polymer film; (c) one Maker fringe for a thin poled polymer film. (After Swalen *et al.*, 1992.)

strong optical-field confinement. The ultimate structure, therefore, will be the second-harmonic–generating channel waveguide (Norwood and Khanarian, 1990). However, the dispersion of the material and of the waveguide structure (modal dispersion) would result in a useless device because after a certain propagation length of the fundamental and the second-harmonic beam (called the coherence length L_c), their relative phase difference would lead to destructive interference of the second-harmonic light. Several concepts have been put forward to overcome this problem called the phase-matching problem. The first approach is based on the modal dispersion of waveguide structures: This term accounts for the fact that different modes (modes of different order) propagate with different phase velocities, and hence can be described by different effective refractive indices. Phase matching in such a concept is achieved by tuning the dimensions of the waveguide, e.g., the thickness of a planar structure, in such a way that the dispersion of the material is compensated by the modal dispersion. This then results in a configuration in which the guided fundamental mode of order m propagates with the same velocity as the second-harmonic mode of order m'. Problems arising from the need to optimize the field-intensity overlap integrals have so far hampered a major breakthrough of this approach, but can be solved.

The second concept, called quasi-phase matching, is schematically depicted in Fig. 33. After the first coherence length in the poled polymer waveguide, the $\chi^{(2)}$ activity is either destroyed (by bleaching or randomization of the chromophores) or reversed in its polar direction (by the use of correspondingly patterned and poled electrodes) [Fig. 33(a)]. The first configuration is called unidirectional poled waveguide, the second bidirectional. Both overcome the problem of destructive interference of the SHG light with the bidirectionally poled structure showing a twice as efficient buildup of the 2ω signal [Fig. 33(b)].

Finally, we should mention a third version called the Cherenkov frequency doubler. Here, the refractive indices of waveguide material and substrate are such that the fundamental light is guided in the film, but that the SH light is constantly coupled out through the substrate (because the condition for total internal reflection at the film–substrate interface is not fulfilled at 2ω). This way, also no destructive interference limits the SHG efficiency.

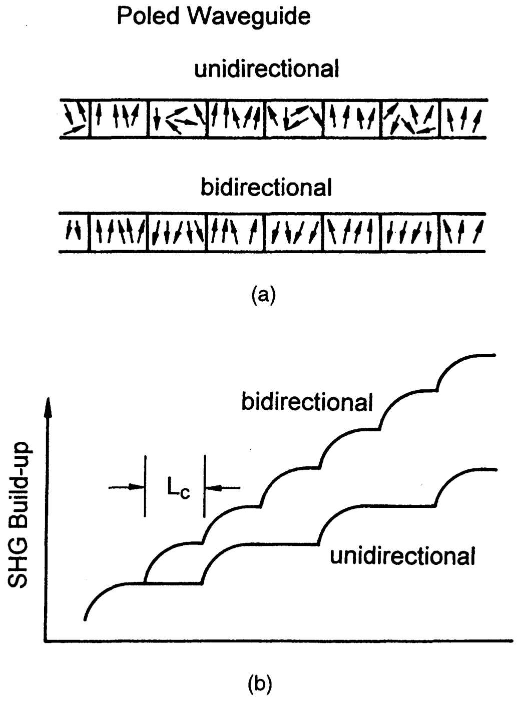


FIG. 33. (a) Schematic of unidirectional and bidirectional poling of waveguides for quasi phase-matching and (b) the resulting buildup of second-harmonic light in the waveguide.

3.2.3 Electro-optic (EO) Modulation

The second major class of $\chi^{(2)}$-based devices uses the Pockels effect, i.e., the manipulation of the refractive index of the material by an applied electric (dc) field. The ultimate structure, again, is certainly a channel waveguide (Shuto *et al.*, 1991) with an architecture schematically shown in Fig. 29(a). If only materials parameters are to be measured, various simplified architectures are sufficient. One setup operating in a reflection mode similar to ellipsometry is given in Fig. 34 (Teng and Man, 1990). The highly reflecting Au or Al electrode on the back side of the EO-active thin film is used to measure differences of the reflectivities for *s*- and *p*-polarized light propagating through the poled polymer in the absence or presence of an applied electric field, respectively. The differences of the reflected-light intensities can be quantitatively analyzed in terms of the two $\chi^{(2)}$ tensor components, $\chi^{(2)}_{13}$ and $\chi^{(2)}_{33}$, needed to describe the nonlinear (Pockels) response of a uniaxial film (Gadret *et al.*, 1991). The advantages of such a simple setup for NLO materials characterization relative to a SHG setup are obvious: No high-power laser is needed, and, therefore, wavelength-dependent measurements are much easier.

A more detailed analysis of the linear and nonlinear optical properties of planar thin-film samples is possible by surface-plasmon (Cross *et al.*, 1988) and by waveguide spectroscopy outlined in Secs. 2.1 and 2.2.1. This has been demonstrated for many samples of poled polymers. In particular, if electrostrictive effects are also present in the investigated material only the waveguide technique allows for a separation of the different processes (Dumont and Levy, 1989). It is straightforward to demonstrate the potential of the method for a waveguide structure prepared by the LBK technique. The example presented in Fig. 35 was obtained with a sample that consisted of 240 buffer layers of an inert material on each side of the EO-active *A*–*B* layer system of 20 layers each. The structure formula of the corresponding chromophore is given in the inset of Fig. 35. The three waveguide modes (m = 0,1,2 as indi-

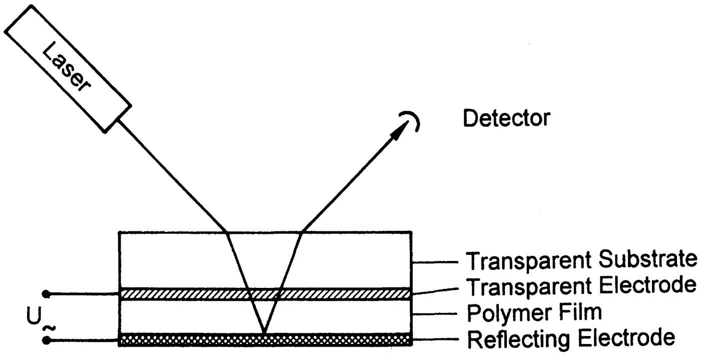

FIG. 34. Setup for EO-coefficient measurement in reflection.

cated) measured with s-polarized light (λ = 593 nm) are shown in Fig. 35(a). Figure 35(b) gives the electro-optic response of the sample under the influence of an applied voltage of 30 V peak to peak. Most remarkable is the alternating magnitude of the effect: The $m = 1$ mode shows only a very small modulation. The interpretation is obvious on the basis of the field-intensity distribution given in Fig. 15. The $m = 1$ mode has a node in the middle of the waveguide right where the EO-active material is located. Any refractive-index modulation by the applied electric field influences, therefore, the overall index configuration for this mode only very little. The even-indexed modes, however, with their intensity maximum in the middle, are influenced much more strongly. The quantitative analysis gives for all three modes the same electro-optic coefficient, $\chi^{(2)}_{13} = 14$ pm/V.

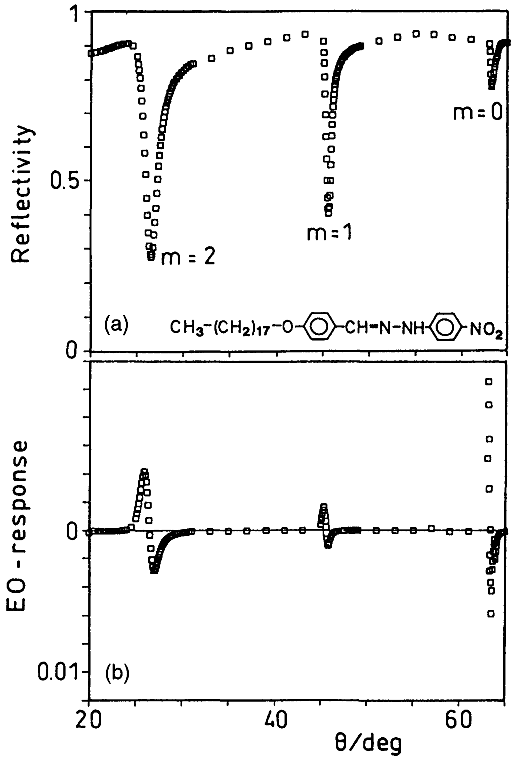

FIG. 35. (a) Waveguide mode pattern and (b) electro-optic response from applying a 30-V peak-to-peak voltage across a LBK multilayer assembly composed of 240 buffer layers, 40 A–B layers (with B being the $\chi^{(2)}$-active material), and 240 buffer layers. Structure of the NLO-active dye is given in the inset. (Aust *et al.*, 1993.)

3.3 Third-Order Nonlinear Optics

In view of possible applications of polymeric materials for all-optical information processing where (nonresonant) $\chi^{(3)}$ values in the range of 10^{-9} esu or larger are estimated to be required, it is somewhat doubtful whether linearly polyconjugated molecules allow reaching this nonresonant $\chi^{(3)}$ value. At present, it is an open question whether materials with an improved nonlinear response and/or an optimized figure of merit will be available in the future.

These figures of merit are defined such as to scale the enhancement of a desired nonlinear susceptibility, e.g., the intensity-dependent refractive-index change in the sample n_2, against other linear or nonlinear response parameters. For example, in a nonlinear directional coupler the (desired) maximum phase shift $\Delta\phi^{NL}$ is given by

$$\Delta\phi^{NL} = n_2 I(2\pi/\lambda)L, \qquad (10)$$

with L being the interaction (device) length. For a given n_2 of the material, the required phase shift of the device could be obtained simply by choosing L correspondingly (high). However, the maximum value of L is limited by the absorption in the polymer: $\max\{L\} < \alpha^{-1}$. Since $\alpha = \alpha_0 + \beta_2 I$, i.e., α contains not only the linear absorption term α_0 but also the nonlinear, e.g., two-photon, absorption term $\beta_2 I$ which is also intensity dependent, one may define (even in the absence of linear absorption, $\alpha_0 < \beta_2 I$) a figure of merit

$$T_m = 2\lambda\beta_2/n_2, \qquad (11)$$

which must be smaller than 1 for a material to be used in a nonlinear directional coupler.

On the other hand, many of these parameters are wavelength dependent. This then defines the need for a rigorous materials characterization and optimization program for those research activities committed to the development of photonic devices based on polymeric systems. First, of course, $\chi^{(3)}$ has to be determined. One experimental technique for this purpose is third-harmonic generation (THG) and is briefly presented in the next section. Of interest are not only the contributions from electronic or thermal processes or from excited states but, in particular, the spectral-dispersion behavior of $\chi^{(3)}$. This must also be known for the linear and, equally important, for the nonlinear absorption coefficients. In fact, it is currently one of the promising strategies to find spectral windows where the device performance is not limited by the two-photon (or three-photon) absorption in the materials.

Since one is interested in fast data-processing devices, with switching times $\tau < 0.1$ ps, the nonlinear recovery time is of vital importance. One experimental technique for its determination is degenerate four-wave mixing (DFWM) briefly outlined below. We should point out, once again, that in addition to these (linear and nonlinear) optical parameters, other material properties like stability, processibility into device configurations such as waveguides, etc., are equally important for a successful application.

3.3.1 Third-Harmonic Generation (THG) Third-harmonic generation describes the process in which an incident photon field of frequency ω generates, through nonlinear polarization in the medium, a coherent optical field at 3ω. It gives directly the electronic hyperpolarizability with ultrafast response time. The typical experiment performed with thin-film polymer samples prepared on suitable substrates in either transmission or reflection geometry monitors contributions from the substrate as well as from the film. Rotating the sample as outlined above for the SHG experiments here, too, leads to a coherent superposition of the free and bound waves giving rise to a fringe pattern similar to the one shown in Fig. 32 for the SHG signal. If one knows the substrate's cubic susceptibility, the experimental data can yield both the real and imaginary parts (or the modulus and the phase) of the third-order susceptibility of the polymer material. If suitable laser systems are available, these data can be obtained covering a wide range of frequencies allowing for the search for suitable spectral windows off the one-, two-, and three-photon resonances. One example is given in Fig. 36 for a polydiacetylene system (after Guo *et al.*, 1992). The experimental data show the strong spectral dependence of both the modulus and the phase of $\chi^{(3)}$. The full curve is a theoretical description of the nonlinear susceptibility of the polymer on the basis of an "essential states" picture with four levels (Guo *et al.*, 1992).

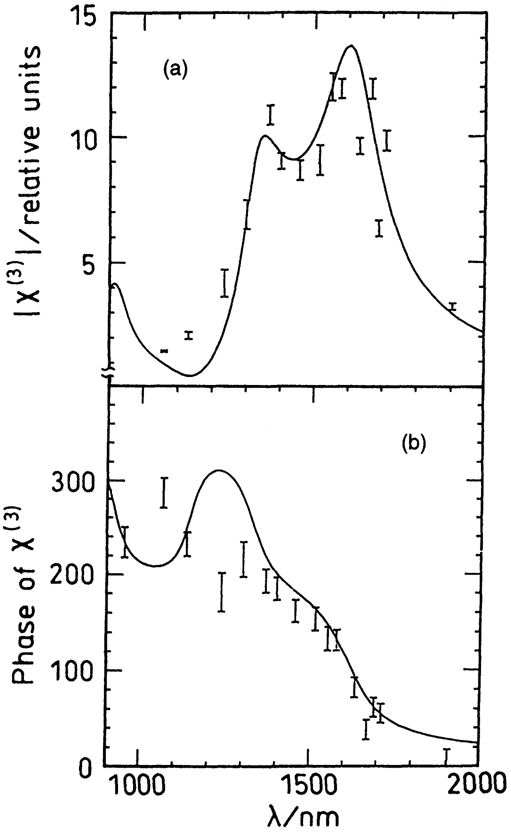

FIG. 36. (a) Modulus and (b) phase of $\chi^{(3)}$ measured for polydiacetylene (cf. Fig. 27, with $R_1 = R_2 = \{(CH_2)_4\ OCONHCH_2COO(CH_2)_3CH_3\}$) as functions of the fundamental wavelength. The full curves are theoretical calculations based on a model with four essential states (Guo *et al.*, 1992).

3.3.2 Degenerate Four-Wave Mixing (DFWM) Degenerate four-wave mixing is a holographic technique in which the output of a laser system is split into three beams. Two of them coherently interfere within the thin-film sample, thus generating a phase grating (refractive-index grating) through the intensity-dependent refractive-index change n_2 in the Kerr medium. The third beam probes this grating: Its diffraction efficiency (the fourth wave!) is monitored during the experiment. If short laser pulses are used, time-resolved experiments can be performed: If the third pulse is slightly delayed relative to the two interfering pulses, the diffracted intensity is a measure of the grating decay.

Thus, information about the important nonlinear recovery time can be obtained. (By comparison with a material of known $\chi^{(3)}$, also the magnitude of the third-order nonlinear susceptibility can be obtained.) Examples are given in the literature for DFWM experiments performed with 60-fs pulse duration showing the ultrafast response times possible with polymeric systems (Prasad, 1991).

Figure 37 summarizes some data aimed at demonstrating the influence of electronic coupling between different chromophores. The close interrelation between the detailed molecular structure of the chromophore, the supramolecular architecture of the matrix into which it is incorporated, and the linear and nonlinear optical properties of the resulting functionalized material is demonstrated for various thin-film samples of phthalocyanines. These dyes are of general interest because of their excellent light and temperature stability. The chemical structure and a few details of the different systems used in these studies are given in Fig. 37(a). In system 4, the phthalocyanine moieties were incorporated into a copolymer with styrene. Figure 37(b) shows the linear absorption spectra and (c) the decay curves as obtained from DFWM experiments at $\lambda \approx 650$ nm. Remarkable differences for the various systems are found (Kaltbeitzel *et al.*, 1989). An isolated phthalocyanine molecule like, e.g., in system 4 gives a sharp absorption spectrum. This leads to a very slow decay time of the transient grating beyond the resolution of the setup. Increasing aggregation eventually leads to an inhomogeneous broadening of the absorption band and a concomitant reduction of the transient time (by orders of magnitude!). Obviously, the electronic coupling between individual resonators affects both the linear and the nonlinear responses of a chromophore system. Various contributions to the observed phenomena may include

1. fluorescence lifetime reduction by aggregational quenching,
2. energy migration (Salcedo *et al.*, 1987), e.g., exciton diffusion into the nonilluminated area,
3. energy trapping at lower states,
4. bimolecular exciton quenching (Ho and Peyghambarian, 1988), etc.

The response times of the conjugated polymers described above are presumably also related to the relaxation processes **3** and **4.** The extended π conjugation with a tight electronic coupling via intrachain and interchain energy migration leads to the ultrafast transient times of these systems, even near resonances.

3.3.3 All-Optical Switching In this section, we just touch on a still very speculative subject, namely controlling light by light (through $\chi^{(3)}$-active materials). Various device concepts have been proposed, some of which were also experimentally tested. A very basic unit is the nonlinear directional coupler. Its realization was reported by Townsend *et al.* (1989). However, it turned out that the intensity-dependent switching of the input laser pulse from one output channel to the other was based on a thermal effect attributed to a three-photon absorption. Recently, a similar structure was presented by Kaneko *et al.* (1992), who claimed, on the basis of their experiments with Ti:Al_2O_3 laser pulses of 100-fs duration at $\lambda = 825$ nm, an electronic mechanism for the observed switching behavior. The high pulse-repetition rate still means a substantial power deposition in the sample, and it will take single-pulse experiments to show unambiguously the fast electronic nature of the all-optical switching phenomena seen in these polymer waveguide samples.

3.4 Photorefractive Polymers

The photorefractive effect was first established in $LiNbO_3$ (Chen, 1967). It arises when charge carriers, photogenerated by a spatially modulated illumination, separate and become trapped to produce a nonuniform space-charge distribution. The resulting internal field then modulates the local refractive index via the linear electro-optic effect, which results in a phase image or hologram of the illumination pattern. A photorefractive material, therefore, needs to combine some functional units that act as photoionizable charge carriers, and some that transport the photogenerated charges until they are trapped at certain sites, and it has to show a nonlinear electro-optic dependence of its refractive index upon a space-charge field. Many possible applications have been suggested including high-density optical data

storage, various image-processing techniques, phase conjugation, programmable interconnection, etc. (Günter and Huignard, 1988).

Polymers again would be ideal materials for photorefractive devices because of their excellent processability and potentially high electro-optic coefficients (see above). Also, photoconductivity in functionalized polymers is a well-established phenomenon because of its importance for the photocopy process (Burland and Schein, 1986) and for laser printing. It was, nevertheless, not until very recently that the first reports on photorefractive polymers were published (Schildkraut, 1991; Ducharme *et al.*, 1991; Tamura *et al.*, 1992) showing indeed very promising features that certainly will stimulate a very dynamic research activity in this field.

4. OUTLOOK

Polymers with their broad variety of optical properties already have their established place in modern products and technologies. The needs of our information societies and the emerging technology of the next century, photonics, mean a rapidly growing demand, chance, and challenge for ever better performing polymers with specifically tuned optical (and other) properties. Optical data storage for consumer products and in information technologies will be a growing area for the use of more and more sophisticated materials. Closely linked to this development is the requirement for a cheap yet powerful blue laser-light source. At present it is an open race whether there will first be available as a commercial mass product the blue solid-state laser diode or a device based on a red laser diode with an integrated frequency-doubling (polymeric) material. Integrated optics, in general, will have its growing share in data transmission, distribution, and processing. Here, a lot will depend on whether improved nonlinear-optical materials will be available.

These ends will be met only if by an interdisciplinary effort a better understanding of the various material parameters at the molecular level can be obtained. The close relation between macroscopic properties and functions on the one side and the microscopic aspects of structure, dynamics, and order on the other side will remain a continuous challenge for modern materials science and technology.

5. ACKNOWLEDGMENTS

It is my pleasure to thank many colleagues and friends for their support and for many helpful discussions. In particular, Y. Koike, H. Kuhn, Y. Levy, W. H. Meyer, V. Mizrahi, M. R. Philpott, H. Ringsdorf, H. Sasabe, K. Sasaki, G. I. Stegeman, J. Stumpe, J. D. Swalen, C. Urban, G. Wegner, T. Wada, and J. Yang contributed also to this article through their stimulating comments. As far as results from our group have been added, I am particularly grateful to my co-workers E. F. Aust, C. Duschl, W. Hickel, H. Motschmann, M. Sawodny, R. Reiter, and B. Rothenhäusler. Financial support came from the Deutsche Forschungsgemeinschaft, the Bundesministerium für Forschung und Technologie, The Volkswagen Stiftung, and the Leonhard-Lorenz-Stiftung.

GLOSSARY

CD-ROM: Compact disk—read-only memory.

Charge-Transfer Chromophore: Dye molecule with an electron donor and acceptor group.

Cladding: Outer part of a waveguide.

Core: Inner part of a waveguide that conducts the light.

Degenerate Four-Wave Mixing: Holographic diffraction technique with transient grating formation in materials with nonlinear polarization.

Electro-optic Modulator: Device that controls the transmission of light by the application of an electrical field to a material with a nonlinear polarization.

Host–Guest Polymer: Polymer matrix (the host) with incorporated small molecules, e.g., dyes (the guest).

Integrated Optics: Optical equivalent to electrical integrated circuits.

Langmuir Layer: Monomolecular film of amphiphilic molecules at the water–air interface.

Liquid-Crystalline Polymer: Polymer with mesophase behavior.

Optical Disk: Digital storage disk for optical readout.

Photonics: Information technology based on photons instead of electrons (electronics).

Photoresists: Polymer used in microelectronic device fabrication for lateral patterning.

(Solid) Polyelectrolyte: Polymeric material with ionic moieties.

Second-Harmonic Generation: Optical frequency doubling by a material showing nonlinear polarization.

Third-Harmonic Generation: Optical frequency tripling by a material with nonlinear polarization.

5.1
Introduction

The history of positron annihilation spectroscopy is, in many ways, an archetypal story of scientific development, from fundamental physics to applications of industrial importance. Predicted by Dirac (1930) and discovered by Anderson (1932), and found to be emitted from artificially produced isotopes in the same decade (Joliot-Curie and Joliot-Curie, 1934), the use of positrons as a subatomic probe of matter was delayed for over a decade by world events.

In 1942, the first fundamental measurement on γ-rays emitted as a result of the annihilation of positrons in solids was performed; Behringer and Montgomery (1942) found that the angle between the two γ-rays which almost always follow annihilation events did not deviate from 180° by more than 15 minutes of arc. DeBenedetti, Cowan and Konneker (1949) were the first to demonstrate that this angle deviated from 180° by an amount linked to the electron momentum and soon afterward published their vision of a new spectroscopy of electron momentum distributions – *angular correlation of annihilation radiation* (now termed *ACAR*) (DeBenedetti *et al.*, 1950). DeBenedetti was joined in his pioneering work by Page and Heinberg (1956), Stewart (1957), and Berko and Plaskett (1958).

Shearer and Deutsch (1949) pioneered the measurement of the lifetimes of positrons in gases, and it was this technique that led to the experimental discovery (Deutsch, 1951) of the positron–electron bound state, positronium (theoretically considered and named *electrum* by Mohorovičić (1934) and renamed *positronium* by Ruark (1945)). Extension of positron lifetime spectroscopy to liquids and solids required faster timing techniques, and these were developed by Bell and Graham (1953) and exploited soon thereafter by Landes, Berko and Zuchelli (1956) and others in the study of structural changes on the atomic scale.

In the 1960s, with the development of more widely available equipment, the level of activity and sophistication increased in both lifetime and angular correlation spectroscopies – for example, yielding new information on positron slowing down and annihilation in gases (Osmon, 1965) and in metals (Weisberg and Berko, 1967). In this decade, experimental problems such as the effect of the radioactive positron source on results, the analysis of data containing

ISBN: 978-3-527-40773-6

multiple lifetime components, and struggles with electronic stability, were still being worked on. In the late 1960s, the role of positron trapping in atomic-scale open-volume point defects in solids was first realized (and explained why different laboratories often produced conflicting results for notionally the same sample). Rather than confusing the issue and burying the technique, this realization gave positron spectroscopy a new lease of life; positrons are so efficiently trapped by these defects that they soon became a sensitive probe of defect structures and open volumes in a wide variety of solids (Petersen, Thrane and Cotterill, 1974).

Further advances in instrumentation, coupled with the traditional resourcefulness and inventiveness which has characterized the positron research community over the years, led to the application of Doppler broadening spectroscopy in the 1970s – a high count-rate, lower-resolution measure of electron momentum densities – which quickly grew as its efficacy and scope for application were realized (Maier *et al.*, 1979). In the same decade, ACAR was enhanced by the development of two-dimensional measurements, first by using an array of discrete photon detectors (Mader *et al.*, 1976) and then by using position-sensitive gamma cameras (West, Mayers and Walters, 1981) or multiwire proportional chambers (Jeavons *et al.*, 1978).

One of the most significant developments in positron techniques also happened in the early 1970s, with the first usable laboratory-based beams of controllable low energy (electronvolts to kilo electronvolts) (Canter *et al.*, 1972). After a few years of application only in atomic physics (i.e., in positron scattering), these beams were applied to solids and, after a number of groundbreaking fundamental studies of positron-surface interactions (Mills, Platzman and Brown, 1978), have been used widely since the 1980s to study surface and near-surface characteristics, thin films, and interfaces (e.g., Triftshäuser and Kögel, 1982). Beam systems – both laboratory and facility based – are now available, delivering positrons with energies controllable between 0.02 eV and mega electronvolts at intensities up to almost 10^9 per second.

We focus on positron spectroscopy of condensed matter; much important fundamental research has been and continues to be performed in atomic physics, but this activity lies outside the scope of this chapter. For an excellent overview of this work, the reader is directed to the book by Charlton and Humberston (2001).

Fundamentals

5.2.1
Annihilation of Free Positrons and Positronium

The annihilation of a positron by its antiparticle, the electron, both stationary, can theoretically result in the emission of any number n of γ-rays if n is greater than 1. The γ-rays take away the rest energy $2mc^2$, where m is the mass of each particle and c is the speed of light. Zero and single γ-ray emission are forbidden for an isolated positron–electron pair at rest because both energy and momentum have to be conserved; both can theoretically occur in the presence of a third body, however. While the emission of two or more γ-photons satisfies both energy and momentum conservation, the probability of n photon emission decreases sharply as n increases (and as the number of vertices on the corresponding Feynman diagrams (Charlton and Humberston, 2001)). For example, Ore and Powell (1949) calculated that the probability of three-γ emission is about 370 times less likely than that for two-γ emission, and the contributions to experimental studies of decays with n greater than 3 are practically negligible. Consequently, almost all annihilation events involving free (or quasi-free) positrons and electrons result in the emission of two γ-rays of energy mc^2 (511 keV) in opposite directions (to conserve momentum).

A positron and electron can exist in the bound hydrogen-like system, called *positronium* (*Ps*). Because the reduced mass is half that of the electron in hydrogen, energy levels are half those in hydrogen (e.g., the ground-state binding energy is 6.8 eV) and interparticle separations are doubled. Ps annihilation events are governed by a selection rule resulting from charge parity (CP) invariance. The parity of the γ-photons is $(-1)^n$, and for ground-state Ps it is $(-1)^S$, where S is the total spin angular momentum of the Ps atom. If the positron and electron in the Ps have opposing spins (the singlet state, *para*-Ps or *p*-Ps) then the total $S = 0$ and consequently n has to be an even number. Conversely, if the positron and electron spins are parallel and $S = 1$ (the triplet state, *ortho*-Ps or *o*-Ps) then n has to be odd. Following the arguments in the previous paragraph, this means that *p*-Ps principally decays into two 511-keV antiparallel γ-rays, whereas *o*-Ps decays into three γ-rays whose total energy is $2\,mc^2$ or 1022 keV. The distribution of γ-energies from *o*-Ps decay was calculated by Ore and Powell (1949) and measured by Chang, Tang and Xi (1985), indicating that the majority of *o*-Ps decays involve the emission of two γ-rays having energies that are a large fraction of mc^2, traveling in roughly opposite directions, with a third low-energy γ-photon emitted at some angle between them. Ore and Powell also computed that the mean lifetime of *o*-Ps in vacuo is about 140 nanoseconds, over 1100 times longer than the 125 picoseconds mean life of *p*-Ps (Wheeler, 1946).

5.2.2
The Fate of Positrons in Condensed Matter

5.2.2.1 Positron Backscattering

A significant fraction of positrons incident upon a target material, whether from a radioactive source or in a monoenergetic beam, are turned around in a few collisions and leave the target with reduced energies. Measurements have shown that there is significant quasi-elastic backscattering and that the angular distribution of backscattered positrons is peaked at angles around the surface normal. Backscatter coefficients η_+ range from a few percent to almost 50%, and depend principally on the incident positron energy and the atomic number of the target material (increasing with both) (MacKenzie *et al.*, 1973; Coleman *et al.*, 1992). The consequences of backscattering have to be considered in experiments involving the detection of annihilation γ-radiation, where the detection of γ-radiation from the decay of backscattered positrons at sites other than the intended target can corrupt data.

5.2.2.2 Positron Implantation

Energetic positrons entering a sample material lose energy via electronic collisions, reaching electronvolt energies in a fraction of a picosecond and then thermalizing in a further time period from one to a few picoseconds, depending on the material. This second phase is dominated by phonon interactions, and, here, the shortest thermalization times are in metals and small band-gap semiconductors; in insulators and wide band-gap semiconductors several picoseconds may be taken for thermalization, and in extreme cases positrons may not reach thermal equilibrium before annihilation. This last scenario is also possible for monoenergetic positrons implanted at very low energies (i.e., below about 1 keV), which may retain ~0.1–1 eV when encountering the sample surface and thus are able to pass through or interact with the surface in ways different from those positrons that have fully thermalized.

Thus, we define positron implantation (or penetration) depth as that at which an incident positron reaches thermal equilibrium. Positrons emitted from the nuclei of a radioisotope decaying via positive β-decay penetrate to depths z below the surface of condensed matter targets whose distribution is traditionally given by the implantation profile $P(z) = \alpha \exp(-\alpha z)$, with $\alpha(\text{cm}) \approx 16\rho {E_m}^{-1.4}$ (ρ = density in grams per cubic centimeter, E_m = maximum β-positron energy in kilo electronvolts). This means that β-positrons can penetrate to depths of ~1 mm, and are thus used to study the bulk properties of materials. A recent experimental study (Foster *et al.*, 2007) has shown that the exponential model provides a reasonable description of β-positron implantation except at small depths, where it underestimates $P(z)$ by ~10%, and very close to the surface, where $P(z)$ should tend to zero rather than its maximum value.

If the incident positrons impinge on a target normally with an energy E, however, their implantation profile has been generally taken to be well described by a Gaussian derivative:

$$P(z, E) = 2\left(\frac{z}{{z_0}^2}\right)\exp\left(\frac{-z^2}{{z_0}^2}\right) \qquad (5.1)$$

where the parameter z_0 (in nanometers) is usually taken to be related to E and to the material density ρ (in grams per cubic centimeter) by the simple expression $(40/\rho)E^{1.6}$. z_0 is 11% larger than the mean implantation depth. While the form for $P(z, E)$ has been shown to be adequate in most cases, the prefactor and the energy exponent have been found to be material dependent (Baker *et al.*, 1991).

5.2.2.3 Positron Diffusion

The diffusive motion undergone by thermalized positrons in condensed matter may be principally considered to involve isotropic elastic scattering from acoustic phonons, and may be described by the diffusion equation because, although the positron is a quantum entity, its wavelength and mean free path (both approximately nanometers) are small compared with typical total distances traveled before annihilation. The positron diffusivity D_+ is proportional to its mobility η_+, with the constant of proportionality being (kT/e). D_+ varies with temperature as $T^{1/2}$ for scattering off acoustic phonons, as $T^{-3/2}$ for optical phonons, and $T^{3/2}$ for neutral impurities; however, the latter two dependencies are only relevant for certain materials and at very high or very low temperatures. At room temperature D_+ has values of a few square centimeters per second for most metals and semiconductors. The diffusion length of positrons $L_+ = (D_+\tau)^{1/2}$, where τ is the mean lifetime of positrons in a material (having values in the range ~100–200 picoseconds); typical values of L_+ are ~100 nm in metals to 270 nm in silicon.

5.2.2.4 **Positron Trapping**

Once considered a problem in positron measurements, the propensity for positrons to be trapped efficiently by open-volume point defects – vacancies, vacancy clusters, and voids – and at shallow trapping sites such as at a negatively charged impurity – is now the mainstay of applied positron annihilation spectroscopy. Although the classical picture of positrons being attracted to a region of lower than average positive charge is commonly used to explain positron trapping, the diffusing positron is a quantum particle and trapping should be considered to be quantum localization. Positrons provide a unique method for nondestructive characterization of such defects at concentrations as low as 10^{-7} per atom, saturating at $\sim 10^{-4}$ per atom.

There are two main models describing positron trapping. For small point defects such as vacancies, the trapping is *transition-limited* – that is, dependent upon the probability of trapping once a defect is encountered; this is described by the specific trapping coefficient ν, which has typical values in the range of 10^{14}–10^{15} per second. The total trapping rate κ is then νC, where C is the defect concentration per atom and ν for semiconductors has a temperature dependence, which can be used to identify the defect type. The second trapping model is *diffusion-limited* – that is, determined by the probability of finding the trapping sites which, once found, have a trapping probability of unity. The total trapping rate is then $\kappa = 4\pi RD_+N$, where R (centimeters) and N (cubic centimeters) are the radius and number density of the defects, respectively, and D_+ is the positron diffusion constant in square centimeters per second.

The charge state of open-volume point defects in semiconductors and insulators can play an important role in positron trapping. The specific trapping rate ν is very small for positively charged defects, whereas neutral sites are effective positron traps and negative charge can increase ν by a significant factor. While open-volume defects are deep traps for positrons, shallow trapping can occur around negatively charged vacancy or impurity defects – this is usually seen at low temperatures and identified by the temperature dependence of the trapping probability (Saarinen *et al.*, 1997).

Thermally induced detrapping from defect sites can occur, depending on the Boltzmann factor $\exp(-E_b/kT)$, where E_b is the binding energy of the positron in the trap; therefore, for example, for deep traps – that is, those for which E_b is a few electronvolts – detrapping can be considered negligible.

5.2.2.5 **Positron-Surface Interactions**

If a positron encounters the surface of a material sample after implantation it can suffer a variety of fates, all of which have found application in various experimental studies. We shall, for the moment, assume that the positron has been thermalized before reaching the surface, and not consider those backscattered positrons that penetrate the surface without any significant interaction with it.

There are three main channels open to the positron on encountering a surface: (i) trapping in the surface potential well, (ii) binding with a surface electron and leaving as Ps, and (iii) being reemitted from the surface by a negative positron work function φ_+. For those materials for which φ_+ is positive, channel (iii) is not open.

Surface Trapping The potential encountered by a positron may be considered for our purposes to be a combination of the attractive image potential, which falls off as the reciprocal of distance from the surface, and the repulsive dipole potential, which falls off significantly more quickly above the surface (i.e., within a few angstroms). The combination of these two potentials thus creates a deep well above the surface in which positrons are efficiently trapped. On an atomically clean perfect surface, the trapped positron can be used as a probe of electronic surface states. If the temperature of the material is increased then the trapped positron can be desorbed, but only via the formation of thermal-energy Ps, which supplies its 6.8-eV binding energy; this, however, is an excellent source of low-energy Ps atoms for spectroscopic measurements.

Positronium Formation For metals and semiconductors, the surface is the only site where the electron density is low enough to permit Ps formation. The formation potential for Ps at surfaces, essentially the energy possessed by the emitted Ps atom, is the balance between the sum of the electron and positron work functions – that is, the energy required to remove both particles independently from the solid – and the 6.8 eV gained by forming the bound state. In the early days of positron-surface experimentation, Ps formation was used as a signature that the positron had diffused back to the surface; however, the probability of forming Ps is critically dependent on surface conditions, which can have a positive or negative influence on measurements. Measurement of the velocity spectra of emitted Ps was also used as a probe of electronic surface states. Of great fundamental importance is the fact that small fractions of the Ps emitted can be in an excited state or as the negative ion Ps^-.

Positron Reemission The sum of the correlation and dipole potentials outlined in Section 5.2.2.5, Surface Trapping (the correlation potential is the asymptotic level of the image potential inside the material) can be positive or negative – that is, positrons are either attracted or repelled by the surface, depending on their relative magnitudes. The difference between the resultant total potential within a solid and the reference vacuum level far from the surface is the positron work function φ_+. For a number of solids the dipole potential is greater than the correlation potential and φ_+ is negative – that is, thermalized positrons are emitted from the surface with an energy of $\sim\varphi_+$. Negative φ_+ values for metals range from close to zero to ~3 eV and, like their electron equivalent, are dependent on surface composition and structure. For a perfect surface, the emission is normal to the surface, smeared only by thermal effects; for a "real" surface, the emitted positrons may undergo inelastic collisions above the surface that lower their average energy and increase their angular spread; if enough energy is lost in such a collision, then the positron may fall into the surface well and be trapped. Thus, there is a correlation between the magnitude of φ_+ and the fraction of positrons reemitted from a surface.

A small fraction of positrons from a radioactive source incident on a solid with negative φ_+ possess energies low enough (i.e., below ~10 keV) to be thermalized, return to the surface, and subsequently be reemitted with work function energies. This is the basis of the generation of monoenergetic positron beams, which have been widely used to study surface and near-surface phenomena for the past 25 years.

Surface Branching Ratios The relative probabilities of these three main channels open to the positron are described by the branching ratios ε. For a solid with a positron work function of ~–1 eV, the three branching ratios are in the approximate ratio of 1 : 1 : 1. For surfaces with a positive φ_+, approximately half the positrons form Ps and half fall into the surface trap at room temperature.

Nonthermalized Positrons If the positrons incident on a surface have energies below about 1 keV, there is a significant probability that they will return to the surface without being fully thermalized – that is, with residual energies of several hundred milli electronvolts. These epithermal positrons interact with the surface with rather different branching ratios; they can more readily overcome surface trapping and leave as positrons with energies above φ_+, and can pick up an electron and form Ps, which again leaves with higher energy than that formed by the process outlined in Section 5.2.2.5, Positronium Formation.

On encountering "real", dirty surfaces – for example, oxide-covered – the branching ratios can be hugely different from those for a clean perfect surface and, in addition, there can be significant, sometimes overwhelming, trapping at surface defects.

We next focus on the annihilation of thermal-energy positrons with electrons, and of Ps-like states, in condensed matter. Other aspects of positron and Ps interactions in solids and liquids are discussed in later sections.

5.2.2.6 Positron Annihilation: Observables

The cross section σ for annihilation is inversely proportional to positron speed v, but the annihilation rate is proportional to σv. Consequently, although annihilation during positron slowing down is possible, has been observed, and may play a role in some positron experiments (Weber *et al.*, 1999), the overwhelming fraction of annihilation events occur after thermalization, when positrons spend most of their time in diffusive motion.

Although positrons rapidly (i.e., in approximately picoseconds) thermalize in condensed matter, and so can be thought of as quasi-stationary, the electrons that annihilate them are decidedly not. Conduction electrons at the top of the Fermi sea in metals, for example, have several electronvolt energies and bound electrons can have kilo electronvolt energies. However, most positrons will perish at the hands of the lower energy conduction or valence electrons, both because of the time of interaction and because of their propensity to spend more time away from the positive ion cores.

If we initially treat the positron and electrons as independent particles (i.e., we ignore mutual interactions), then the probability $\rho(\boldsymbol{p})$ that a pair of γ-rays with total momentum $\boldsymbol{p}$ will result from the annihilation of a positron and an electron is given by

$$\rho(\boldsymbol{p}) = \left(\frac{r_0^2 c}{8\pi^2}\right) \sum_{i,j} n_i{}^{+} n_j^{-} \left| \iiint \exp (-i\boldsymbol{p}\boldsymbol{r}) \psi_i{}^{+}(r) \psi_i^{-}(r) d^3 r \right|^2 \quad (5.2)$$

where n_i^+ and n_j^- are the occupancies of the positron and electron states, the former being close to a delta function, and $\psi_i^+(\boldsymbol{r})$ and $\psi_j^-(\boldsymbol{r})$ are the positron and electron wave functions, respectively. If we assume that the positron momentum is relatively negligible, then $\boldsymbol{p}$ represents the electron momentum at the moment of annihilation.

Direct complete evaluation of the so-called momentum density $\rho(\boldsymbol{p})$ would be possible if one could perform a three-dimensional measurement of the momenta of the annihilation photons. In principal, one could achieve this by measuring the x and y components via the angles between the photons (see Section 5.3) and the z component via the Doppler shifts in the measured photon energies. In practice, we integrate over the z component and record the two-dimensional contour "map", that is, $\rho(p_x, p_y) = \int \rho(\boldsymbol{p}) dp_z$. This is the basis of the experimental technique known by the acronym 2D-ACAR (two-dimensional angular correlation of annihilation radiation).

If instead we integrate over both x and y components of $\boldsymbol{p}$, then we arrive at the momentum density in the z direction, which gives rise to the Doppler broadening of annihilation radiation (DBAR), an extremely useful spectroscopy for following changes or differences in electronic structure: $\rho(p_z) = \iint \rho(\boldsymbol{p}) dp_x dp_y$.

Finally, the total annihilation rate is given by the integral of $\rho(\boldsymbol{p})$ over all three components of $\boldsymbol{p}$: $\lambda = \iiint \rho(\boldsymbol{p}) dp_x dp_y dp_z$. Reference to Eq. (5.2) shows that λ is proportional to electron density in the vicinity of the annihilated positron. The mean positron lifetime τ is the reciprocal of the annihilation rate λ, and measurement of the various possible lifetime components for positrons in condensed matter forms the basis of positron annihilation lifetime spectroscopy (PALS). The independent particle model leading to Eq. (5.2) is inadequate for the calculation of λ; $\rho(\boldsymbol{p})$ has to be multiplied by a positron–electron enhancement factor $\boldsymbol{\varepsilon}$ to take account of the interactions between positron and electrons and between the electrons in the material being studied (Kahana, 1963).

5.2.2.7 **Positronium Annihilation**

Although the quasi-stable bound-state Ps cannot form in metals or semiconductors, as a result of electron screening (except above the surface – as discussed later), it can exist in insulating solids and liquids.

A small variety of models have been proposed to describe Ps formation in such solids and liquids, and their applicability depends to a large extent on the material under study. The Ore Model (Ore, 1949) considers Ps formation to occur principally in the range of energies from $(E_i - B)$ to E_{ex}, where E_{ex} and E_i are the threshold energies for atomic excitation and ionization, respectively, and $B = 6.8$ eV is the ground-state binding energy of Ps. Above E_{ex} other interactions are assumed to outcompete Ps formation. A second prominent model is the Spur Model, due to Mogensen (1974), in which the positron binds to an electron released in a spur during the slowing-down process, under conditions of small relative momentum. An extension of this model is to consider the end of the positron track to be a ''blob'', rather than a spur (Stepanov and Byakov, 2002). A third, particularly considered with respect to Ps in polymers, involves the formation of Ps in open volumes or holes, the electron being picked up from the surface (Brandt, Berko and Walker, 1960); if the positron is not completely thermalized, then the Ps atom may undergo thermalizing collisions with hole walls.

There have been many groundbreaking fundamental measurements on Ps over the past 50 years, from precise measurements of vacuum decay rates to measurements on excited states, observations of the negative ion and hydride, and of Ps–Ps interactions en route to a Bose–Einstein Ps condensate (Cassidy and Mills, 2007). In Section 5.4, however, we briefly summarize only some of those applications in which Ps decay has been used to characterize condensed matter on the atomic scale, mostly involving the measurement of Ps lifetimes and intensities.

5.3
Experimental Methods

5.3.1
Sources of Positrons

The two methods for obtaining positrons for use in spectroscopic measurements are (i) radioactive sources and (ii) pair production. The most common radioisotope used in the laboratory is sodium-22 (half-life 2.7 years), with cobalt-58 sometimes used in experiments requiring higher intensities over shorter periods (half-life 71 days). These and other positron-emitting sources are created in reactor cores by nuclear bombardment; a number of steps have been taken toward the in-house creation of strong positron sources using tabletop proton and deuteron accelerators to produce short-lived but high-activity radionuclides (Hirose, Nakajyo and Washio, 1997). In-house or facility-based sources are primarily used in the production of intense positron beams, as are positrons created by pair production in a linear accelerator (LINAC). In the latter case, bremsstrahlung radiation from pulsed energetic LINAC electrons created electron–positron pairs in a target of high atomic number; the energetic positrons are then moderated to form an intense, often pulsed, positron beam.

Positrons emitted via the positive β-decay of radioactive sources are longitudinally polarized (i.e., spin-polarized in the direction of their emission) as a consequence of parity nonconservation; the weak interaction that mediates β-decay leads to a nonvanishing helicity. This property has been exploited in a number of experiments to study the bulk magnetic properties of materials, principally using ACAR (Section 5.3.3). The principle underlying its application is that positrons are $\sim$1000 times more likely to annihilate an electron in the opposite spin state. Therefore, if the spin states of some of the electrons in a sample are changed (e.g., by measuring magnetic and nonmagnetic samples, or by changing the external magnetic field direction), the difference in the experimental data yields information specifically on those electrons and thus on the magnetic species.

5.3.2
Lifetime Spectroscopy

The first positron spectroscopy to be developed, and still widely used currently, involves the measurement of the mean lifetimes of positrons in condensed matter. As introduced in Section 5.2.2.5, the mean lifetime of positrons in condensed matter is related directly to the electron density in the vicinity of the positrons at their moment of annihilation. For example, if positrons are annihilated while trapped in open-volume defects, the average electron density is reduced and the mean lifetime is increased, and there is, in general, a characteristic lifetime value for every different annihilation state.

In the most general case, positrons can decay from a range of states s each with annihilation rates $\lambda(s)$ (λ being the reciprocal of the mean lifetime τ), with the probability of being in state s at annihilation being $P(s)$. The resultant lifetime spectrum is

$$I(t) = \int P(s)\exp(-\lambda(s)t)ds \tag{5.3}$$

which, if the annihilation proceed via a small, discrete states labeled i, reduces to

$$I(t) = \sum_i I_i \exp(-\lambda_i t) \tag{5.4}$$

This spectrum can be fitted with standard programs to extract the decay rates (and thus lifetimes) and corresponding intensities, deconvoluting the time resolution of the measuring system and allowing for system-related components such as that associated with positron decay in the source. In practice, the number of discrete components that can be reliably obtained from experimental spectra is crucially dependent on the range of values of λ_i and the number of states involved; a maximum i value of 3 is typical. A common strategy in many experiments is to use the average positron lifetime $\overline{\tau}$ (or decay rate $\overline{\lambda}$), defined as

$$\begin{aligned}\overline{\lambda} = \overline{\tau}^{-1} &= \int \lambda(s)P(s)ds \quad or \\ &= \sum_i I_i\lambda_i \end{aligned} \tag{5.5}$$

particularly when it is the change in λ with some external parameter that is important.

5.3.2.1 Experimental Lifetime Systems

Conventional positron lifetime spectrometers have at their heart a radioactive source, commonly sodium-22 deposited between two thin low-Z films, sandwiched between two pieces of the sample to be studied. If the sample is to be cooled or heated during the measurements, it may be mounted in a small evacuated chamber. Sodium-22 provides a "prompt" 1.28-MeV γ-ray essentially coincident with the emission of the positron, as a result of the de-excitation neon-22; this is detected by a scintillator with a fast response (e.g., barium fluoride or doped plastic) coupled to a photomultiplier. The 511-keV annihilation "death" γ-ray is recorded by a second similar detector assembly, and the fast pulses (rise time ~1 nanosecond) created are fed into a timing system, which records up to about 10^6 time intervals between birth and death γ-rays. Traditionally, the timing systems have included single channel analyzers to select pulses of appropriate

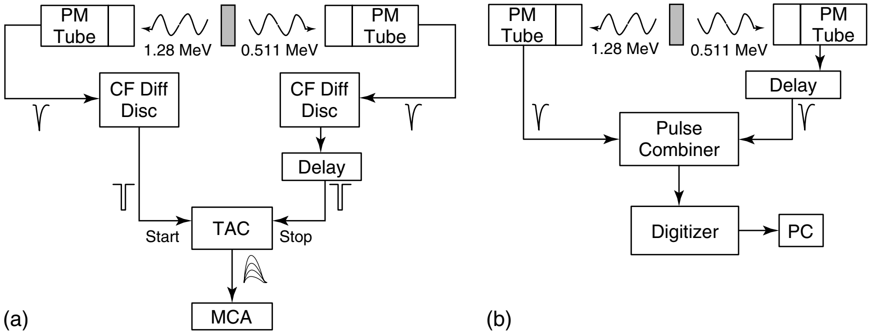

Fig. 5.1 (a) Standard fast–fast analog timing system: PM TUBE, photomultiplier tube/scintillator assembly; CF DIFF DISC, constant fraction differential discriminator; DELAY, nanosecond delay box or cable; TAC, time-to-amplitude converter; MCA, multichannel analyzer. (b) Digital equivalent of an analog timing system.

size, a time-to-amplitude converter (usually with a suitable delay line before the "stop" input) and a multichannel analyzer to collect the entire range of pulse heights in parallel (i.e., the entire range of positron lifetimes). In recent years, this analog system has been replaced by a digital equivalent in which every pulse representing a time difference is digitized and stored, allowing postcollection timing optimization (Figure 5.1).

5.3.3
Angular Correlation of Annihilation Radiation

Although, as discussed in Section 5.2.1 for stationary particles, in two-γ annihilation in the center of mass frame the two photons leave the site of the annihilation with identical energies (mc^2, 0.511 MeV) in exactly opposite directions (to conserve momentum), in the laboratory frame, the momentum of the annihilating pair moving with a velocity v means that the angle between γ-rays – as shown in Figure 5.2 – is no longer 180°.

Relativistic transformation from one frame to the other yields expressions for $\tan\theta_1$ and $\tan\theta_2$. Then $\delta\theta \approx \tan(\theta_1 - \theta_2)$ which, ignoring terms in $(v/c)^2$, reduces to $(2v/c)\sin\theta_0$. Now if we set $\theta_0 \approx \theta_1 \approx \theta_2 = \theta$, then $\delta\theta \approx 2mv\sin\theta/mc = p_t/mc$, where p_t is the component of momentum of the annihilating pair in a direction transverse to the γ-emission. Measurement of $\delta\theta$ thus directly yields information on p_t. $\delta\theta$ typically ranges up to 20 mrad; in order to achieve the necessary resolution, the γ-detection regions have to be small and spaced many metres from the sample being

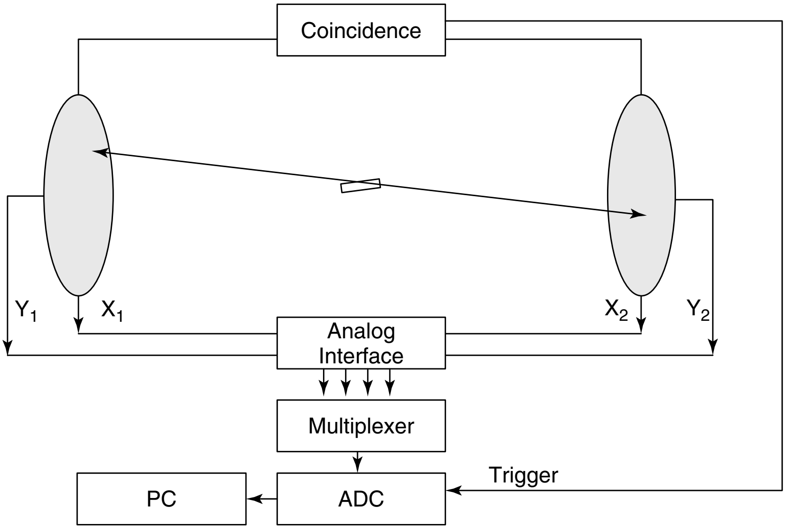

Fig. 5.3 Schematic diagram of 2D-ACAR apparatus. Positrons are guided from source to target by a strong (~1 T) magnetic field. (Courtesy Bristol positron group.)

studied. In one-dimensional studies (1D-ACAR) long thin slits – usually between lead blocks – define the γ-directions; in two-dimensional (2D-ACAR) experiments (Figure 5.3) annihilation photons are detected by position-sensitive detectors such as Anger cameras or multiwire ionization chambers. To effectively eliminate background events, positrons are guided from the approximately giga becquerel source to the samples by a strong (~1 T) magnetic field over a few centimeters from a radioisotope source, or by a guiding magnetic field in a low-energy positron beam system. About 2×10^8 coincident annihilation events are typically recorded. Samples are commonly mounted in a small vacuum chamber on a cold finger to enable measurement at temperatures down to $\sim 10^1$ K, and can be fixed at different crystalline orientations. Anger cameras have spatial resolution of 2–3 mm, so that if they are mounted at ~15 m on either side of the sample they provide angular resolution of ~0.2 mrad. A somewhat better resolution is possible with multiwire proportional counters. These high-resolution capabilities have found their place in the measurement of occupied electron states, and thus the Fermi surfaces of a number of simple and complex solids (see Section 5.4.5 for examples). The Lock–Crisp–West (LCW) procedure (Lock, Crisp and West, 1973) folds the momentum density back into the first Brillouin zone, which then gives a distribution that directly indicates the occupancy of states across the projected zone. (The Fermi surface is defined by whether a particular state is occupied or not for each band, and these occupancy breaks are revealed directly by 2D-ACAR.) The full three-dimensional Fermi surface can be reconstructed tomographically from an appropriate number of two-dimensional projections along different crystallographic orientations.

5.3.4
Doppler Broadening of Annihilation Radiation

The component of the momentum p_p of an annihilating positron–electron pair in the direction of emission of the annihilation γ-photon gives rise to a Doppler shift in the photon energy of $\pm cp_p/2$. For example, if p_p arises almost wholly from an electron moving close to the Fermi level with a kinetic energy of 5 eV, $cp/2 = 1130$ eV. This is of the same order as the energy resolution of a high-purity germanium detector. Because the electrons can have a component of momentum toward or away from the detector at the moment of annihilation, Doppler broadening around mc^2 (511 keV) is measured. Changes in the annihilation linewidth from a fraction of 1% to a few percent are typically measured and, although the technique provides a measure of the average electron momentum, which is of considerably lower resolution than ACAR, its high signal rates and relative simplicity has found wide application in the study of defects and phase changes in materials. This is referred to as *Doppler broadening spectroscopy* (*DBS*) or *DBAR*.

A typical system for DBAR is sketched in Figure 5.4. The Ge crystal is cooled by liquid nitrogen or by an electrical cooler to effectively eliminate thermal noise. A preamplifier is routinely mounted inside the cooled detector head. The optional biased amplifier allows expansion of the photopeak into a larger number of channels on the multichannel analyzer (MCA). Since small drifts can broaden the spectrum, stabilization is necessary, and this is achieved by temperature control and by using a digital stabilizer set to a nearby reference line – for example, the ^{7}Be 478-keV γ-line. Digital systems have been developed, which house all the elements shown in Figure 5.4.

Samples for DBAR are typically mounted in an evacuated chamber to avoid sample contamination on heating or cooling, and data contamination by annihilation signals in air; such mounting also enables temperature control. For traditional bulk measurements using a radioactive source, two pieces of the sample material sandwich a source held in low-Z films, and correction has to be

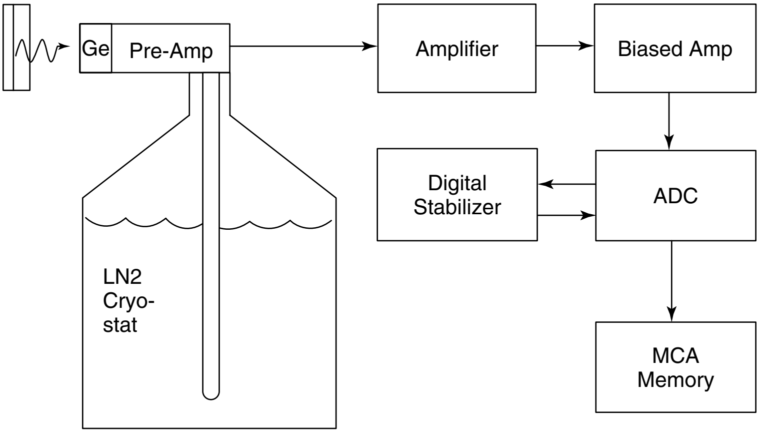

Fig. 5.4 Basic setup for Doppler broadening spectroscopy.

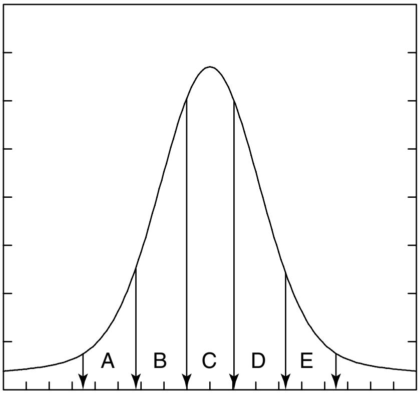

Fig. 5.5 Regions of interest defined for DBAR: sharpness parameter $S = C/T$, wing parameter $W = (A + E)/T$, where $T = A + B + C + D + E$.

made for annihilations in the source itself; if the sample is at the target end of a positron beam system, then no source correction is necessary.

Resultant "photopeak" spectra corresponding to the annihilation γ-line are quasi-Gaussian in shape; entirely free (i.e., conduction) electrons would lead to a parabolic peak, and core electrons to a number of increasingly small "side" peaks; the sum of these contributions has a Gaussian, or multi-Gaussian, appearance. The central part of the annihilation line thus preferentially contains contributions from the lower momentum conduction and/or valence electrons, while the wings contain contributions from annihilation with core electrons. Analysis routines have been developed which take account of the detailed shape of the peak, with a view to maximizing the amount of information obtained in Doppler broadening experiment, although it is more common to use the raw data to track *changes* in lineshape parameters under changing experimental conditions.

As discussed later, by decreasing background significantly, detailed analysis of the peak shape can exploit the technique's sensitivity to the elemental environment. However, we first consider the standard method for describing the Doppler-broadened linewidth – that is, the use of simple lineshape parameters. The most common parameters used are called S and W – the sharpness and wing parameters, respectively – which are defined in Figure 5.5. Three regions of the peak – here A (central) and C and E (the two wings) – are chosen, symmetrically about its centroid. The limits of these regions are chosen such that the central and total wing fractions of the peak area – which are called the S and W parameters – are $\sim$0.5 and $\sim$0.1–0.2, respectively. Background is first subtracted if deemed necessary. Following our argument above, S and W should principally reflect changes in the momentum density of lower and higher momentum electrons, respectively. For example, positron annihilation in open-volume defects typically leads to an increase in S and a decrease in W.

Neither S nor W has an absolute value, as it is their dependence on external parameters that is of common interest. However, it is common to express the parameters normalized to bulk values – that is, S/S_{bulk} and W/W_{bulk}, where the denominators are the parameters associated with the defect-free bulk material being studied, measured with the same apparatus. The choice of which parameter to use (S and W are not the only choices) and the limits of regions defining the parameters are system-dependent.

If S_f and W_f are the S and W parameters characteristic of free positrons, then we can define a new parameter $R = |(S - S_f)/(W - W_f)|$, which depends only on the nature of the defect, and not on its concentration. If R is found to be constant, then this points to the existence of only one kind of defect (Mantl and Trifthäuser, 1978).

5.3.4.1 Two-Detector DBAR

This technique was proposed many years ago by Lynn *et al.* (1977) but has been reintroduced and developed in the past decade. If a sample is viewed by a second γ-photon detector, and pulses from the two detectors (in coincidence) are fed into the inputs of a two-dimensional multichannel analyzer array, a photopeak results that not only has vastly reduced background (i.e., by two or more orders of magnitude) but the resolution is also decreased by a factor of $\sqrt{2}$. Example data for such a system are shown in Figure 5.6. This method enables one to study annihilations with core electrons and, in the case of recent studies with positron beams, identify the chemical environment in which the positron decays. The measurement typically involves the accumulation of single annihilation line spectra of high statistical precision whose shape is analyzed carefully and compared with calculations.

5.3.4.2 Age-Momentum Correlation (AMOC)

Simultaneous measurement of positron lifetime and the momentum of the annihilating pair (i.e., PALS + DBAR) can give information on thermalization and transitions between positron states (and hence on chemical reactions of positrons or Ps). The most recent version uses a mega electronvolt positron beam (Siegle *et al.*, 1997).

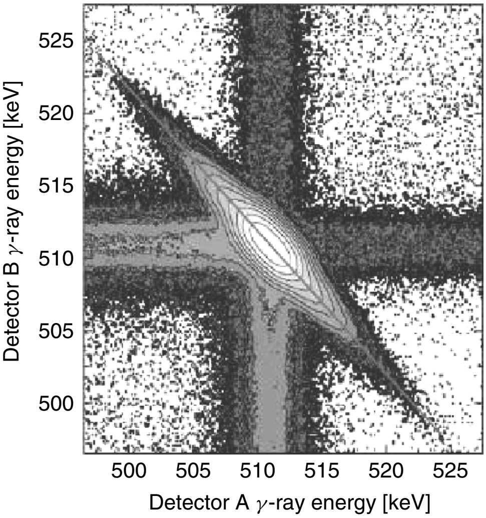

Fig. 5.6 A 2D raw data from coincidence DBAR measurement. The peak, indicated by the diagonal from top left to bottom right, is $\sqrt{2}$ narrower than a single-detector spectrum, and has essentially no background. (Courtesy Halle positron group.)

5.3.5
Positron Beams

Positron beams offer two major advantages over traditional positron systems: (i) the control of incident positron energy, and thus average implantation depths from the surface to depths of a few micrometers, and (ii) the separation of the thermalization of positrons implanted into a material from their eventual annihilation in another. This has led to new applications in surface, near-surface, interface, and thin-film studies.

The reemission of work–function–energy positrons from a solid surface was outlined in Section 5.2.2.5, Positron Reemission. In the case of simple metals, the fraction of implanted positrons reaching an exit surface is optimized if the moderator metal contains very few nonequilibrium defects. This means annealing, preferably *in situ*, to as high a temperature as possible (say $\sim$0.8 T_m) in as low an ambient pressure as possible (e.g., $\sim 10^{-6}$ Pa or less). Because of its high positron work function ($\varphi_+ \sim 2.7$ eV), however, tungsten operates well as a positron moderator after greatly varying preparation procedures. The same is not true, for example, with nickel or copper – whose $\varphi_+ \leq 1$ eV – for which careful surface cleaning and maintenance is required.

Many moderator geometries have been used; the simplest and most common is the mesh, which has quasi-transmission geometry. Moderator efficiencies are commonly in the $10^{-4} - 10^{-3}$ range. Choice of moderator material and geometry is governed by the application of the positron beam – for example, for many applications, the priority is simply to maximize moderator efficiency, whereas for others a well-collimated parallel beam requires a planar low-ϕ_+ surface cooled to minimize thermal smearing.

The highest moderation efficiencies (above 10^{-3}) recorded are for solid rare gases, in which positrons do not fully thermalize and have a long effective diffusion length, which can be condensed directly onto the radioactive source capsule.

It has long been recognized that moderation efficiency could be greatly enhanced by drifting a larger fraction of thermalized positrons to the exit surface by an internal electric field, but there has been little practical progress to date on the realization of such field-assisted moderators.

5.3.5.1 Laboratory-Based Beams

A standard slow positron beam system (Figure 5.7) comprises a flight tube pumped to high or ultrahigh vacuum; positrons ($\sim 10^5$ s^{-1} from a $\sim$4 GBq primary source) are transported in an axial magnetic field, sometimes with focusing elements. Unmoderated (β) positrons may be filtered from the beam by a curved section or an ExB velocity filter and the positrons are accelerated to the final desired energy either by raising the source of the system to a positive potential or by holding the sample at a negative potential. Beam positioning may be fine-tuned by using a pair of trim coils. Annihilation radiation from the sample target passes through a thin foil window to the Ge detector for DBAR measurements; detection of radiation from the source is minimized by shielding and by making the system a few metres in length. These considerations are relatively unimportant if the

system is to be used for particle spectroscopies – see Figure 5.8 – especially if electrostatic transport and focusing is in use (Roach, Bakshi and Canter, 1995).

Brightness enhancement is achieved in positron beams by repeated focusing and remoderation (see Figure 5.9). Although remoderation losses may be 70%, the

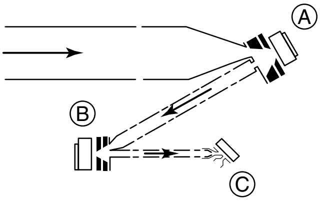

Fig. 5.9 Reflection-geometry brightness enhancement stage. A and B, remoderator surfaces; C, target.

beam area can decrease by a factor of ~50 at each stage; hence beam intensity per unit area can increase after *n* stages by a factor 15^n.

5.3.5.2 High-Intensity Positron Beams

Standard laboratory beam intensities up to $\sim10^6$ controllable-energy positrons per second are currently available, and a great range of experiments have been performed with such beams. However, to extend the capabilities and realize the full potential of positrons as a spectroscopic tool, more intense beams are essential for many studies in which the probability of an outcome is very small, for example, the combination of controlled implantation with 2D-ACAR, many surface spectroscopies where rapid measurements are required, and the study of many-positron systems.

Facility-based systems – both reactor and LINAC based – are still a main focus for intense positron beam generation, but in recent years there has been a movement toward the use of small-scale laboratory-based accelerator systems to produce short-lived but intense positron sources. In the case of LINACs (Section 5.3.1), the beam is pulsed (Section 5.3.5.3); this property can be exploited in applications where timing is an advantage. In laboratories in reactor complexes, an intense positron beam is guided far from the core and possibly subjected to remoderation, focusing, and bunching for timing applications. The production of positrons in reactor cores is not solely via the creation of intense radioactive sources, but can also proceed via pair production by energetic photons; steps have to be taken to overcome radiation damage problems in the reactor core. Several intense beam systems are in operation or are currently being developed across the world.

5.3.5.3 Beam Bunching

LINAC beam pulses are of widths from several nanoseconds to microseconds; if subnanosecond timing resolution is required, the positrons must be put through a buncher. Several buncher designs have been put into practice; the first, by Mills (1980), used magnetic mirrors. Later bunchers used radiofrequency chopping and bunching techniques – for example, the system at Munich (Bauer *et al.*, 1987), which can now achieve a timing resolution below 200 picoseconds.

5.3.5.4 Positron Microbeams

Beams of approximately micrometer dimensions have been created in the laboratory (Figure 5.10) for (i) optimum areal brightness and (ii) position-sensitive annihilation spectroscopy. Optimum areal brightness is important in positron reemission microscopy systems in which the microscope optics requires a small but very bright spot – the contrast mechanism in positron reemission microscopy (PRM) is based on the position dependence of the probability of positron

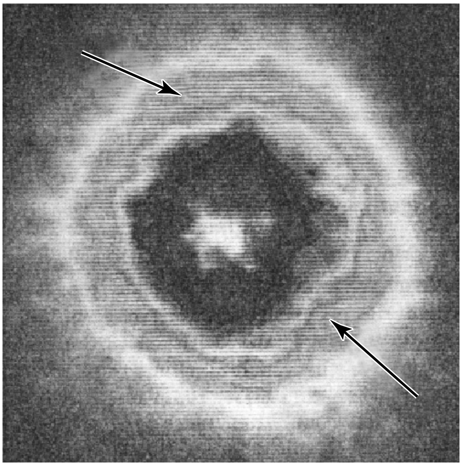

Fig. 5.10 A 10-μm square intensity cross-sectional image of a 5-keV positron microbeam at Brandeis (Canter *et al.*, 1994). The central white peak area contains approximately 465 counts per pixel, and the ring marked with arrows contains about 180 counts per pixel. Reproduced by permission, AIP.

reemission from a surface. Position-sensitive annihilation spectroscopy is required for the building of micrometer-resolution annihilation maps of near-surface structural defects by beam rastering, as has been achieved in Munich (David *et al.*, 2001).

5.3.5.5 **Polarized Positron Beams**

It was discovered in 1979 that the depolarization resulting from moderation of the β-positrons by a moderator, the basis of the creation of controllable-energy positron beams, is negligible (Zitzewitz *et al.*, 1979). Highly polarized positron beams can, in principle, probe, nondestructively, and with a degree of depth sensitivity, spin-polarized electrons in thin films or in modified near-surface regions (to depths of a few micrometers) of materials. Standard laboratory-based beams have to be adapted in two main ways: (i) the high-Z backing behind the radioactive source has to be replaced by a low-Z material to minimize backscattering, and (ii) the source has to be positioned further away from the moderator so as to select primary positrons emitted into a small forward cone (both (i) and (ii) result in loss of beam intensity). The spin polarization of a positron beam is given by

$$P = \left(\frac{v}{2c}\right)(1 + \cos\,\alpha) \qquad (5.6)$$

where v is the emission velocity, c the speed of light, and α the half-angle of the cone of acceptance of β-positrons at the moderator. (v/c is called the *helicity*.) For positrons emitted in a cone of half-angle 30° from the commonly used source ^{22}Na, $P \sim 70\%$.

There has been little exploitation of this property of positron beams, apart from an early experiment that demonstrated their capacity to probe surface magnetism (Gidley, Köymen and Capehart, 1982). The principle of the measurements is based on the comparison of DBAR or annihilation line profile data for differently polarized samples.

5.3.5.6 **MeV Positron Beams**

High-energy (approximately mega electronvolts) monoenergetic positron beams have been built and used in recent years. Megavolt accelerators used in this work have been of Pelletron or Van de Graaff type. Source-free lifetime measurements in a wide range of materials, beam-based age-momentum correlation (AMOC), and novel annihilation spectroscopies are possible with such systems – for example, positron channeling and in-flight annihilation studies, and bulk annihilation measurements, which are free of problems associated with the presence of a positron source.

5.3.5.7 Trap-Based Beams

Surko and co-workers have developed a source of very low energy positrons with extremely low energy (approximately milli electronvolts) energy spread (Gilbert *et al.*, 1997), which has found wide and important applications, particularly, but not solely, in atomic and molecular physics. The principle of their system is that positrons are extracted from a plasma of thermalized positrons stored in a Penning-type trap (Figure 5.11). The resulting beam can be DC or pulsed. Similar trap-based positron beams have been successfully employed in the antihydrogen work at CERN and other laboratories prosecuting new fundamental research.

5.3.5.8 Positron-Beam-Based Spectroscopies

The traditional spectroscopies (PALS, ACAR, and DBAR) have all been performed with positron beams, giving the extra information on depth dependence and the ability to probe depths up to approximately micrometers from a sample surface. The acronyms for such spectroscopies may be constructed by inserting VE (for variable energy) before those for the bulk spectroscopies. In all these cases, codes such as VEPFIT (Van Veen *et al.*, 1990) and POSTRAP (Aers *et al.*, 1995) are commonly used to separate and identify contributions to the measured parameters from annihilation events over a range of depths from different states such as vacancy-type defects, bulk material, interface regions, and the sample surface. The diffusion equation is solved – for example, with VEPFIT – and the positron parameter (like the lineshape parameter S) and associated effective positron diffusion length, characteristic of each chosen layer below the surface, are evaluated to achieve best fit to the experimental data. In some cases – for example, where there is one type of trapping center of concentration C_D per atom – the fitted parameter and diffusion length are linked, and self-consistency can be

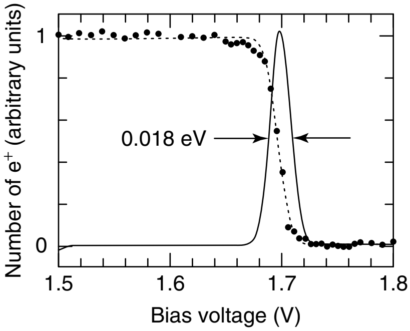

Fig. 5.11 Energy distribution of a pulse of positrons extracted from a thermalized room temperature positron plasma stored in a Penning trap (Gilbert *et al.*, 1997). Reproduced by permission, AIP.

checked. As an example, let S be the fitted lineshape parameter for a particular layer beneath a surface (i.e., between two given or fitted depths). Then $C_D = (\lambda/\nu)(S - 1)/(S_D - S)$, where λ and ν were defined in Section 5.2.2.4. Additionally C_D can also be written in terms of the effective diffusion length L as $(\lambda/\nu)[(L_+/L)^2 - 1]$, where L_+ is the positron diffusion length in the undefected "perfect" material. Equating these two expressions one arrives at $L^2 = L_+{}^2[(S - S_D)/(1 - S_D)]$.

The depth resolution of position beam techniques degrades as the mean positron implantation depth increases; the width of $P(z, E)$ (Section 5.2.2.2) is comparable to the mean depth. This means that, although resolutions of $\sim$50 nm are possible for near-surface characterization, one relies on fitting codes or known sample parameters (like film or layer thicknesses) to model depth profiles at deeper depths. The only method for maintaining depth resolutions similar to that near the surface is to employ an etch-and-measure technique, removing sequentially thin layers of material and probing the progressively revealed new surface regions with low-energy positrons. The problem with very near surface layers or thin films is the propensity for positrons to diffuse out of them, either to the surface or to nearby material, and careful fitting and/or data interpretation is required; this problem is less severe for thin layers with a very short positron diffusion length (e.g., oxides). The effects of internal electric fields must also be considered. Finally, the influence of nonthermalized positron interactions at low incident positron energies E has to be recognized, and for this reason data for E below $\sim$1 keV is often ignored.

An alternative to the use of fitting codes is the identification of different annihilation sites (e.g., layers) using the graphical method of plotting S versus W parameters for each incident energy E. An example is shown in Section 5.4.4. If there are two possible annihilation states with their characteristic S and W values – such as the sample surface (subscript S) and bulk (subscript B) – then an $S{-}W$ plot will be a straight line joining the two points (S_S, W_S) and (S_B, W_B) on the graph. Consider a third state, corresponding, say, to a defected layer with characteristic $S = S_D$ and $W = W_D$ (note that these are average *layer* values, not those specific to a particular defect); if there are energies E for which effectively all the positrons are annihilated in this layer, then the $S{-}W$ plot will have two straight lines joining (S_S, W_S), (S_B, W_B), and (S_D, W_D). Importantly, however, even if only a *fraction* of the positrons decay in the layer at any energy E, extrapolation of lines on the resulting $S{-}W$ plot will still identify the point (S_D, W_D) – just as a fitting code such as VEPFIT does. $S{-}W$ plots are thus a powerful visual tool for identifying different annihilation sites.

Positron Surface Spectroscopies Notwithstanding the fact that full realization of positron beams as a surface probe via positron diffraction, reemission, or annihilation will not come until intense positron beams are widely available, much progress has been made over the past 25 years. Positron microscopy is not mentioned in this section as it was discussed earlier in Section 5.3.5.4.

Low-energy positron diffraction (LEPD) was pioneered by Canter and co-workers at Brandeis University in 1980 (Rosenberg, Weiss and Canter, 1980) and developed by the same group over the next two decades to a level at which they could demonstrate that LEPD can be used to achieve, qualitatively and quantitatively, better agreement between experimental and theoretical $I-V$ profiles (diffracted beam intensity vs. energy), leading to significantly more reliable determinations of the surface structure than is possible using the traditional electron equivalent, low-energy electron diffraction (LEED). This improved performance is for the following reasons: (i) the phase shifts for positron scattering are less sensitive to atomic number than those for electrons, so that LEPD is more sensitive to structural parameters in multicomponent systems; (ii) the inelastic mean free path, which plays an important role in the determination of probe depth, is smaller for positrons than for electrons, and so LEPD has a greater surface sensitivity than LEED; (iii) uncertainties in the positron–electron correlation term used in LEPD calculations are less important than the equivalent electron–electron uncertainties in LEED; (iv) positrons are decelerated as they approach ion cores and so relativistic effects such as spin-orbit coupling are reduced for positron scattering from surfaces containing high-Z atoms, and LEPD $I-V$ profiles are only weakly spin-dependent when compared to LEED; and (v) as a result of the absence of spin-exchange repulsion, positrons interact more weakly with interstitial valence electrons and so the muffin-tin model works better for LEPD than for LEED for covalently bonded semiconductors.

Reflection high-energy positron diffraction (RHEPD) has been demonstrated by Kawasuso and Okada (1998). A 20-keV highly parallel positron beam is incident upon the surface being studied at glancing ($<5^\circ$) angles. The most important difference between RHEPD and its electron equivalent, RHEED, is that the high-energy positrons can undergo total reflection from the surface because of the positive crystal potential, and are thus very sensitive to the presence of adsorbate atoms, topological irregularities, and lattice vibrations in the topmost surface layer.

Positronium reflection from LiF was observed by Weber *et al.* 1988; to date, it is the only report of experimental work in this area.

Positron-annihilation-induced Auger electron spectroscopy (PAES) was developed by Weiss *et al.* (1988) in the late 1980s. Auger electron emission in PAES results from annihilation of a surface core electron by a positron implanted with very low ($\sim$10 eV) energy, rather than from impact ionization as in its electron equivalent, electron-induced Auger electron spectroscopy (EAES). The two major advantages of PAES over EAES are the elimination of secondary electron background and the extremely high surface sensitivity. Ohdaira *et al.* (1997) have developed a time-of-flight PAES system at ETL, Japan.

Positronium emission spectroscopies can provide information on electronic surface states; for example, assuming that Ps formation is a sudden process, a measurement of the Ps velocity distribution should yield information on the electronic density of states, although there remains a discrepancy between theory and experiment at low Ps energies.

2D-ACAR was first used in the mid-1980s to attempt to directly observe the positronic surface state; the observed symmetrical momentum distribution may have instead been a signature of localized surface trapping (Lynn *et al.*, 1985). 2D-ACAR was, however, successfully used to study Ps momentum distributions, and showed sensitivity to electronic structure (Chen *et al.*, 1987).

Reemitted positron spectroscopy measures the energy spectra of positrons reemitted from a film-covered surface as a function of overlayer thickness (Gidley, 1989; Ociepa *et al.*, 1990), which has been shown to be an excellent probe of any processes that affect the sum of the positron and electron bulk chemical potential, including alloying of the overlayer film.

Positronium formation spectroscopy, that is, monitoring variations in Ps yield (both in magnitude and dependence on incident positron energy) or in the Ps contribution to 2D-ACAR spectra, is an extremely sensitive tool for monitoring oxide growth on metals and semiconductors.

Future developments in positron surface studies may include *positron-induced ion desorption, surface barrier potential measurements* via very low energy (approximately electronvolts) positron reflection, glancing-angle RHEPD, and the dependence of the Ps formation probability on incident positron energy (coupled with LEED, for the surface atomic configuration, and angle-resolved ultraviolet photoemission spectroscopy, for information on electronic states). Similar measurements can give information on the atomic positions of the adatoms, even if these are hydrogen (in contrast to the conventional angle-resolved photoemission). In *inverse Ps formation spectroscopy*, a beam of Ps atoms bombards a surface, the electron is given up to an unfilled state, and the positron takes away information on that state; this spectroscopy should be more sensitive than existing probes.

The advance of positron surface science, however, awaits more widespread availability of intense positron beams. Examples of developments that may flow from such availability include *positron holography*, proposed as intrinsically more suitable than electron holography because of the positron's weak scattering and large damping in solids; *polarized PAES*, in which a highly polarized incident beam of positrons creates polarized core holes to enable novel studies of magnetic surfaces; *reemitted positron energy loss spectroscopy; Ps diffraction*; and *inverse Ps formation.*

5.4
Examples of Research Using Positron Spectroscopies

The following examples are designed to provide an overview rather than a detailed summary of every important result obtained using positron annihilation spectroscopy (PAS) and VEPAS techniques. A relatively small number of examples will thus be selected to demonstrate the applicability of the various techniques.

5.4.1
Vacancy-Type Defects

The propensity for diffusing positrons to trap in open-volume point defects has been the basis of one of the major applications of positron spectroscopy.

The measurement of formation enthalpies H_V^F for thermally generated equilibrium defects has long been a staple of PAS in bulk solids. Both DBAR and

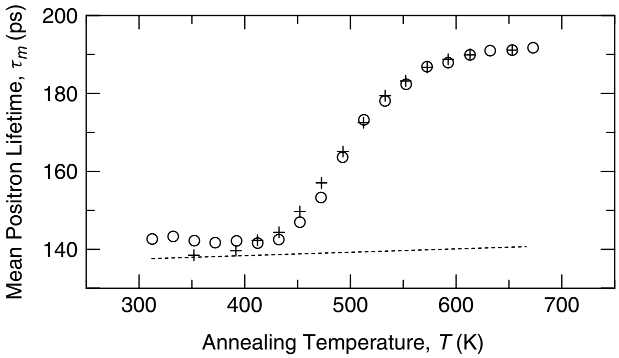

Fig. 5.12 Temperature dependence of the mean positron lifetime in Cu_3Sn. Error bars are within the points. Circles, ramping up; crosses, ramping down in temperature (Shishido *et al.*, 2007). Reproduced by permission, Wiley-VCH.

PALS have been used for such studies. Figure 5.12 shows a recent measurement of mean positron lifetime τ_m in the alloy Cu_3Sn; the rise in τ_m above 433 K indicates the formation of vacancy traps. The positron trapping rate κ is deduced from the measured positron parameters (either lineshape or mean lifetime – called P here) normalized to the bulk defect-free value P_b (so that $P_b = 1$) as

$$\kappa = \frac{(P-1)}{(P_d - P)} \tag{5.7}$$

where P_d is the parameter associated with the defect (in Figure 5.12, the high-temperature asymptotic value). The slope of the Arrhenius plot of κ versus $1/T$ then yields the vacancy formation enthalpy H_V^F. In this example, the value of H_V^F was similar to that measured for Cu, suggesting that the vacancies are being formed on Cu sites.

Nonequilibrium vacancy defects, such as those induced by strain or implantation, have also been widely studied by PAS. Figure 5.13 shows raw VEDBAR data with a typical response to defects (principally divacancies) produced by 2 MeV Si^+ ion implantation into Si for a range of ion doses from 10^{11}–10^{15} cm^{-2} (Coleman, Burrows and Knights, 2002). Observations from this and other measurements for mega electronvolt ions of widely different masses led to the universal expression for divacancy concentrations at approximately half ion range

$$C_D = (2.79 \times 10^{10})\,\phi_A{}^{0.63}\ \text{cm}^{-3} \tag{5.8}$$

where ϕ_A is the ion dose corrected by a multiplying factor equal to the vacancy/ion/Å value provided by the widely used simulation code SRIM (www.srim.org).

PAS can give information about dislocations – both in bulk materials and in thin films (e.g., relaxed SiGe) – primarily because it is thought that vacancies exist in kinks along the dislocation line and diffusing positrons are thus trapped by them.

5.4.2
Structural Changes

PAS has been, and continues to be, exploited in the study of structural

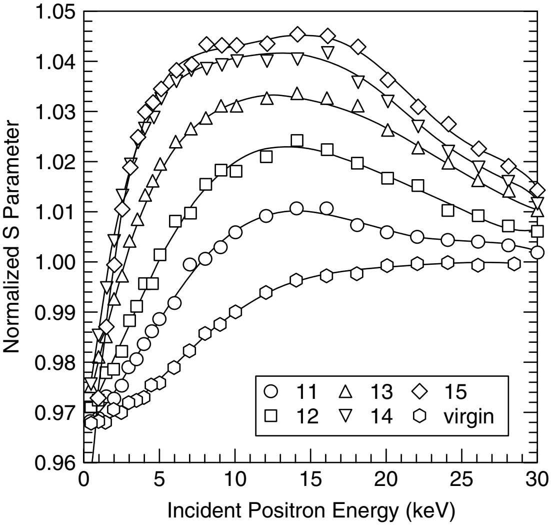

Fig. 5.13 Normalized S(E) for *FZ* Si unimplanted and implanted with 2 MeV Si^+ ions at doses of 10^n cm^{-2} ($n = 11, 12, 13, 14$, and 15) (Coleman, Burrows and Knights, 2002).

changes associated with phase transitions, precipitation, deformation, and so on, induced thermally (including aging at room temperature) or mechanically. For example, monitoring the S parameter as the steel Fe–Mn–Si–Cr–Ni is deformed (Mostafa *et al.*, 2007) shows no response below a few percent strain, as the macroscopic deformation associated with reorientation of martensite plates does not create microdefects that trap positrons. Above ~5% strain S increases as vacancy sites are created, some perhaps along dislocations, until at ~16% strain and above the response starts to saturate as all positrons become trapped; this behavior is also seen in CuZnAl shape memory alloys. The nonlinearity of the corresponding S–W plot (see Section 5.3.5.8) suggests that there is a variety of defect types created, and/or that the alloy undergoes a γ–ε phase transition during deformation (as seen in microscopic images).

5.4.3
Nanoparticles

An important recent advance in PAS has resulted from the observation that positrons can act as "magic bullets" in the study of embedded nanoparticles, either residing in the open volume around the particles or being preferentially attracted to them via their greater positron affinity. In both cases, the positrons are much more sensitive to the nanoparticles than would be expected from geometrical arguments alone. An example of this, which, in addition, illustrates the use of coincidence DBAR to gain chemical information on the atomic environment of the annihilated positrons, is shown in Figure 5.14 (Nagai *et al.*, 2000). The spectra shown are ratios of the outer

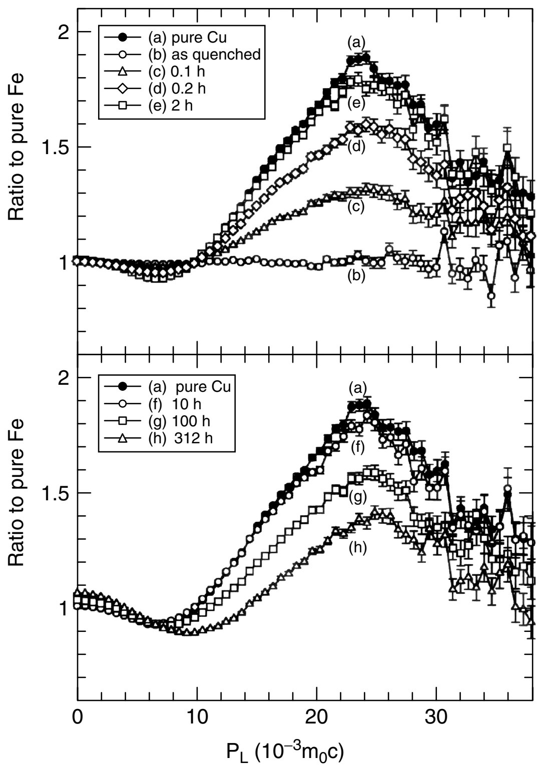

Fig. 5.14 CDBAR ratios of $Fe_{0.99}Cu_{0.01}$ to pure Fe: (a) pure Cu, (b) alloy as quenched, the after aging at 550 °C for (c) 0.1 hour, (d) 0.2 hour, (e) 2 hours, (f) 10 hours, (g) 100 hours, and (h) 312 hours (Nagai *et al.*, 2000). Reproduced by permission, APS: http://link.aps.org/abstract/PRB/v61/p6574.

wing parts of the measured annihilation line to that of Fe. Positrons are shown to be annihilated preferentially by Cu electrons as Cu nanoparticles form in a dilute (1%) alloy of Cu in Fe, by virtue of the 1 eV-deep well created by the relative positron affinities of Cu and Fe.

5.4.4
Interfaces

Generally, positrons are significantly more sensitive to interface states than geometric models would suggest, as they are commonly trapped there during diffusion. An example of VEPAS response to interfaces is shown in Figure 5.15, which also demonstrates the usefulness of the graphical parameter–parameter method; here, two *W* parameters, rather than the more usual *S* and *W*, have been plotted (Coleman *et al.*, 2007).

5.4.5
Fermi Surfaces

Knowledge of the details of Fermi surfaces can aid understanding of material properties, and 2D-ACAR represents a major tool for probing such surfaces. An example is a study of a rare-earth nickel borocarbide, which exhibits competing or coexisting antiferromagnetism and superconductivity. Dugdale *et al.* (1999) found evidence supporting this from the nesting behavior found in a particular sheet of the Fermi surface for $LuNi_2B_2C$ (Figure 5.16).

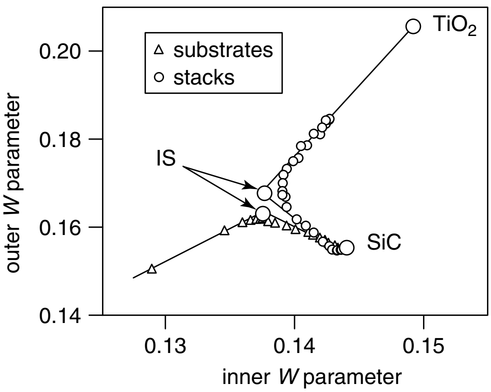

Fig. 5.15 $W_o - W_i$ map for TiO2 stacks on SiC stacks and for SiC substrates. The "pure state" points for SiC and TiO$_2$ are shown as circles, as are the two closely related interface state (IS) (Coleman *et al.*, 2007).

(b): Fermi surface topology of LuNi$_2$B$_2$C – experimental (top) and theory for third band in the (001) plane through the Γ point. The arrow indicates the nesting feature. From Dugdale *et al.* (1999). Reproduced by permission, APS: http://link.aps.org/abstract/PRL/v83/p4824.

5.4.6
Nanoporous Materials and Open Volumes in Polymers

The application of Ps and positron lifetime measurement have long been used as a probes of open volume in polymers, often used in conjunction with other experimental techniques such as differential scanning calorimetry and ionic conductivity measurements. An example of a recent application was the study of polyethylene glycol dimethacrylate (Figure 5.17), where PALS was performed for temperatures in the range 100–370 K (Bamford *et al.*, 2001). These measurements allow the evaluation of the glass transition temperature, coefficients of expansion of the hole volume, fractional free volume, and hole number density.

There has been much activity in recent years in the area of pore size measurement and distribution in thin

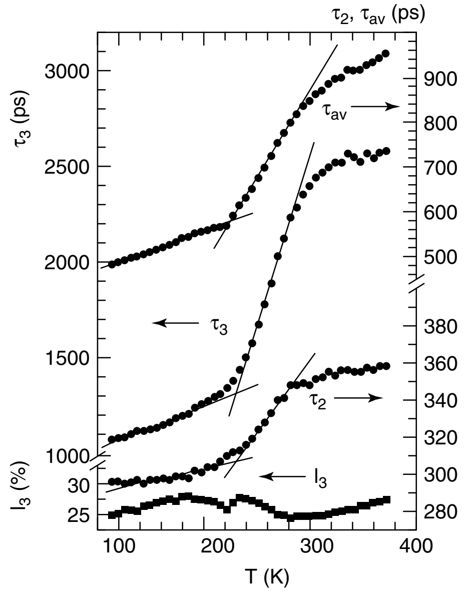

Fig. 5.17 The o-Ps lifetime τ_3, its intensity I_3, the e^+ lifetime τ_2, and the average positron lifetime τ_{av} in poly[(EG)$_{23}$DMA]; from Bamford *et al.* (2001). Reproduced by permission, AIP.

low-*k* dielectric layers grown for nanoelectronics applications. The basis of these measurements is that Ps can form in nanometer-sized pores, and its lifetime is linked to pore size. It is also possible to measure lineshape parameters and the ratio of three-γ (*o*-Ps) to two-γ decay events, both sensitive to the decay of Ps, to obtain some measure of the size, number density, and interconnectivity of the pores. These methods can be applied to films of thickness of approximately micrometers, and can provide some depth sensitivity, if linked to a positron beam system. Because Ps lifetimes can be approximately nanoseconds, timed beam systems can be constructed with relatively long timing resolutions, such as that of Gidley *et al.* (2000), Figure 5.18, who use the detection of secondary electrons to tag incident positrons. Interconnectivity can result in Ps escape as a long-lived naturally decaying entity in the vacuum space above the sample.

5.4.7
Surfaces

Although there have been several new initiatives in recent years in positron-surface studies, and activity in the ultrathin film and polymer coating field, which could be considered as surface science, we focus here on the two spectroscopies with the longest history and the most impressive results to date – that is, PAES and LEPD.

A recent example of the power of PAES, illustrating the advantages outlined in Section 5.3.5.8, Positron Surface Spectroscopies, involved the study of Se passivation layers on the Si(001) surface by time-of-flight PAES (Zhu *et al.*, 2005). The Se monolayer was found to be stable after days of air exposure, the physisorbed oxygen on the passivated surface being desorbed below 400 °C. The Se passivation layer desorbs from the Si(001) surface above 800 °C in ultrahigh vacuum (Figure 5.19).

In the clearest demonstration of the advantages of LEPD over LEED for the evaluation of the surface structure of some materials – specifically compound semiconductors – Chen *et al.* (1993) showed that the multiple-scattering theory fits LEPD data better than LEED and hence yields structural parameters with smaller uncertainties, and suggested that the differences between LEPD and LEED results were real (see Figure 5.20).

5.4.8
Positron Microscopy

The Brandeis positron reemission microscope used brightness enhancement to obtain a bright microbeam of ~5-μm diameter full width half maximum and $\sim 10^6$ positrons per second. The microscope was able to image defect structures on the surface of a thin Ni(100) film with a spatial resolution of 300 ± 10 nm (Brandes, Canter and Mills, 1988) (Figure 5.21). Improved resolution should be possible with the application of intense positron beams. More recently, there has been work aimed at further exploitation of positron reemission microscopy in Japan, and in Munich an approximately micrometer-pulsed beam (David *et al.*, 2001) was rastered across a surface exhibiting a fatigue crack on the micron scale, creating the two-dimensional positron lifetime image shown in Figure 5.22, which showed the presence of vacancy defects around the crack invisible to standard microscopic methods (Egger *et al.*, 2002).

5.4.9
Positron and Positronium Chemistry

Some current areas of activity in positron and Ps chemistry were mentioned earlier

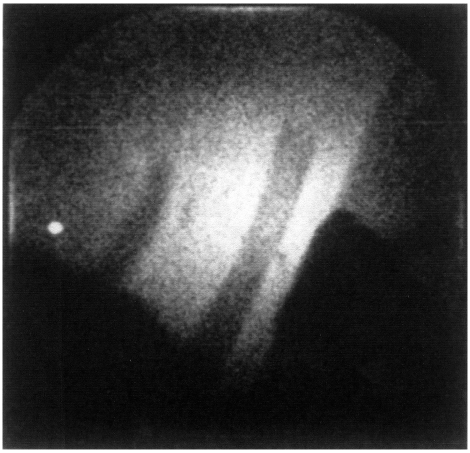

Fig. 5.21 Positron reemission microscope image of Ni foil with contrast due to positron trapping at defects. Magnification 1150. Data collection time 14 hours, white areas have ~40 counts/pixel. From Brandes, Canter and Mills, 1988. Reproduced by permission, APS: http://link.aps.org/abstract/PRL/v61/p492.

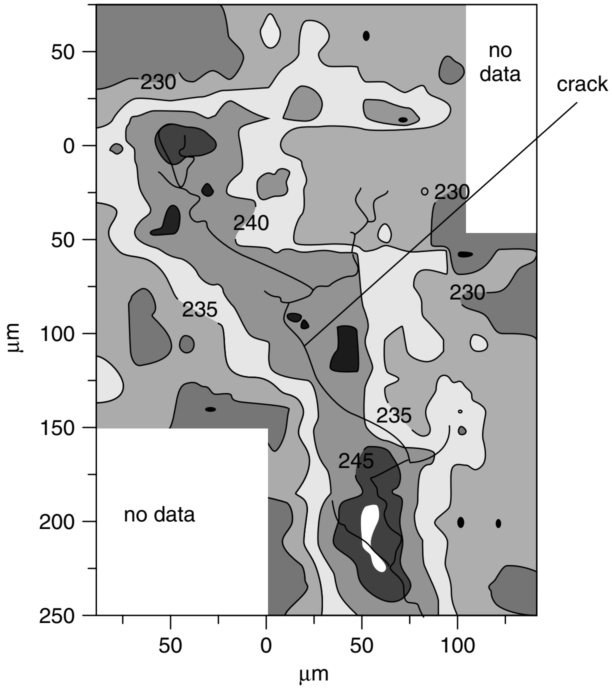

Fig. 5.22 Positron lifetime image of a fatigue crack in copper taken by the Munich scanning positron microscope; lifetimes range from 200 to 250 picoseconds. Incident positron energy = 5 keV (David *et al.*, 2001). Reproduced by permission, Elsevier.

in Section 5.4.5. The formation of Ps in liquids, its enhancement and inhibition, electron and positron scavenging reactions, the formation of positron and Ps bound states, Ps trapping in "bubbles" in liquids, Ps oxidation and spin conversion, have been studied experimentally using PALS, DBS, and ACAR spectroscopies as well as AMOC (Section 5.3.4.2). Rate constants for Ps reactions have been deduced; because Ps is a light particle its diffusion time has to be taken into account. Further details on the chemical reactions of positrons and Ps can be found in the book edited by Jean *et al.* (see the section Further Reading).

Acknowledgments

The author is grateful for the support of the Engineering and Physical Sciences Research Council, UK, over many years, and currently under grant EP/F029829/1. He also acknowledges the guidance he obtained from the earlier contribution to this Encyclopedia of Csaba Szeles and Kelvin Lynn.

Glossary

Angular correlation: The angular distribution of two annihilation γ-photons about 180°, directly related to the momentum distribution of the annihilating pair (and hence, in condensed matter, essentially the electron momentum density).

Annihilation: The decay of a positron–electron pair, with the emission of energy in the form of γ-radiation; for free particles, two photons are most commonly emitted.

Doppler broadening: The broadening of the annihilation γ-line due to the nonzero momentum of an annihilating positron–electron pair.

Lifetime: The mean life of a positron in a material.

Positron: The antiparticle of the electron.

Positronium (Ps): The quasi-stable positron–electron bound state, existing as *ortho*-Ps (spin 1) or *para*-Ps (spin 0), decaying naturally with the emission principally of three or two photons, respectively.

Specific trapping coefficient: The probability of positron trapping by a particular type of defect per second per defect site. The product of this coefficient and the defect concentration (per atom) gives the trapping rate.

Trapping: The localization of positrons (and sometimes Ps) in defects sites; vacancy-type defects are deep traps and negatively charged impurities are shallow traps.

INTRODUCTION

Power electronics, as the name indicates, is electronics that deals with high power, and the power level may vary from a few watts to a number of gigawatts. Basically, the subject deals with conversion and control of electrical power and its applications. The core of a power electronics apparatus consists of a converter built with a matrix of power semiconductor switching devices that work under the guidance of control electronics. The converters can be classified as rectifier (ac-to-dc converter), inverter (dc-to-ac converter), chopper (dc-to-dc converter), ac-power controller (at same frequency), and cycloconverter (direct frequency converter), which will be discussed later. The motivation for using switching devices in a converter is to increase converter efficiency because an ideal switching device has no loss. A converter can be looked upon as a power amplifier. However, compared to a class A or class B linear amplifier where the efficiency is low because of large device dissipation, the switching-mode amplifier efficiency is high. One drawback for switching-mode operation of a converter is that it introduces harmonics in the source and load sides.

Recently, the application of power electronics is growing extensively in industrial, commercial, residential, aerospace, and military environments for applications such as heating and lighting control, electrochemical processes, ac- and dc-power supplies, electronic welding, and dc- and ac-motor drives. Some of these applications will be reviewed later. Power electronics is helping industrial productivity and quality improvement of products. Another aspect of power electronics application is saving of electrical energy, which indirectly helps to solve the environmental pollution problem. In this article, the power semiconductor devices are reviewed

first. Then, topologies of converters for different types of conversion are reviewed. Finally, a few selected applications are discussed. The references cited at the end will help the reader to broaden his horizon in power electronics and its applications.

1. POWER SEMICONDUCTOR DEVICES

The power semiconductor device (Bose, 1992) is the heart and muscle of modern power electronics. In fact, the evolution of power electronics in the present state has been possible because of the advent of so many types of advanced power semiconductor devices. It may be of interest to mention here that prior to the modern power electronics age, gas tubes, such as thyratrons, phanotrons, and pool-cathode mercury-arc devices, were used in power electronics. Although basically the power semiconductor device is an on-off switch, its practical behavior is far more complex in switching and conduction states. A power electronics engineer needs to understand the devices thoroughly for designing efficient, reliable, and cost-effective equipment. In this section, the operating principles and characteristics of important devices are reviewed.

1.1 Diode

The power diode, as shown in Fig. 1, is the simplest of all power semiconductor devices. Basically, it has a *p-n* junction, which, if forward biased, conducts freely, but blocks conduction with reverse polarity of voltage. A power diode has normally a near-intrinsic layer between the *p* and *n* layers to increase the voltage-blocking capability. High-power line-frequency *p-i-n* diode rectifiers are somewhat sluggish in recovery characteristic. They are available in ratings such as 5000 V, 2000 A. The applications of these diodes include battery charging, power supply, electroplating, traction, welding, and uninterruptible power supply systems (UPS). Fast-recovery diodes are used in high-frequency rectification and switching applications where the reverse recovery current and recovery time are required to be small. Gold or platinum diffusion is used to reduce the carrier lifetime but gives the adverse effect of larger conduction drop. Schottky diodes are formed by metal–semiconductor junctions and are defined as majority-carrier devices because the semiconductor does not store any minority carrier. These diodes are characterized by low conduction drop, very fast switching time, large reverse leakage current, and low voltage-blocking capability. The application of Schottky diodes includes high-frequency switching-mode power supplies and instrumentation. Zener diodes are specially made to operate with reverse breakdown so as to provide a reference voltage. The electrical and thermal characteristics of power diodes are somewhat similar to those of thyristors, and these are reviewed in the next section.

1.2 Thyristor

The thyristor, or silicon-controlled rectifier (SCR), is the main workhorse in today's power converters. The modern era of power

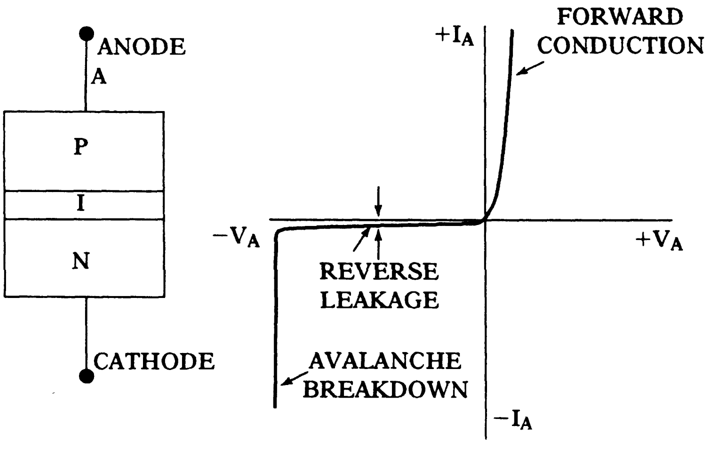

FIG. 1. Diode structure and characteristics.

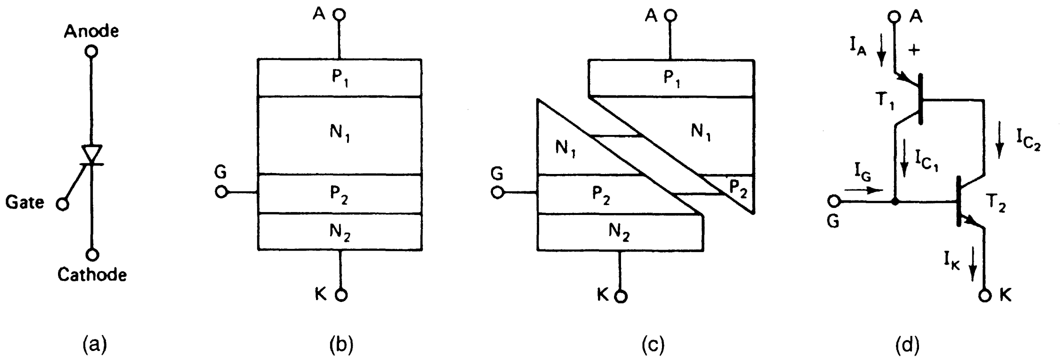

FIG. 2. Thyristor structure and two-transistor analogy.

electronics was born with the invention of the thyristor in the late 1950s. Figure 2 shows the thyristor structure, and Fig. 3 gives its volt-ampere characteristics. Basically, it is a trigger-into-conduction device that can be turned on by a positive gate-current pulse. However, once the device is on, a negative gate pulse cannot turn the device off. Commutation or turnoff is possible by applying temporarily a reverse voltage across the device. A thyristor has basically a *p-n-p-n* structure, and its triggering action can be explained by the regenerative feedback configuration of its constituent *pnp* and *npn* transistors, which give increasing current gain at higher emitter currents. A thyristor can also turn on by excessive anode voltage or its rate of rise (*dv/dt*), by a rise in temperature, or by light shining on the junctions. The device turns on rapidly, and the time is limited by the rate of rise in anode current (*di/dt*). The turnoff process is slow because the minority carriers are to be cleared from the inner junctions by "recovery" and "recombination" processes. Like other power semiconductor devices, a thyristor is connected with snubber elements for protection. A turnon snubber (inductance in series with the device) limits anode *di/dt* of the device to limit the turnon switching loss. A turnoff snubber can be unpolarized (resistance–capacitance series circuit across the device) or polarized (resistance–capacitance series circuit across the device with a bypass diode across the resistor), and it protects the device from transient voltage, reduces device *dv/dt* to prevent switch-on, and limits switching loss within the device. However, the total switching loss (including snubber loss) can be increased. A thyristor can tolerate large fault-current transiently and can be protected by a fast fuse. Within a specified junction-temperature limit (125 °C), the device can carry large current with a small duty cycle, and the current can be increased further by improved cooling. The thermal capacitance of the device and the heatsink improves the current loading within the constraint of junction temperature.

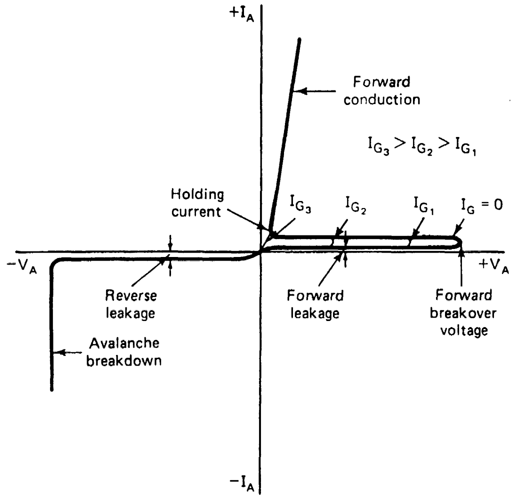

FIG. 3. Volt-ampere characteristics of thyristor.

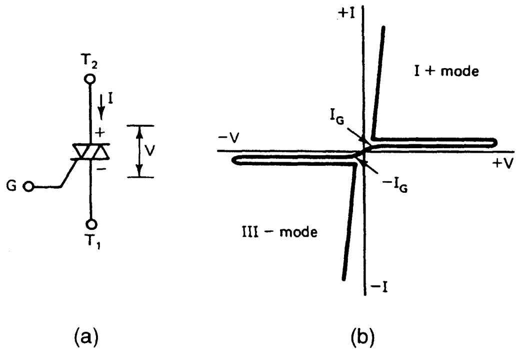
Commercial thyristors can be classified into phase-control and inverter types. Phase-control thyristors operate on an ac line and use the line commutation (commutation by a segment of inverse line voltage) principle. Modern phase-control light-triggered thyristors are available with ratings up to 6000 V, 3500 A. While a phase-control thyristor can block voltage in either polarity, an inverter thyristor blocks voltage in the forward direction only and has faster turnoff time. Thyristors are widely used in dc- and ac-motor drives, power supplies in electrochemical processes, lighting and heating control, welding control, high-voltage dc (HVDC) conversion, and solid-state circuit breakers.

1.3 Triac

A triac is basically an integration of a pair of phase-controlled thyristors connected in inverse parallel on the same chip. Figure 4 shows the triac circuit symbol and its volt-ampere characteristics. The three-terminal device can be triggered into conduction in both positive and negative polarity of supply voltage. When the supply is positive, i.e., T_2 is positive, a positive gate pulse turns on the device. On the other hand, if T_1 is positive, a negative gate-current pulse switches on the device. A triac is less expensive than a pair of inverse-parallel thyristors, and the gate-control circuit is somewhat simpler. However, there are a few disadvantages because of complex integration of two devices on a chip. The gate-current sensitivity of a triac is poor, and turnoff time is longer because of storage-charge effect. The reapplied *dv/dt* of a triac is low on account of storage charge, and it becomes difficult to supply an inductive load by a triac converter. Triacs are normally used in 50/60-Hz power lines for incandescent lamp dimming, heating control, appliance-type low-power motor drives, and solid-state ac relays. The devices are commercially available with ratings up to 800 V, 40 A.



(a) (b)

FIG. 4. Triac symbol and volt-ampere characteristics.

1.4 Gate-Turnoff Thyristor (GTO)

A gate-turnoff thyristor (GTO), as the name indicates, is basically a thyristorlike device that can be turned on by a positive gate-current pulse but, in addition, has the capability of being turned off by a negative current pulse. It has thyristorlike *p-n-p-n* structure, but permits diversion of *pnp* collector current by the gate and thus breaking of the *pnp-npn* regenerative feedback effect. The GTO is characterized by poor turnoff current gain (typically 4 or 5), i.e., a 4500-V, 3000-A state-of-the-art device needs a gate drive of −750 A for turnoff. However, because of the low duty cycle of the gate-drive current, the power rating of the gate drive is not large. GTOs are available with symmetric (both directions) and asymmetric (one direction) voltage-blocking capabilities. Voltage-fed converters use asymmetric devices whereas current-fed converters use symmetric devices. These will be discussed in Sec. 2. The turnon behavior of the GTO is similar to that of a thyristor, but its turnoff characteristics are somewhat complex and may cause second-breakdown failure. The GTO is a slow-turnoff switching device. This, in addition to the long tail current, aggravates the switching loss. Therefore, a large-size well-designed snubber is essential for GTO operation. As indicated before, a snubber diverts the switching loss from the device to the snubber circuit. Because of large switching loss, the switching frequency is limited to 1–2 kHz. For a multimegawatt GTO converter, the switching frequency may be only 500 Hz. Recently, regenerative snubbers are being suggested to improve the converter efficiency. In a regenerative snubber, the stored energy in the snubber capacitor, instead of dissipating in the snubber resistor, is pumped back to the source with the help of additional circuit elements. In spite of several disadvantages, GTOs have practically replaced the force-commutated inverter thyristors in voltage-fed inverter applications because of overall advantages of reduced size and cost and improved efficiency. Commercial GTOs are available in high power ratings, and are used in dc- and ac-machine drives, UPS systems, static reactive power compensators, induction heating, and photovoltaic and fuel-cell converters.

1.5 Power Transistor

A power transistor, also known as power bipolar junction transistor (BJT) or bipolar power transistor (BPT), is a two-junction self-controlled device where the collector current is under the control of the base-drive current. Basically, it is a linear device but is operated in switching mode to improve the converter efficiency. The fault overcurrent in the device can be suppressed by inhibiting the base drive. It has asymmetric voltage-blocking capability, and application is therefore limited to voltage-fed inverters and choppers.

The current gain of a power transistor is low but can be increased to a high value in a Darlington transistor as shown in Fig. 5. Basically, it is a cascaded connection of two *npn* transistors. The bypass diode fabricated on the monolithic chip permits reverse current to flow freely. The shunt resistances R_1 and R_2 reduce the collector leakage current and help to establish bias voltages across base–emitter junctions. The intermediate base lead B_2 can be used for fast turnoff of the T_2 transistor. The base-drive power requirement is lower than that of a single transistor, but it is at the cost of slightly reduced switching frequency and higher conduction drop.

An important property of the transistor is that its current gain varies with collector current and junction temperature. The normal dc-current rating of the device can be increased with a low–duty-cycle basis within the limits of junction temperature and wire-bond melting. Double or triple Darlington power transistors are available in module form with matched parallel devices for ratings up to 1200 V and 800 A, and converters up to several hundred kVA can be built with transistors. The device turnon and turnoff times are somewhat low, and the switching frequency can be several kHz. A polarized snubber is usually used with a transistor. The switching frequency of a device is essentially dictated by the switching loss, and at higher frequency, the losses will be higher, demanding more efficient cooling.

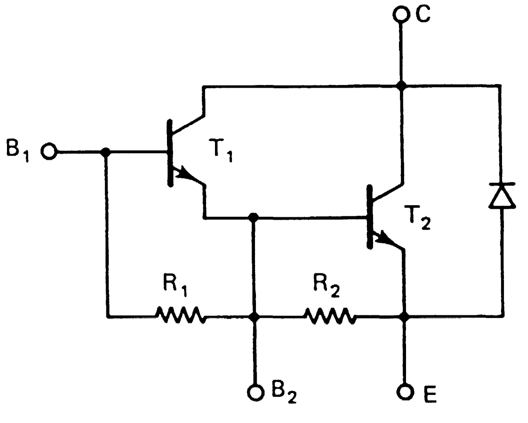


FIG. 5. Darlington transistor with bypass diode.

Power transistors are susceptible to second-breakdown failures. When the collector current is switched on, it tends to crowd on the base-emitter junction periphery (emitter crowding effect), thus constricting the collector current in a narrow area of the reverse-biased collector junction. This tends to create a hot spot, and the junction fails by thermal runaway, which is known as second breakdown. A similar problem arises when an inductive load is switched off. As the base-emitter junction becomes reverse-biased, the collector current tends to concentrate in a narrow area of the collector junction. The manufacturers provide specifications in the form of safe operating areas (SOAs) during turnon (FBSOA) and turnoff (RBSOA), as shown in Fig. 6. The load lines of the device on the volt-ampere plane should be controlled by turnon and turnoff snubbers so that FBSOA and RBSOA are not exceeded. Power transistors are popularly used in dc- and ac-motor drives, power supplies, UPS systems, static reactive compensators, induction heating, etc. Very recently, they have been challenged by IGBTs, which will be discussed later.

1.6 Power MOSFET

Unlike the bipolar transistor, a power MOSFET (metal-oxide-semiconductor field-effect transistor) is a unipolar, majority-carrier, "zero junction" voltage-controlled device. Figure 7(a) shows the circuit symbol of an *n*-channel power MOSFET. If the gate voltage is positive and beyond a threshold value, an *n*-type conducting channel will be induced that will permit current flow between the drain and the source if the drain has positive supply voltage. The gate impe-

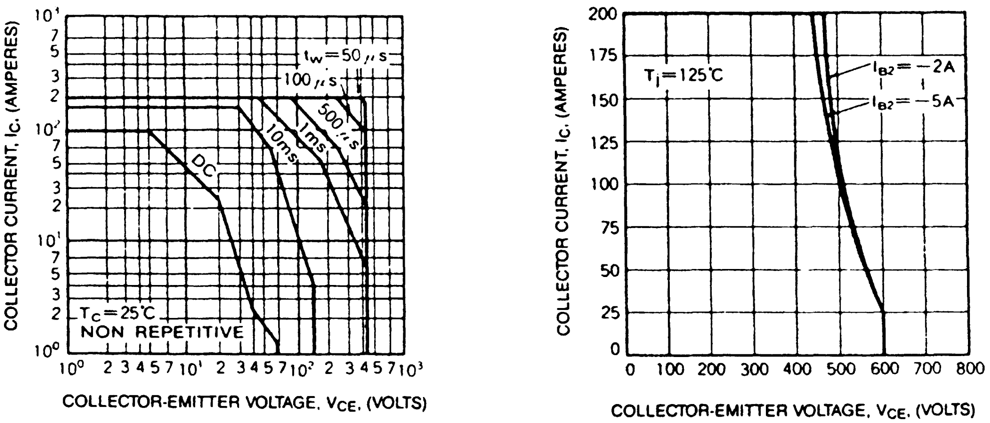

FIG. 6. Safe operating areas (FBSOA and RBSOA) of the Darlington transistor.

dance is extremely high at steady state, but the small gate-source capacitance will demand a pulse current during fast turnon and turnoff. The device is basically linear with asymmetrical blocking capability, and has an integral body diode that can carry full current in reverse direction. The diode is characterized by slow recovery and is often bypassed by external fast-recovery diodes in high-frequency applications. Being a majority-carrier device, the switching speed (turnon and turnoff times) is extremely fast, and therefore, it needs a very small-size snubber. Power MOSFETs have been used in converters with hundreds of kilohertz switching frequency. However, the device has the disadvantage of higher conduction drop, particularly with higher voltage rating. The "on" resistance of the device has a positive temperature coefficient, and therefore permits

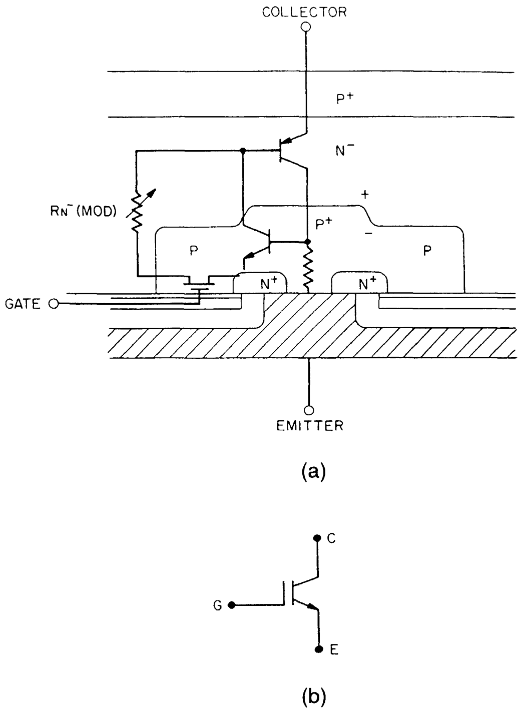
FIG. 7. Power MOSFET symbol and safe operating areas.

easy paralleling of large number of devices. The second-breakdown effect of the device is negligible. If localized heating occurs for any reason, an increase of resistance forces the current distribution to be uniform. The peak current of the device can, therefore, be increased to high value on a short–duty-cycle basis, as shown in Fig. 7(b). Power MOSFETs are very popular in low-voltage, low-power, and high-frequency switching applications, such as switching-mode power supplies, brushless dc-motor drives, and solid-state relays. State-of-the-art modules are available with ratings up to 500 V, 140 A.

1.7 Insulated-Gate Bipolar Transistor (IGBT)

Recently, the IGBT is emerging as a very important device in power electronics for converter ratings up to several hundred kilowatts. Basically, it is a hybrid MOS-gated turn on/off bipolar transistor that combines the attributes of MOSFET, BJT, and thyristor. Figure 8 shows the IGBT structure and its circuit symbol. The device architecture is similar to that of the MOSFET except that the n^+ layer at the drain is replaced by a p^+ layer at the collector, as shown. The device has the high input impedance of a power MOSFET but BJT-like conduction characteristics. If the gate is positive with respect to the emitter, an *n* channel is induced in the *p* region. This forward biases the base-emitter junction of the *pnp* transistor, turning it on and causing conductivity modulation of the *n* region, causing low conduction drop compared to that of a MOSFET. The device is turned off by zero gate voltage, which removes the conduction channel in the *p* region. The device has a higher current density than the BJT and the power MOSFET, and needs only a fraction of the die size of a MOSFET. The input capacitance is very small compared to that of a MOSFET. Also, it has improved Miller feedback effect (feedback from collector to the gate due to junction capacitances) during turnon and turnoff *dv/dt*. The device does not show any second-breakdown effect, and the RBSOA and FBSOA are thermally limited by junction temperature. IGBT converters can be designed with or without snubbers.



(a)

(b)

FIG. 8. IGBT structure and symbol.

Recently, IGBTs are being popularly used in applications such as dc- and ac-motor drives, UPS systems, power supplies, and drivers for solenoids, relays, and contactors. Although IGBTs are slightly more expensive than BJTs, the lower gate-drive requirement, availability of integrated gate drivers with protection capability, small snubber or snubberless operation, low switching loss, and higher switching frequency make the IGBT apparatus more efficient with less size, cost, and reliability. State-of-the art devices are available with ratings up to 2000 V, 500 A.

1.8 Static Induction Transistor (SIT)

A SIT is a high-power, high-frequency normally on device that has the characteristics of a triode vacuum tube that has been known for a long time. It is a majority-carrier *n*-channel device with gate electrodes buried in the channel. It is nearly identical to the junction FET except that the vertical and buried gate construction gives low channel resistance, causing lower conduction drop. The high-voltage, high-power device has been used in linear mode in audio, VHF/

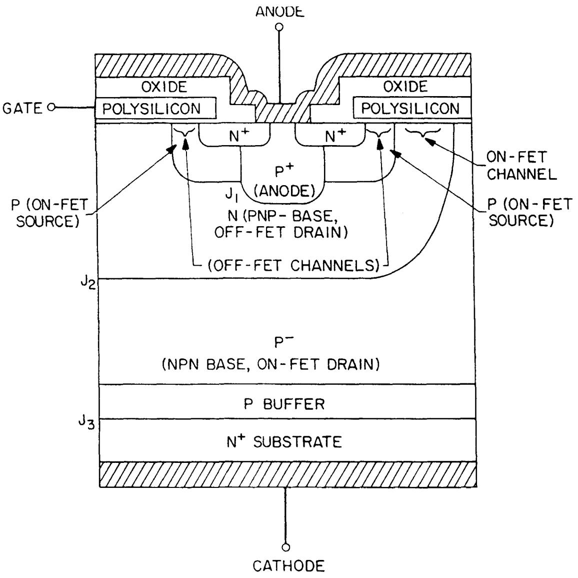


FIG. 9. MCT structure.

UHF, and microwave amplifiers and high-frequency induction heating, and ultrasonic generators in switching mode. The highest available power capability of the device is 1200 V, 300 A.

1.9 MOS-Controlled Thyristor (MCT)

A MCT, as the name indicates, is a thyristorlike trigger-into-conduction device that can be turned on and off by a voltage pulse on the MOS gate. It is more of a GTO-like switching device except that the turnoff current gain is very high. A MCT is a high-power, high-frequency, low-conduction-drop device. In switching frequency, it is somewhat comparable to the IGBT, but it has a lower conduction drop (slightly above a volt). The device has been available commercially (600 V, 75 A or 1000 V, 65 A) since 1992.

A MCT is basically a parallel connection of thousands of identical microcells on the same chip. The individual microcell structure is quite complex and is shown in Fig. 9, and Fig. 10 shows its equivalent circuit and symbol. It is turned on by a negative gate-voltage pulse (with respect to anode) and is turned off by a positive voltage pulse. The device has thyristorlike *p-n-p-n* layers, and the *pnp-npn* regenerative effect turns on the device. The device has asymmetric voltage-blocking capability, and its limited SOA demands a polarized snubber. Unlike the MOSFET, its input capacitance is fixed because of the absence of Miller effect. With the *n*-FET normally on, the device is extremely insensitive to *dv/dt* and junction-temperature triggering effect. The MCTs can be connected in parallel for higher-power equipment. In next-generation power electronics, MCTs will be serious contenders against IGBT's and GTO's.

2. POWER ELECTRONIC CONVERTERS

As mentioned before, the function of a converter is to convert and control electrical power for various applications. The conversion process may be dc to dc, ac to dc, dc to ac, or ac to ac at the same or different frequency. The type of power semiconductor used in a converter depends on the converter topology, the power rating, and the desired performance. This section will review the basic converter types for various power conversion processes (Bose, 1992).

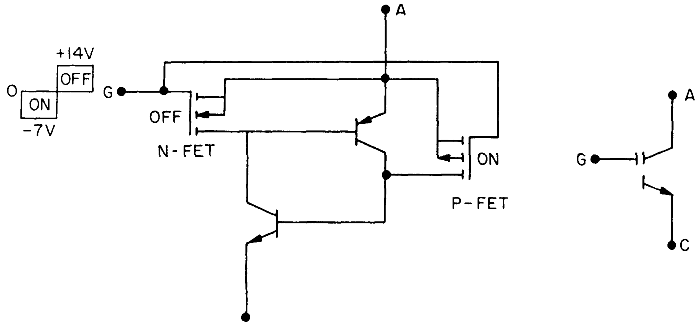

FIG. 10. MCT equivalent circuit and symbol.

2.1 dc-to-dc Converter

This type of converter changes unregulated dc voltage to regulated or variable dc voltage at the output for applications such as dc-motor speed control and switching-mode power supply. The input dc is usually a battery, or can be derived from single-phase or three-phase ac through a rectifier (as will be discussed later) and a capacitance filter. It can also be obtained from photovoltaic or fuel-cell–type dc generators. Figure 11(a) shows a simple pulse-width–modulated (PWM) dc-dc converter (also known as a chopper) for speed control of a dc motor. The power semiconductor device used is an IGBT that receives a duty-cycle–modulated wave from the control circuit. A polarized snubber is shown across the device. When the gate is positive, the IGBT switches on and the supply voltage is impressed across the machine armature. At zero gate drive, the device switches off and the freewheeling diode provides a closed path for the inductive armature current and clamps zero voltage across the armature. Therefore, by varying the duty cycle, the average dc voltage across the armature can be varied to control speed of the motor. This "one-quadrant" buck converter permits power flow from source to load only. To obtain a larger range of duty cycle, the control wave frequency can be decreased, maintaining constant on time or off time. At high speed, the motor counter emf is large, and therefore, machine current can be discontinuous. The same principle can be used in switching-mode power supply where the output dc voltage is regulated to be constant irrespective of supply and load variation. The circuit can use power MOSFETs for low-power, high-frequency application, whereas GTOs can be used for large power.

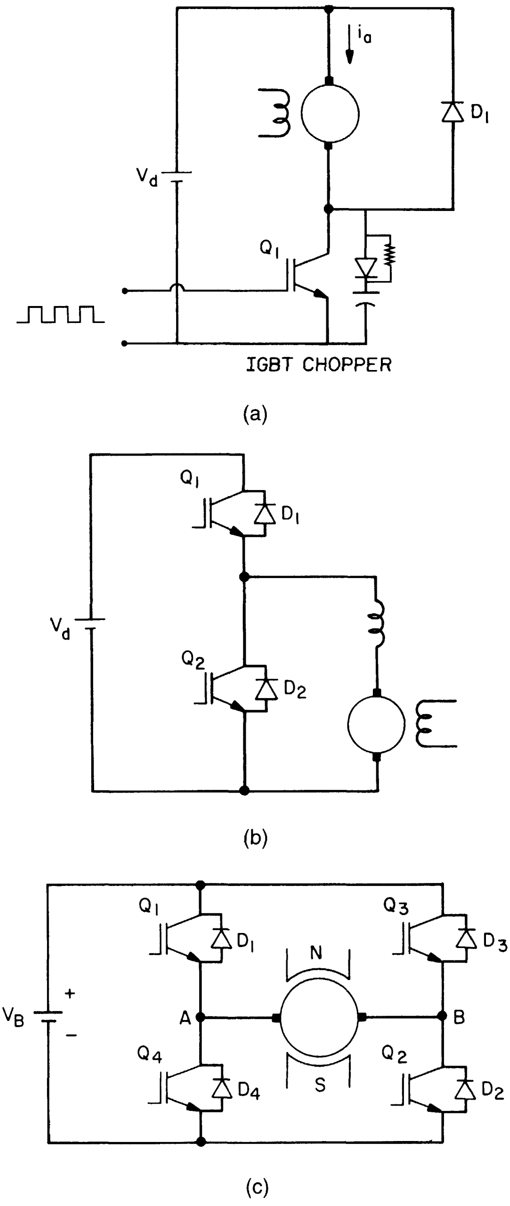

FIG. 11. dc-dc converters for speed control of dc motor: (a) buck chopper, (b) buck-boost chopper, and (c) four-quadrant chopper.

Figure 11(b) shows a "two-quadrant" buck-boost chopper for speed control with regenerative braking effect. The IGBT Q_1 with diode D_2 supplies variable voltage to the machine for motoring mode operation with or without acceleration. The devices Q_2 and D_1 operate to provide regenerative braking torque on the machine. The machine acts as a generator in this mode, and the energy is pumped back to the source. When Q_2 is on, the short-circuited armature builds armature current in the reverse direction. When Q_2 turns off, the inductor stored energy is fed to the source at higher voltage (boost operation).

A "four-quadrant" buck-boost converter for reversible and regenerative speed control using an H bridge is shown in Fig. 11(c). The four quadrants of operation can be summarized as follows:

1. Buck-converter forward motoring operation when Q_1 is on, Q_2 is chopping, and D_3–Q_1 are freewheeling.
2. Boost-converter forward regenerating operation when Q_4 is chopping and D_2–D_1 are freewheeling.
3. Buck-converter reverse motoring operation when Q_3 is on, Q_4 is chopping, and D_1–Q_3 are freewheeling.
4. Boost-converter reverse regenerating operation when Q_2 is chopping and Q_3–D_4 are freewheeling.

2.2 Phase-Controlled Rectifier

Phase-controlled rectifiers convert ac to dc by using devices such as thyristors and triacs, and are extensively used for industrial applications. As the name indicates, the converter uses the phase-angle control principle to control the dc output voltage, and a segment of ac voltage in reverse polarity is used for commutation (line commutation) of the devices. Historically, this class of converter has been available from the beginning of this century, although primitive converters used gas-tube devices, such as the mercury-arc tube (glass bulb and metal tank), ignitron, thyratron, phanotron, etc. The applications of present phase-controlled rectifiers include electrochemical processes (such as electroplating, anodizing, chemical gas production, aluminum reduction, metal refining, etc.), dc-motor speed control, dc-power supply for inverter, high-voltage dc (HVDC) converters for transmission systems, magnet power supplies, battery chargers, etc.

Figure 12 shows the popular three-phase, six-pulse bridge rectifier, and Fig. 13 gives the wave forms for a highly inductive resistance–inductance load. The delta-wye transformer on the ac-line side helps to establish the appropriate secondary voltage on the bridge and the neutral point, if needed. Each of the positive- and negative-side thyristors conducts for 120° ($\frac{1}{3}$ of a cycle), and the conduction of the negative-side device is phase shifted by 60°, as shown. The firing angle α, as indicated in (a), is controlled to control the dc output voltage. If $\alpha = 0$, the thyristor acts as a diode and the output voltage becomes maximum. Therefore, thyristors can be replaced by diodes for simple uncontrolled rectifier operation. If $\alpha = 90°$, the dc voltage or the delivered output power is zero in the ideal case. It can be shown that by varying the angle in the range $90° < \alpha < 180°$ the circuit can function as an inverter, and power from a battery (inversely connected) or energy trapped in the load inductance can be pumped to the ac line with the dc-current direction remaining the same. It is defined as a two-quadrant converter and can be used for dc-motor speed control where motoring and regenerative braking operations are possible. Because of limited load inductance, the load and line currents can be wavy, unlike that shown in Fig. 13. Again, the conduction may be continuous, as shown in the figure, or discontinuous at light load, particularly if the load contains counter emf.

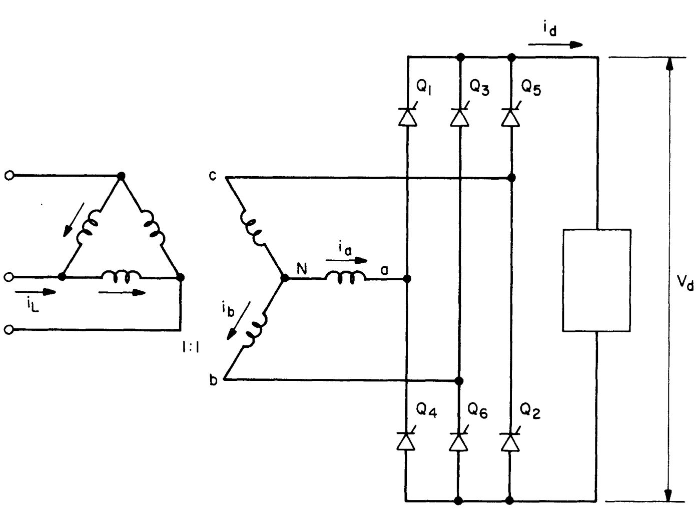

FIG. 12. Three-phase thyristor bridge rectifier.

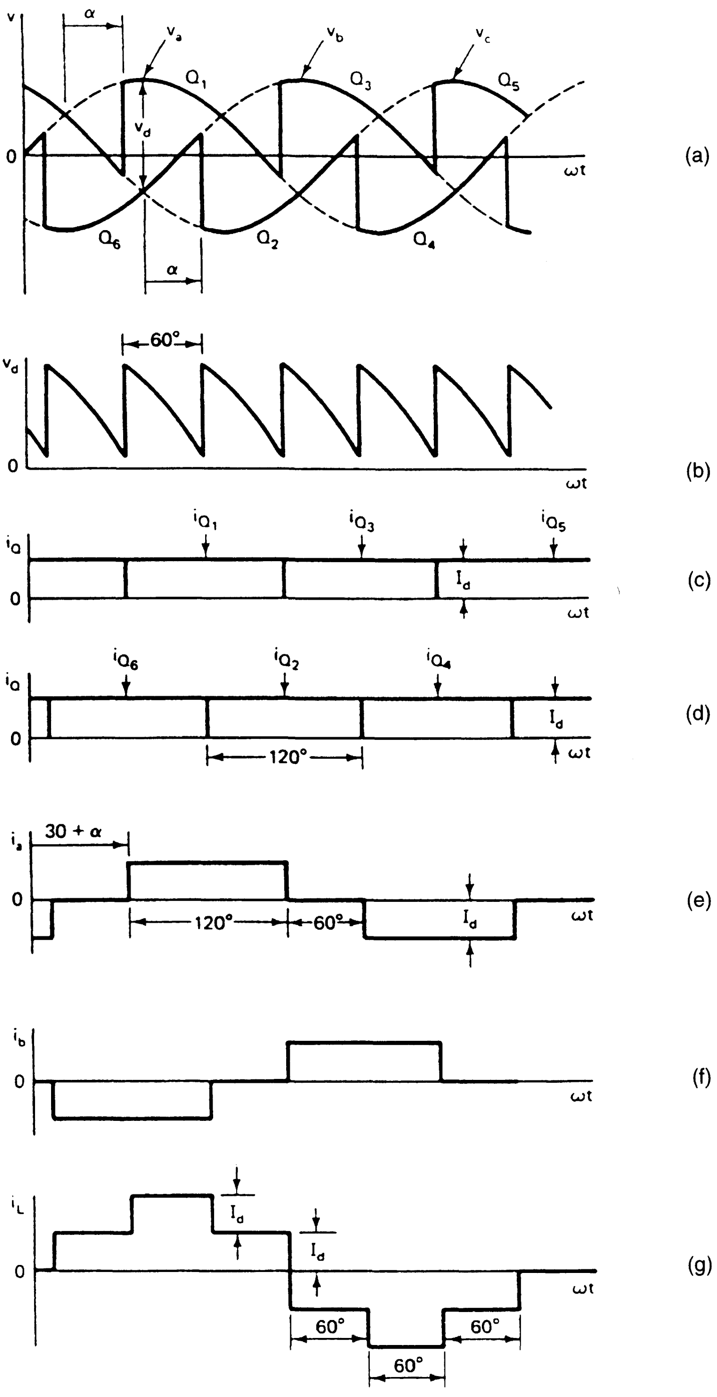

FIG. 13. Rectifier voltage and current waves: (a) envelopes for dc voltage, (b) dc-voltage wave, (c) thyristor currents for Q_1, Q_3, and Q_5, (d) thyristor currents for Q_2, Q_4, and Q_6, (e) input current i_a, (f) input current i_b, and (g) input line current.

For low power, a single-phase diode or thyristor rectifier can be used, which can have half-wave, transformer-coupled center-tapped, or full-bridge topology. A circuit can also be semibridge ($\frac{1}{2}$ of the devices are diodes) or full bridge in configuration. For high-power application, the number of phases or pulses can be multiplied (i.e., 12, 24, etc.) with a large number of devices. Such multiphase converters produce waves with low harmonic content in both dc and ac sides that can be easily filtered.

The rectifier can be considered as a nonlinear load, and the line-current and load-voltage wave forms contain rich harmonics. Besides, the fundamental component of line current lags the voltage wave form. The distorted line current tends to distort the line voltage as a result of source impedance. The large increase of phase-control–type converters on utility systems is causing power quality problems. Recently, harmonic standards, such as IEEE (Institute of Electrical and Electronic Engineers)-519 and IEC (International Electrotechnical Commission)-555 have been proposed to limit severely the harmonic injection into the utility system. Obviously, some type of filter must attenuate the harmonics, or the converter should be designed such that it does not generate any line harmonics.

2.3 Cycloconverter

A phase-controlled cycloconverter is basically a frequency changer that converts ac input power at one frequency to output at different but lower frequency with one-stage power conversion. The cycloconverters are used in ac-motor drives, slip power recovery wound-rotor induction motor drives (Scherbius drives), and varable-speed, constant-frequency (VSCF) systems, such as aircraft engine power generation at fixed frequency.

Figure 14 shows an 18-thyristor, three-phase, half-wave–type cycloconverter for an ac-machine load. For higher power, a 36-thyristor circuit can be used. In Fig. 14, each phase group consists of two half-wave converters connected in inverse parallel, which provides four-quadrant power control capability. The firing angle of each phase group is modulated sinusoidally to fabricate a mean sinusoidal voltage, as shown in Fig. 15. The other phase groups are identical except that the modulating waves are phase shifted by 120°. The output frequency (including zero frequency) and the depth of modulation can be varied for variable-frequency, variable-voltage output. The positive half-cycle of load current is supplied by the positive converter whereas the negative half-cycle is supplied by the negative converter. The nonconducting converter is blocked to prevent a short circuit.

A cycloconverter is basically a phase-controlled converter; therefore the basic characteristics, such as distortion of load voltage and line current and lagging input displacement factor, are retained. Because of modulation of firing angle, the displacement factor and harmonic content are worse. The typical output-frequency range is from zero (dc) to $\frac{1}{3}$ of the input frequency. A cycloconverter can also be operated in circulating-current mode where an intergroup reactor prevents the short circuit and limits the circulating current caused by harmonics. Although the reactor adds weight and the cycloconverter needs current derating, the advantages are that control is simple and the harmonic distortion is less, permitting higher output-frequency range (typically dc to $\frac{2}{3}$ of input frequency). Cycloconverters are used in the megawatt power range for ac-drive applications.

2.4 ac Controller

The ac controller, as the name indicates, controls the output voltage, but the output frequency remains the same as the supply

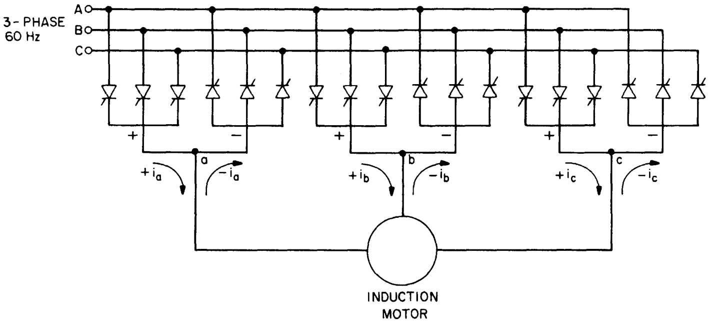

FIG. 14. 18-thyristor phase-controlled cycloconverter.

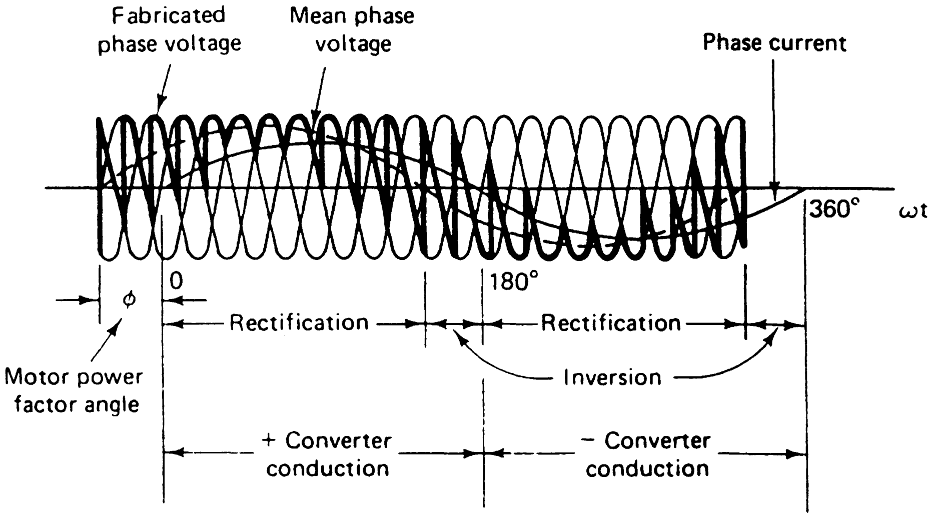

FIG. 15. Cycloconverter voltage and current waves.

frequency. An ac controller can be considered as a solid-state autotransformer where the output voltage is always less than the input voltage and the voltage control is done with the help of power semiconductor switches. Figure 16 shows a popularly used three-phase ac controller. The circuit can be used as a solid-state circuit breaker where the switches can be turned on at any instant, but can be turned off with a time delay when the device current falls to zero within a fraction of a cycle. In the "on" condition, there is power loss caused by conduction drop of the devices, which can be eliminated by bypass mechanical contactors. The control circuit can be designed to vary the thyristor firing angle gradually to get smoothly variable voltage at the output. The circuit has been popularly used as a solid-state starter for induction motors, where the voltage is gradually varied to limit the large starting current. The three-phase or single-phase version of the circuit has also been used in induction-motor speed control, transformer tap changing, induction heating, and static reactive power generation. If the load is nearly resistive, the antiparallel thyristors can be replaced by triacs. Triac-controlled circuits are used for incandescent lamp dimming control and heating control applications. Because of phase control, both line and load sides contain heavy distortion, and the line-side power factor (lagging) tends to be low. The harmonic currents flowing through the machine cause large copper loss, and the machine efficiency becomes low if the circuit is used for speed-control applications.

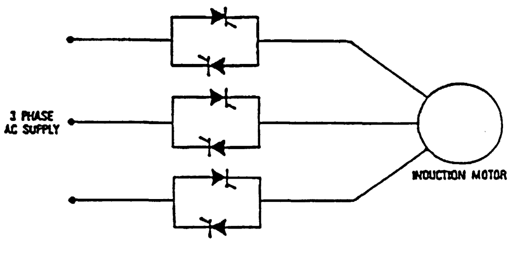

FIG. 16. Three-phase ac controller.

2.5 Voltage-Fed Inverter

The function of an inverter is to convert dc to ac, as mentioned before. In a voltage-fed inverter, the input supply is voltage, whereas in a current-fed inverter (which will be discussed later) the input supply is current. Often, a large electrolytic capacitor is connected at the input of a voltage-fed inverter. The inverter can be single-phase or polyphase type. The single-phase type can be of half bridge, full, or H bridge, or push-pull center-tap configurations. The single-phase half-bridge units can be combined to form three-phase or other multiple-phase to-

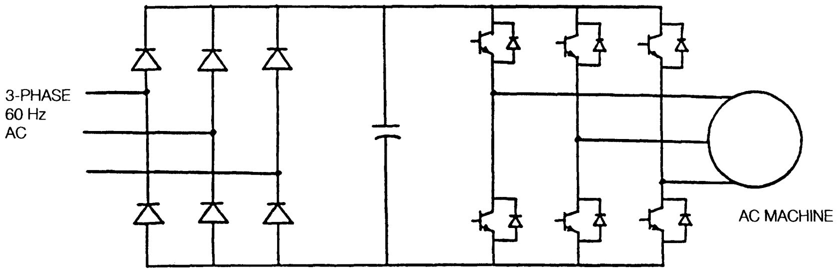

FIG. 17. Three-phase PWM inverter with diode rectifier.

pologies. Voltage-fed inverters are used for ac-machine drives, regulated voltage and frequency power supplies, uninterruptible power supplies, induction heating, ultrasonic wave generation, static reactive power generators, and active harmonic filters.

Figure 17 shows a popularly used three-phase bridge voltage-fed inverter with a diode bridge rectifier in the front end. The diode rectifier converts 60-Hz line ac into dc without any control, and the large dc-link filter capacitor filters harmonics from the voltage and provides a smooth voltage source for the inverter. The rectifier can be single-phase or three-phase type and generates discontinuous line-current wave. The inverter can generate the output voltage at a desirable frequency, as demanded by the load. The inverter uses the pulse-width modulation (PWM) principle to generate the output. Among several PWM techniques, the sinusoidal PWM (SPWM) is very popular and is explained in Fig. 18. The sine-wave signal voltage at the desirable frequency is compared with a triangular carrier wave and at intersection the upper and lower devices of an inverter leg are switched on, as indicated. There are three such controllers for the three phases where each signal wave is 120° phase shifted from the others. The output phase voltages contain harmonics of the carrier frequency, which are easy to filter. The carrier frequency is the same as the device switching frequency of the inverter. The output voltage can be regulated irrespective of supply and load variation, and the range can be from zero to a maximum value determined by the dc voltage. The fundamental frequency may vary from zero (dc) to an upper value at square wave dictated by the load. In square-wave mode, the inverter generates maximum fundamental frequency voltage. The power flow in an inverter can be controlled to be in either direction. For regenerative braking of an ac machine, the machine mechanical energy can be converted to electrical energy and pumped to the dc link through the inverter. In this mode, the in-

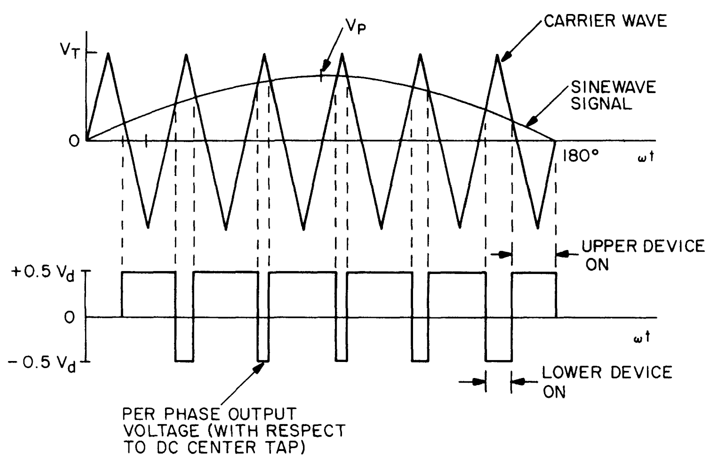

FIG. 18. Principle of sinusoidal pulse-width modulation.

verter operates as a rectifier. However, the excess dc power will raise the dc-link voltage to a dangerous level. Normally, a dynamic brake that consists of a buck chopper with a resistive load is connected to the dc link to absorb this power. In fact, the diode rectifier can be replaced by the inverter circuit to recover the energy into the ac line. Such an addition of a PWM "rectifier" on the line side not only permits full four-quadrant operation of the drive but shapes the input line current to be sinusoidal at unity power factor. Modern multimegawatt voltage-fed converter systems use GTOs, whereas IGBTs and power MOSFETs are preferred for medium- and low-power converters, respectively.

2.6 Current-Fed Inverter

A current-fed inverter requires a stiff dc-current source, as indicated before. A voltage source can be converted to a current source through an inductor and then controlling the voltage through the input converter. The phase-controlled, line-commutated, current-fed inverter (inverting mode of a rectifier) was discussed in Sec. 2.2. The inverter has various single-phase and polyphase configurations, and their applications include ac-motor drives, induction heating, ac-power supplies, static reactive power generators, and ac-line active harmonic filters.

A current-fed inverter can be classified into load-commutated, force-commutated, and self-commutated types. The former two types operate in six-pulse mode with a bridge configuration (similar to a phase-controlled converter), whereas the self-commutated type operates in PWM mode. A load-commutated inverter, which has identical topology with a phase-controlled rectifier, requires the load to be of leading power-factor type, such as an overexcited synchronous machine, so that the converter thyristors can be commutated by a segment of inverse load voltage. A practical load-commutated inverter has a phase-controlled rectifier in the front end and therefore provides easy four-quadrant speed control capability of the drive. Large multimegawatt wound-field synchronous machine drives use load-commutated converters. The converter system is very economical, but a minimum machine speed should be maintained for satisfactory load commutation by machine counter emf.

A current-fed inverter that supplies a lagging power-factor load, such as induction motor, needs forced commutation. Figure 19 shows the autosequential–type current-fed inverter (ASCI) where the capacitors and the diodes constitute the commutation elements. The diodes tend to isolate the commutating capacitors from the machine terminal. When an incoming thyristor is fired, capacitor voltage with inverse polarity is impressed across the outgoing thyristor to turn it off. This type of inverter is used in medium- to high-power applications, but recently, its importance is diminishing. The harmonic current in both line and load sides and machine torque pulsation at low frequency are problems.

The ASCI in Fig. 19 can be replaced by a self-commutated PWM GTO inverter, as shown in Fig. 20. The advantages are that

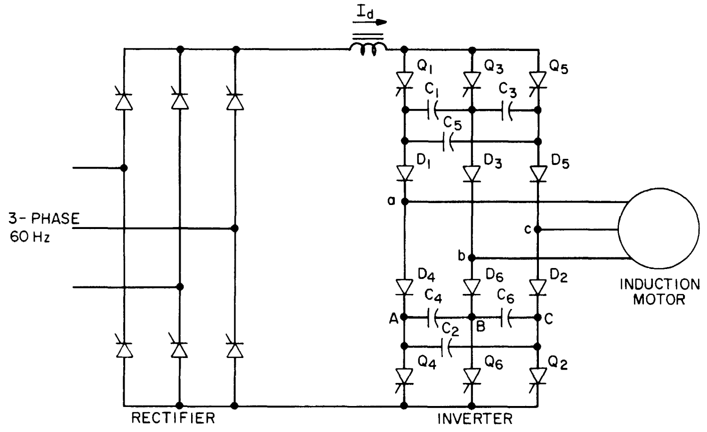

FIG. 19. Force-commutated autosequential inverter with thyristor rectifier.

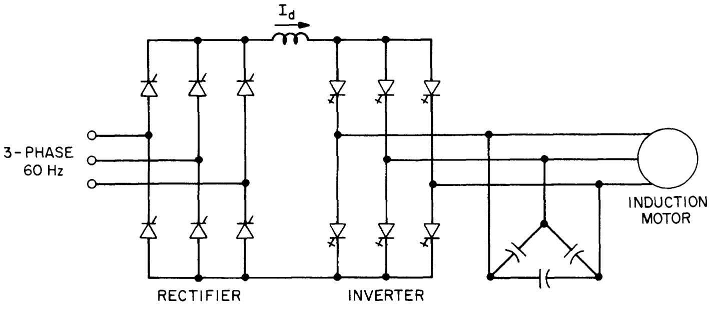

FIG. 20. PWM current-fed inverter with thyristor rectifier.

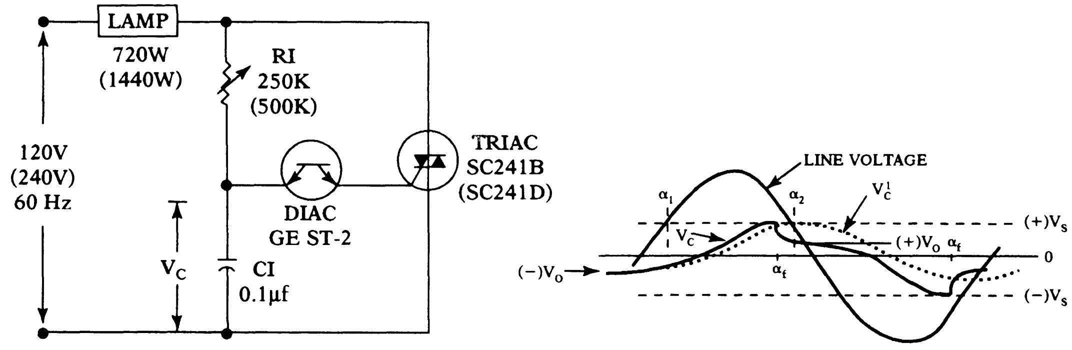
the PWM machine-current wave can be easily filtered, there is no torque pulsation problem, and the dc-link inductor size is lower. The reverse-blocking GTOs can be replaced by IGBTs with series diodes for medium-power drives. The delta shunt capacitor bank, as shown in the figure, has the functions of providing a bypass path for the load inductive current so that the GTOs can be commutated without undue voltage overshoot, and low-pass filtering the PWM harmonics so that the machine currents are nearly sinusoidal. Therefore, machine harmonic copper loss, torque pulsation, and the characteristic acoustic noise disappear. Since the inverter can carry power in either direction, the line-side phase-controlled rectifier can be replaced by the inverter unit, giving the advantage of sinusoidal line current at unity power factor.

3. SELECTED APPLICATIONS OF POWER ELECTRONICS

Many of the previous sections have touched on various applications of power electronics. In this section, a few more selected applications will be systematically reviewed.

3.1 Incandescent-Lamp Dimming

A simple application of power electronics is incandescent lamp dimming control with the help of a diac-triac phase control circuit (GE SCR Manual, 1979), shown in Fig. 21. The single-phase ac supply is connected in series with a lamp through a triac. The firing angle of the triac is controlled by the *R-C* circuit and diac to control the rms voltage across the lamp. A diac is basically an *npn* negative-resistance threshold device. The potentiometer RI is adjusted to control the dimming, where the lowest RI value gives maximum brightness of the lamp. A typical capacitor voltage (V_c) wave is shown in the figure. When the phase-lagged V_c wave crosses the diac threshold voltage V_s, a pulse of gate current flows, firing the triac. With a lower RI value, the threshold will be reached earlier in the cycle, giving a control angle in the range from α_1 to α_2. The critical resistance that will not fire the triac is shown by



NOTE:
VALUES IN PARENTHESES ARE FOR 240VAC SUPPLY.

FIG. 21. Incandescent lamp dimming control.

the dotted wave. As the resistance is decreased from this value, V_c will rise and cross the V_s threshold, and the triac will switch on with a "snap-on" effect.

3.2 High-Frequency Ballast for Fluorescent Lamps

The efficiency of a fluorescent lamp is much higher than that of an incandescent lamp although the lamp is somewhat more expensive. The efficiency can be improved further by using high-frequency lamp ballast. A typical high-frequency ballast system (Bose, 1992) is shown in Fig. 22. The 60-Hz, single-phase supply is rectified to dc with the help of a diode-bridge rectifier and then inverted to 30-kHz ac with a half-bridge voltage-fed PWM inverter. The lamp cathodes of the two lamps are continuously heated by the three secondary windings, as shown. The inverter output is boosted by an autotransformer and applied across the two lamps in series. The transformer winding leakage inductances provide the series ballast needed for stable operation at lamp conduction when its resistance is low. A filter is normally used at the input of the rectifier to suppress conducted electromagnetic interference. A high-frequency ballast not only has smaller size, but also gives better efficiency, reduces the low-frequency stroboscopic effect, and provides lamp dimming capability by control of the tube current.

3.3 Switching-Mode Power Supply

A switching-mode power supply (SMPS) (Bose, 1992) generally converts an unregulated dc voltage to a regulated dc voltage; the unregulated dc can be obtained from a battery or ac line through a diode rectifier and a filter. The SMPS generally supplies power to an electronic circuit of a television, personal computer, VCR, tape recorder, etc. Primitive power supplies used linear regulators where efficiency was poor. The switching-mode power semiconductor device improves efficiency at the cost of harmonic generation. However, with high-frequency devices, such as power MOSFETs, only a nominal filter size is needed.

The SMPS can generally be classified into two types: PWM buck, boost, or buck-boost dc-dc converter, as indicated before, and resonant-link dc-dc converter. Figure 23 shows a typical voltage-fed parallel resonant-link converter. The primary dc voltage (from a rectifier or a battery) is split with the help of capacitors and then inverted to high-frequency (several megahertz) ac by a MOSFET half-bridge inverter. The inverter supplies a series resonance (L_r-C_r) load, and the transformer connected across the capacitor feeds the high-frequency Schottky-diode rectifier, which then supplies the dc output. The inherent body diode of the device is used, and the snubber consists of a simple capacitor, as shown. The high-frequency link, al-

though it requires an additional conversion stage, provides several advantages. The operation at higher than resonant frequency permits zero-voltage switching (ZVS) of the devices, eliminating switching loss. The result is that efficiency is improved, and switching frequency much higher than that of PWM reduces the size of the isolation transformer and output passive filter. The transformer helps to change the primary voltage level. The output voltage can be regulated by varying the inverter frequency. The snubber capacitor acts as a lossless snubber, i.e., it stores energy that is returned back to the supply. For higher power, the half bridge can be replaced by a full bridge.

3.4 Induction Heating

For induction heating of metal, ac current is passed through a coil surrounding the metal workpiece. The iron loss (hysteresis and eddy-current losses) raises temperature of the metal. The induction heating for melting uses low frequency so that the heat is developed throughout the body, whereas the frequency for heat treatment may be very high where the skin effect confines the heat near the surface.

The induction heating system can use either a voltage-fed series resonance inverter or a current-fed parallel resonance inverter where the resonance-circuit inductance constitutes the work coil. Figure 24 shows a practical voltage-fed inverter induction heat-

ing system using a static induction transistor (Ogiwara *et al.*, 1987). The dc supply for the inverter is obtained from a 60-Hz line through a diode bridge rectifier and a transistor boost chopper. The boost chopper not only regulates the capacitor voltage but shapes the line current to be sinusoidal at unity power factor. The feedback voltage loop error is multiplied by the full-wave rectified line-voltage wave to generate the command-current wave of the rectifier. This current is then controlled by the boost chopper using the hysteresis-band PWM control principle. The inverter is a full-bridge type where the output is stepped down through a transformer and applied to the work coil through a series tuning capacitor. The equivalent-circuit R and L parameters of the coil vary with temperature, and therefore the resonant frequency also varies. The inverter frequency tracks the resonant frequency so that a slightly higher inverter frequency always permits lossless zero-voltage switching, as indicated before. The load power flow is regulated by control of the dc-link voltage. The basic control elements of the self-controlled converter system are indicated. The capacitor voltage, which lags the coil current by 90° and the load voltage V_L by an additional lag angle, is phase shifted for control of the inverter. The signal is converted to high frequency by a phase-locked loop (PLL) circuit and then used to synthesize a triangular wave by an UP-DOWN counter. The triangular wave is phase split and compared with a bias voltage V_B to generate the logic drive signals for the devices. The bias signal generates the appropriate lockout time to prevent shoot-through fault. Since the devices are normally on, they are biased off outside the desired conduction intervals.

3.5 Uninterruptible Power Supply (UPS)

Reliable and improved-quality power supply is important for critical loads, such as computers, communication equipment, and medical systems. The utility power supply, however, has the problems of outage, brownout, and wave form distortion. In a UPS system, a battery-backed supply is available to supplement the utility supply. The UPS system may be ac or dc, and the system topology varies widely, depending on the application. Figure 25 shows a typical three-phase UPS system (Griffith, 1989) where the load can be supplied either from the utility line or from the battery-backed inverter. An electronic circuit breaker consisting of antiparallel thyristor switches helps in the fast transfer of the source. In the figure, the utility system normally supplies the load and the inverter is the standby. The inverter system consists of a diode rectifier, battery charger, storage battery, LC filter in the dc link, PWM voltage-fed inverter, and output LC filter. The inverter generates sinusoidal regulated voltage at 60 Hz at the output from the unregulated dc input. Normally, the rectifier directly supplies the inverter input when the thyristor Q remains off. At utility

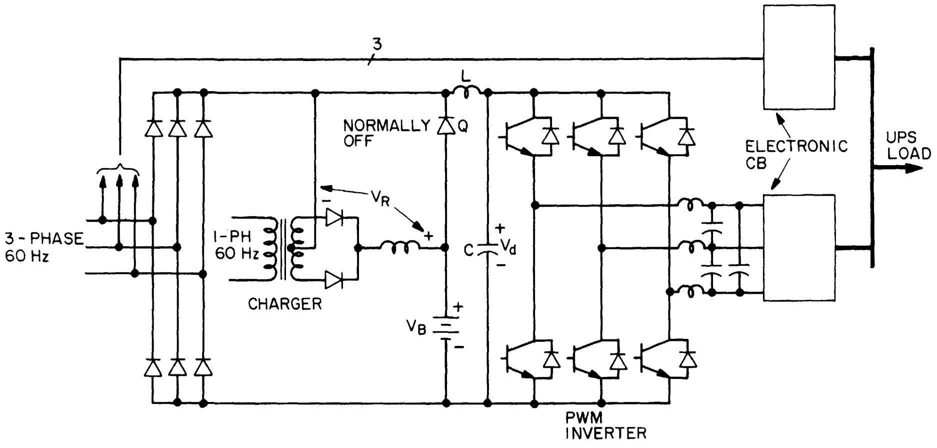

FIG. 25. Three-phase UPS system with standby inverter.

power interruption, Q is switched on and the output circuit breaker switches over the supply from the inverter. When the inverter is remaining as standby, the battery is charged by the single-phase thyristor rectifier. The rectifier boost voltage $+V_R$ acts in series with the voltage V_d to charge the battery. The transfer of load from line to inverter and back causes power interruption for fraction of a cycle, and this should be tolerated by the load.

3.6 dc-Motor Drive

One of the earliest applications of power electronics is the speed control of dc motors. dc-motor drives (Sen, 1981) in the power range of a few watts to several megawatts are widely used in industry, and the applications include instrumentation drives, robotics and machine tool drives, paper and textile mills, rolling mills, etc. In a dc drive, normally the field current is maintained constant to establish the desired flux and the armature current is varied to control the torque, which varies the speed. Generally, there are two classes of dc drives: dc-dc converter or chopper-fed drives and phase-controlled converter-fed drives. Chopper-fed one-, two-, or four-quadrant drives were already discussed in Sec. 2.1. The machines in these drives are of permanent magnet type and are of small power rating. Larger-power machines with separate field supply are generally controlled by a thyristor phase-controlled rectifier, shown in Fig. 12. The converter can provide two-quadrant speed control of the machine. This can be explained as follows: If the firing angle of the converter is reduced, the output dc voltage will increase, giving higher speed. The regenerative braking mode of operation in the same direction of rotation can be obtained by reversing the field supply and controlling the firing angle above 90°. The rectifier will then operate as an inverter with the negative counter emf load and the machine speed will fall.

Figure 26 shows a thyristor dual converter for four-quadrant speed control that is popularly used in industrial process-control applications. The positive converter (left side) can generate positive (rectifier) or negative (inverter) voltage, but the dc current is always positive. This converter will function for forward motoring and reverse regeneration. The negative converter (right side) can

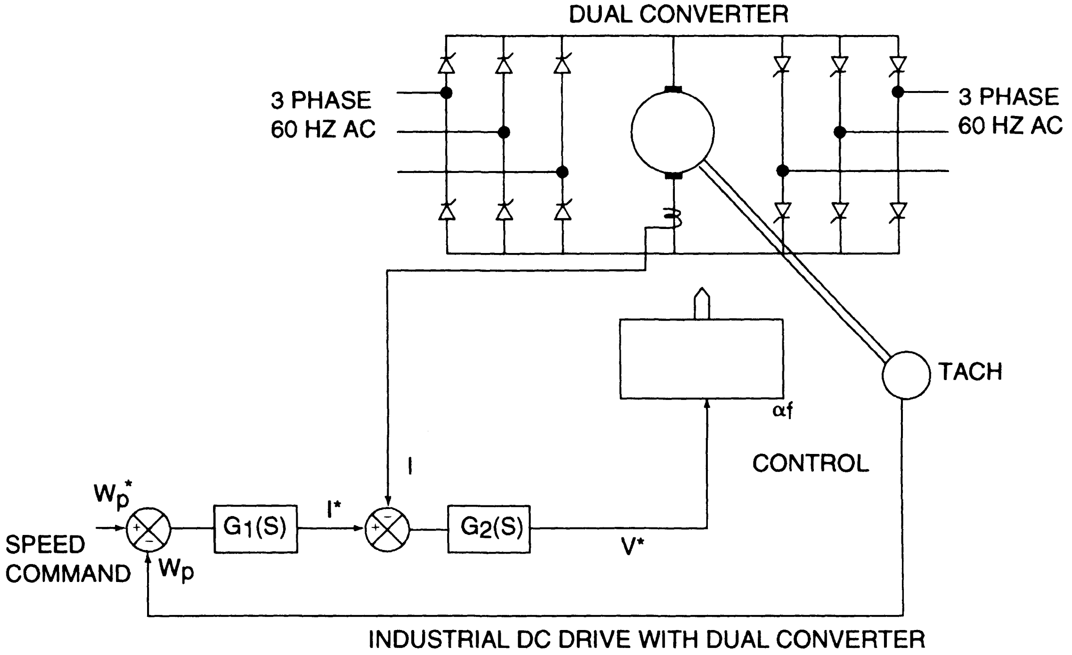

FIG. 26. Thyristor dual-converter speed control of dc motor.

generate negative (rectifier) or positive (inverter) voltage, but the dc current is always negative. This unit will permit the other two quadrants, i.e., reverse motoring and and forward regeneration. When one converter unit is operating, the other unit should be blocked to prevent short circuit. The simplified speed-control block diagram is indicated in the figure. The command speed is compared with the motor shaft speed, and the error through a controller establishes the current command for the motor armature. The armature current is then controlled by controlling the firing angle.

3.7 ac-Motor Drive

ac machines of induction and synchronous types are widely used in industry, and the application of variable-speed ac drives is increasing extensively. In this section, the popularly used induction-motor drives using squirrel-cage machines (Bose, 1986) will be discussed.

3.7.1 Open-Loop Volts/Hz Control

The speed of an induction motor can be efficiently controlled by a variable-frequency, variable-voltage power supply, as shown in Fig. 27. The converter system (same as Fig. 17) generates such a power supply for the machine. It can be shown that the airgap flux of the machine remains constant like that in a dc machine if the ratio of voltage to frequency remains constant. In Fig. 27, the speed of the machine is commanded by the frequency because the machine slip frequency is very small. The voltage signal is proportional to frequency, except that at lower speed range the signal is boosted to compensate the stator drop. The machine speed can be varied by variation of the frequency signal. However, a sudden variation of the frequency command will cause loss of machine stability. The acceleration capability is limited by the machine and inverter power ratings, and the load torque. Since there is no closed-loop control of speed, the actual speed will be slightly lower (by the slip frequency) than the desired speed. The slip frequency can be calculated from the stator voltage and current signals and added with the command signal to compensate the speed droop. The drive is simple and economical, but the performance (including the transient response) is not very good.

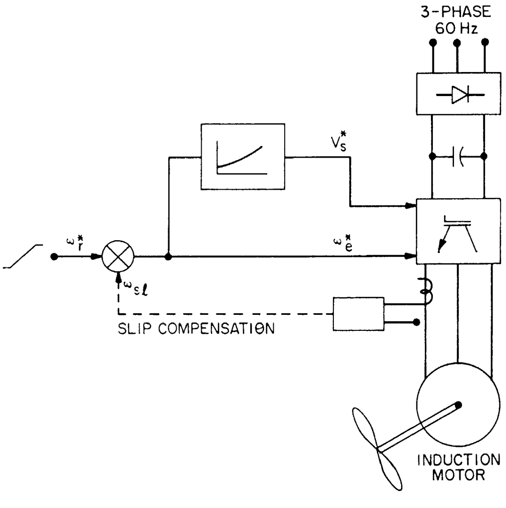

FIG. 27. Open-loop volts/Hz speed control of induction motor.

3.7.2 Vector Control

An induction motor with vector or field-oriented control gives performance that is almost identical to that of a separately excited dc motor. This means that the transient response is dc machinelike, the conventional instability problem does not arise, and the machine torque and flux can be controlled independently. The vector control can be classified into two types, i.e., direct or feedback and indirect or feedforward methods. The popularly used indirect method will be reviewed in this section. Figure 28 shows a position servo drive using the indirect vector-control method. The power circuit (same as Fig. 17) of the drive includes a dynamic brake to give four-quadrant control capability of the drive. In Fig. 28, the position-control loop generates the speed command and the speed-control loop generates the torque command (essentially the torque component of current i_{qs}), as shown. The machine is operated at a rated flux that is determined by the field component of current (i_{ds}). The slip-frequency command (ω_{sl}^*) is generated proportional to i_{qs}, and the proportionality factor is defined as the slip gain K_s. The slip frequency is added with the speed signal to

generate the frequency command, which is then converted to unit vector signals. The vector rotator converts the input dc-current commands into the ac stator-current commands of the machine. The command-phase currents are then compared with the actual currents, and the IGBT gate-drive signals are generated through the hysteresis-band current controller. Note that in vector control the current (instead of voltage) is controlled, and the machine frequency is essentially determined by the speed signal (self control). In braking mode, the polarity of i_{qs} becomes negative. For speed reversal, the phase sequence of the inverter output automatically reverses at zero speed.

GLOSSARY

Asymmetric Blocking: Blocking of device voltage in forward direction only.

Boost Chopper: A chopper in which the output voltage is higher than the input voltage.

Buck Chopper: A chopper in which the output voltage is lower than the input voltage.

Carrier Wave: A control wave in a PWM inverter that determines the switching frequency.

Commutation: Transfer of current from one device or circuit to another.

Firing Angle: Control phase angle of thyristor or triac.

Forced Commutation: A commutation that is performed forcibly by an auxiliary circuit.

Harmonic Frequency: A frequency that is a multiple of the fundamental frequency.

Line Commutation: Commutation that is performed by a segment of inverse ac-line voltage.

Load Commutation: Commutation that is performed by a segment of inverse ac-load voltage.

Power Factor: Ratio of effective power to apparent power.

Regenerative Braking: Braking of a machine by operating it as a generator and pumping back its stored mechanical energy to the source in electrical form.

Slip Frequency: Frequency of the induced voltage in the rotor of an induction motor.

Square Wave: Mode of operation of an inverter where each phase generates a square voltage wave.

Symmetric Blocking: Blocking of device voltage in both directions.

Vector Control: Control method of an ac machine that gives it dc-machine–like performance.

INTRODUCTION

Electricity, in a form useful for commercial application, does not exist naturally in the same way as a source such as natural gas. Electric power must be generated by large central power plants from some other energy source, such as water at a hydroelectric plant. For a variety of reasons, the power-generating stations are normally located far from population centers, the location of the major electrical usage. The electricity then needs to be delivered to the customers through transmission and distribution lines, which form a required portion of the metallic connection between the gen-

erating plant and the customer end-use appliance or device.

1. POWER TRANSMISSION SYSTEM

Figure 1 shows a simplified electric power system (Bonneville Power Administration, 1989). The transmission system efficiently transports bulk electric power long distances from the generator to the main substation that services a given area. The voltage of the transmission lines is usually above 69 kV and, in some parts of North America, may be as high as 765 kV. At the main substation, the voltage is reduced, or stepped down, to distribution-level voltages, normally 2.4–35 kV. The distribution lines carry the electricity into the neighborhoods, offices, and factories for individual customers.

Through the years, transmission lines have been built to operate at progressively higher voltages, as shown in Fig. 2 (EPRI, 1982). With each advance in voltage level, greater amounts of power could be transported more efficiently, economically, and with fewer circuits on less right of way. Unfortunately, the increase in voltage levels also brought about public conflicts. Before 345-kV transmission lines were introduced, the most noticeable effects were conflicts over land use and the aesthetic appearance of the line. With the introduction of extra-high-voltage (EHV) lines (i.e., 345 kV and above), new public conflicts occurred dealing with radio and television reception, audible noise, and electric and magnetic field effects. Section 4.5 discusses these electrical environmental considerations in more detail.

1.1 Transmission-System Link between Generation and Customer

The primary function of the transmission line is to transport electricity from the generating plant to the customer in a reliable,

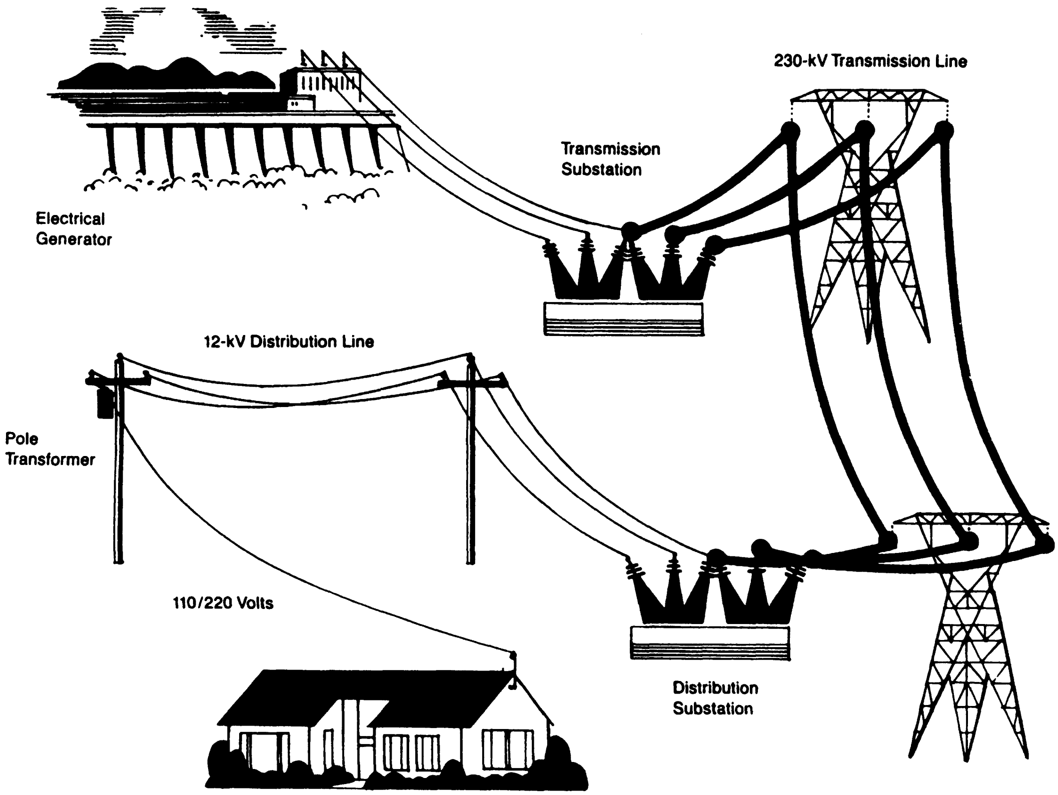

FIG. 1. Simplified electric power system.

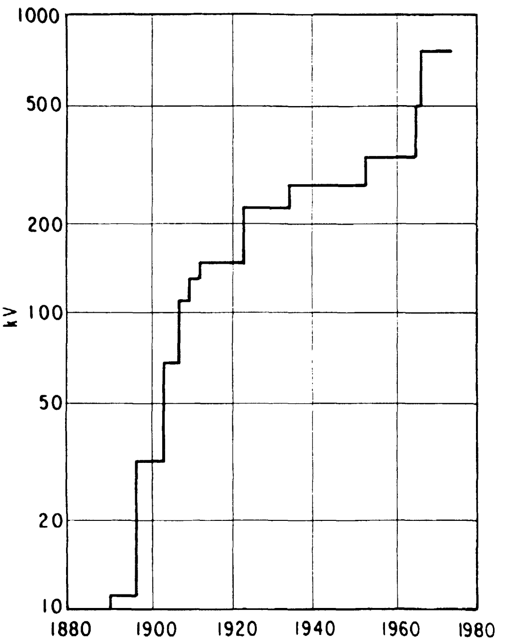

FIG. 2. Maximum ac transmission voltages in North America.

efficient, and economical manner. To meet these objectives, transmission-line design has evolved in the last century as a result of continual research and refinement. For technical and economical reasons, power transmission lines are typically constructed overhead. On the basis of aesthetic and other land use considerations, transmission lines may also be constructed underground.

1.2 Substations

In large, modern power systems, the transmission and distribution system functions to deliver bulk power from generating sources to the end users. Transmission facilities generally include step-up transformers, interconnecting transmission lines, switching stations, and step-down transformers. As an integral part of the transmission system, the substation or switching station functions as a connection and switching point for power to transmission lines, subtransmission feeders, generating circuits, and step-up/step-down transformers. The electrical equipment in a typical substation may include circuit breakers, disconnecting switches, grounding switches, current transformers, voltage (potential) transformers, power transformers, coupling capacitors, line traps, lightning arresters, shunt reactors, shunt capacitors, series capacitors, station buses, and insulators.

The substation design objective is to provide maximum reliability, flexibility, and continuity of service and to meet these objectives with the lowest investment costs that satisfy system requirements. Many factors influence the proper selection of the type of substation for a given application. The most appropriate type of station depends on voltage levels, load capacity, environmental considerations, and site space limitations.

There are two basic types of insulation for substations: air and gas. Air-insulated substations use the surrounding air as electrical insulation between energized buses, much in the same way that air is used as the primary insulation between bare conductors on transmission lines. The basic principle of gas-insulated equipment is that current-carrying parts are within a metal enclosure and are held in a concentric configuration by spacer insulators. The space between the conductor and the enclosure is filled with sulfur hexafluoride gas (SF_6) under pressure. High-voltage gas-insulated substations have been in service since the early 1960s. Operation of 800-kV gas-insulated equipment has proved successful since 1979.

1.3 Transmission Lines

Electric power worldwide is primarily transmitted by means of alternating current (ac). Direct-current (dc) transmission allows certain economic and performance advantages over ac transmission in specific situations. Specific applications where dc transmission may be superior include long-distance overhead transmission, underwater or underground transmission, and asynchronous ties between distinct power systems.

Although direct-current transmission has seen some use in the United States, the concept has been around for a long time. In the 1880s and 1890s, there was widespread controversy over whether direct-current or alternating-current systems would be best for meeting the nation's electricity needs. High-voltage direct-current (HVDC) transmission was first seriously considered in the United States in the 1930s but became a commercial reality in 1954 in Sweden.

High-voltage dc is inherently more stable than ac and requires smaller lines for transmission, less insulation, and narrower rights of way. For long-distance lines, dc lines are cheaper to build than ac lines. A "bipolar" dc line requires two phase positions as opposed to an ac transmission line, which requires three sets of conductors. dc transmission lines may also aid the overall power-system stability—the ability to maintain an electrical connection following a major disturbance. Unfortunately, even with modern technological advances, the termination facilities for converting the ac electricity into dc electricity and back again are very expensive. Therefore, dc transmission remains practical only for transmitting large amounts of power over long distances. A dc transmission line is not easily tapped or sectionalized to create a network of dc lines, as exist for the ac power system. Furthermore, dc power still cannot be directly stepped down to a level appropriate for home and business use.

1.4 Typical Transmission Voltages and Capable Power Transfer

Standard transmission voltages are established in the United States by the American National Standards Institute (ANSI). There is no clear delineation between distribution, subtransmission, and transmission level voltages. Table 1 shows the standard ac voltages listed in ANSI Standards C84 and C92.2, all of which are presently in use, and approximate loadability in megawatts (MW).

The nominal system voltages of 345, 400, 500, and 765 kV in Table 1 are classed as extra-high voltages (EHV). They are used extensively in the United States and in certain other parts of the world. The 400-kV transmission class voltage is principally used in Europe. EHV is used for the transmission of large blocks of power and for longer distances than would be economically feasible at the lower voltages. EHV may be used for interconnections between systems or superimposed upon large power-system networks to transfer large blocks of power from one area to another.

Table 1. Standard ac system voltages

Rating (KV)		Approximate loadability (MW)
Nominal	Maximum	
34.5	36.5	3
46	48.3	7
69	72.5	12
115	121	36
138	145	55
161	169	75
230	242	135
345	362	350
400	420	525
500	550	900
765	800	2250
1100	1200	5200

One voltage level above 800 kV, namely, 1100 kV nominal, is presently standardized and is referred to as ultrahigh voltage (UHV). This level has not as yet been installed commercially, although sufficient research and development have been completed to prove it technically feasible (EPRI, 1982; Barnes and Thoren, 1973; Bonneville Power Administration, 1974).

The maximum loading capability of a given transmission line is based on the line's surge impedance, which is determined by the line configuration (number of conductors per phase, phase geometry, and spacing). The actual power-transfer capacity is limited by thermal, voltage-drop, and stability considerations.

2. TRANSMISSION-LINE THEORY

2.1 Low-Frequency Approximation to Electromagnetic Equations

One wavelength at 60 Hz is 5000 km. Hence, at power frequencies of 60 Hz and below and the dimensions typically associated with electric power transmission lines, the electromagnetic fields of transmission and distribution facilities can be assumed to be quasistatic (Adler *et al.*, 1960). The quasistatic approximation is valid not only for calculation of line parameters but also for calculation of electric and magnetic field profiles and coupling to nearby objects (Olsen and Wong, 1992). If the line conductors had zero resistance, the waves would be transverse electromagnetic (TEM), and the electric and magnetic field behavior could be represented by static capacitances and inductances (Harrington, 1961). The resistance is sufficiently small for practical power transmission lines that the TEM approximation yields accurate values for the line parameters.

2.2 Traveling-Wave Considerations

Because electric power-facility dimensions are small with respect to a wavelength, it is customary to ignore traveling-wave effects for most engineering studies. The simple model shown in Figure 3 is adequate to represent power lines on a lumped-parameter basis. There are, however, several cases when traveling-wave behavior is important:

- power-frequency studies of very long lines (50 or 60 Hz),
- switching surge and lightning transients (millisecond to microsecond time frame), and
- power-line carrier communication (30–300 kHz).

Even for long lines and higher frequencies, it is still adequate to use the TEM approximation and lumped-parameter equivalent circuit, if the effects of wavelength are properly incorporated. The long-line correction is given in Sec. 2.3.1.

2.3 Pi-Equivalent Circuit

Power transmission and distribution lines can be represented for many purposes by the pi-equivalent circuit shown in Figure 3 (Bergen, 1986). The term Z represents the series impedance of the line, and $Y/2$ represents half the shunt admittance divided equally between the two line ends.

2.3.1 Short- and Long-Line Models. For "short" transmission lines, the parameters in Fig. 3 become

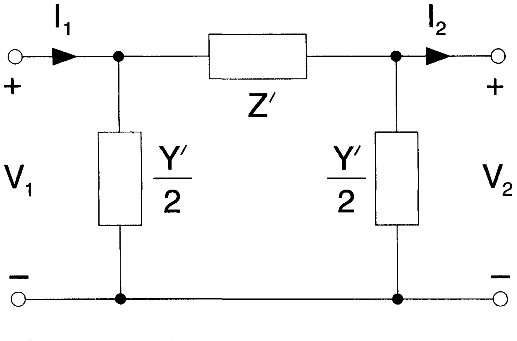

FIG. 3. Pi-equivalent circuit.

$$Z = R + j\omega L, \tag{1}$$

$$Y = G + j\omega C, \tag{2}$$

where R = series resistance, L = series inductance, G = shunt conductance, C = shunt capacitance, and $\bar{\omega}$ = angular frequency, $2\pi f$.

Most transmission and distribution lines are three phase, with three conductors per circuit. Each conductor is represented by a pi-equivalent circuit, with mutual capacitance and inductance terms between each pair of conductors. For most studies of balanced three-phase circuits, it is sufficient to use a single pi-equivalent, as if it were single phase. The terms R, L, and C are determined by a matrix transformation, called the symmetrical component transformation, from the self and mutual parameters of the three phases (Bergen, 1986). The "positive-sequence" values from the transformation are used for the single-phase pi-circuit. Fault and other studies that involve unbalanced operation of the transmission line also require the zero-sequence equivalent, which has the same form except for zero-sequence values for the parameters taken from the matrix transformation.

The short-line approximation is valid for lines shorter than about 0.05–0.1 wavelength, or about 250–500 km at 60 Hz. For longer lines, the series and shunt branches use the characteristic impedance Z_c and propagation constant γ, defined as

$$Z_c = \sqrt{Z/Y}, \tag{3}$$

$$\gamma = \sqrt{ZY}. \tag{4}$$

For the long-line model, Z and Y in the pi-equivalent circuit of Fig. 3 are replaced by

$$Z' = Z_c \sinh \gamma l, \tag{5}$$

$$Y' = (2/Z_c) \tanh (\gamma l/2). \tag{6}$$

2.3.2 Parameters that Affect Resistance, Inductance, and Capacitance. The shunt conductance G represents power dissipation in the line insulation. For an overhead line, G only represents corona loss and losses in insulators and is totally negligible compared with shunt resistance in the loads. The shunt conductance is somewhat greater for the dielectric in underground cables but is still negligible on a system basis. The only time G is considered is when one is making calculations of the current-carrying capacity (ampacity) of underground cables, where heat dissipation in the dielectric can be significant.

The series resistance R is primarily a function of the conductor size, material, and stranding. The inductance L and capacitance C are functions of the conductor diameter and geometry. The calculation procedure for positive- and zero-sequence parameters involves construction of a 3×3 series matrix and a 3×3 shunt matrix of self and mutual phase impedances for the three-phase conductors. The 3×3 matrices are converted to positive- and zero-sequence impedances and admittances by the symmetrical component matrix transformation (Bergen, 1986). Practical transmission lines normally have shield wires and may have more than one conductor per phase, or a total of from 4 to 14 conductors in a single circuit. Phase matrices of order 8×8 are required for two shield wires and two conductor bundles per phase. The 8×8 matrix is reduced to an equivalent 3×3 matrix for transformation to symmetrical components. The matrix reduction preserves the effect of shield wires and conductor bundles on the system properties of the line but eliminates detailed knowledge of shield-wire and phase-subconductor currents.

Shield wires and conductor bundles affect the line parameters. For example, conductor bundling results in a significant reduction in series reactance. Shield wires primarily affect the zero-sequence parameters, decreasing the series reactance but increasing the resistance. Shield wires do slightly change the positive-sequence values, even though hand calculation formulas ignore their effect.

The resistivity of the earth has an effect on the line resistance and inductance, which is customarily represented by Carson's series (Olsen and Pankaskie, 1983). Because of the relaxation time of the earth, the earth resistivity has no effect on line capacitance. Numerical values of line parameters are generally computed today by line-parameter computer programs, eliminating the approximations that formerly went into hand calculations.

2.4 Surge Impedance and Surge-Impedance Loading

Several factors enter into the loading capability of a given transmission line, among which are conductor thermal capacity, voltage drop, and system stability. Conductor thermal capacity is a function of the conductor resistance, the maximum design temperature of the line, and weather conditions. Voltage drop and system stability are functions not only of line reactance but also of the system to which the line is connected.

A useful measure of loading limitation due to line reactance is given by the surge-impedance loading. Surge impedance Z_s of a three-phase transmission line is the characteristic impedance Z_c assuming a lossless line and defined as

$$Z_S = \sqrt{L/C}, \tag{7}$$

where L and C are given in positive-sequence henries and farads per unit length. The units of Z_S are ohms. When a three-phase line is loaded by a Y-connected resistance of Z_S ohms per phase, it is said to be surge-impedance loaded. This is equivalent to terminating the line in its characteristic impedance, resulting in a pure forward-traveling wave. Surge-impedance loading power P_{SIL} is given by

$$P_{\text{SIL}} = \frac{N_{\text{phases}} V^2_{\text{phase-ground}}}{Z_S}. \tag{8}$$

Surge-impedance loading (SIL) is that loading where the reactive power generated in the line capacitance equals the reactive power absorbed in the line inductance. SIL is a function of the line inductance per kilometer and capacitance per kilometer and is independent of line length. SIL is a handy tool for estimating the relative loading capabilities of overhead lines of different lengths, as shown in Fig. 4 (Dunlop *et al.*, 1979). While a transmission system would not be designed on the basis of Fig. 4, the limitation on practical loading of a line can easily be seen.

For an overhead transmission line, a typical surge impedance is on the order of 300 Ω, while for an underground cable, it may be 30 Ω or less. At 345 kV, SIL of an overhead

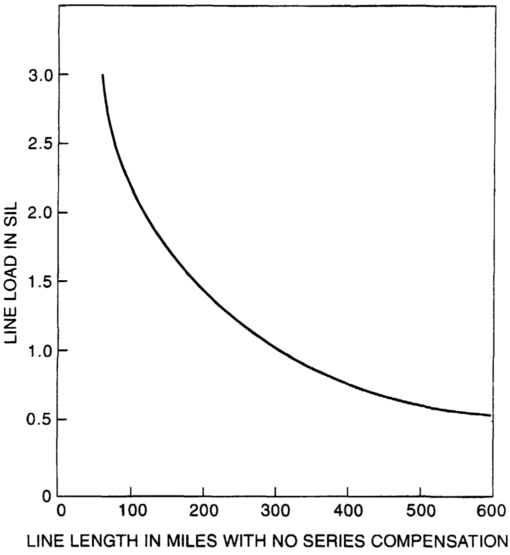

FIG. 4. Transmission-line loading in terms of surge-impedance loading.

line is approximately 400 MVA. Short overhead lines are often loaded at 2 or 2.5 times SIL and need reactive power support to maintain the voltage. Long overhead lines may be limited to 1.0 times SIL or less. SIL for a 345-kV underground cable may be on the order of 4000 MVA or an order of magnitude above the ampacity of an underground cable. Underground cables always operate well below SIL and appear as a large capacitance to the system. Differences in system behavior of overhead and underground transmission lines become apparent from an SIL analysis.

Surge-impedance loading is proportional to the square of the voltage for any transmission line configuration. If a specific line is limited by system considerations such as voltage drop or stability, there may be nothing to be gained by increasing the current rating of the line. In such a case, increasing the voltage may increase the power-handling capability of the line by the square of the factor by which the voltage is raised, assuming adequate ampacity. This variation of line loadability proportional to the square of the voltage is the driving force behind increasing transmission-system voltages.

3. POWER-TRANSMISSION SYSTEM CONSIDERATIONS

3.1 Power Control

The classical power flow equation (Stevenson, 1982) is

$$P = V_1 V_2 \sin \delta / X, \qquad (9)$$

where P = the power transfer, V_1 = the sending end voltage, V_2 = the receiving end voltage, X = the total reactance between V_1 and V_2, and δ = the power angle between V_1 and V_2.

Increasing the power flow, while keeping the voltage and reactance constant, causes the power angle to increase toward its theoretical maximum of 90°. If the power flow tries to increase further, the angle becomes greater than 90°, whereby the actual power transfer decreases and the system becomes unstable. If the voltages V_1 and V_2 are increased, the power transmitted increases by the square of the voltage, for the same reactance and power angle. For the same power flow, the power angle decreases with the higher voltage. The maximum power flow with a 90° power angle is proportional to the square of the voltage.

An operating electric utility system has multiple parallel paths, involving different circuits of different lengths and reactances and different voltage levels. For lines connecting any two buses, the bus voltages and the angle between the two voltages are the same. From Eq. (9), the power flow on each individual line is inversely proportional to the line reactance. This has two consequences:

- Power flow can be controlled only in a general overall manner by rescheduling generation. Generation changes do not change the relative flow along parallel paths.
- Power flow does not necessarily divide proportionally to the line loading capability. Particularly when an underground circuit parallels an overhead circuit, the underground circuit with the lower impedance takes a disproportionately large share of the power flow, especially when it is considered that the thermal rating (ampacity) is usually significantly less for an

underground cable than for an overhead circuit.

When it becomes necessary to control the flow on a specific circuit or group of circuits, several methods are possible: series capacitors, series inductors, or phase-shifting transformers. Series capacitors reduce the series reactance and increase power flow but have several significant drawbacks. Adding a series capacitance creates the possibility of subsynchronous resonances (Larsen *et al.*, 1990), which can cause considerable damage to generating plants and cause system stability problems. Protection of series capacitors from fault currents is difficult and costly. Series capacitors are generally only used where the reactance of very long overhead lines limits system performance (Allustiarti *et al.*, 1988).

Series inductors increase the series reactance and reduce power flow, but again, they have disadvantages of size, cost, and losses. Series inductors are generally only used when fault-current limitation is required.

The most commonly applied power control method is phase-shifting transformers, which change the power angle δ in Eq. (9). Phase-shifting transformers have the advantage of adjustment of phase angle, at the expense of cost and reliability (Bean *et al.*, 1959).

A method of power control under investigation is flexible ac transmission systems (FACTS) (Mountford *et al.*, 1993), in which thyristor technology is proposed as a means of making a solid-state phase regulator. The rapidity of phase-angle change possible with thyristors, combined with computer control, make this a promising approach for obtaining maximum possible power flow on limited transmission facilities.

3.2 Voltage and Reactive Power Control

Power in an ac circuit is given by

$$S = VI^* = P + jQ, \tag{10}$$

where S = apparent power in volt amperes, V = phasor (complex number) voltage in volts, I = phasor current in amps, P = real power in watts, Q = reactive power in vars, and the asterisk denotes complex conjugate. The difference between real and apparent power is caused by the phase-angle difference between voltage and current. The out-of-phase component, reactive power, represents flow of energy stored in inductive and capacitive elements in the system. Control of power flow on a power system involves the flow of both real and reactive power.

Changing the relative phase angle between two buses primarily changes power flow but has a secondary effect on the flow of reactive power. Small changes in bus-voltage magnitude have a significant effect on reactive power flow. Control of voltage within tight tolerances is necessary to meet equipment and customer requirements, while excessive var flow uses valuable circuit thermal capacity. Four methods are used to control voltage and secondarily reactive power flow: shunt capacitors, shunt reactors, synchronous condensers, and static var compensators.

The system effects of overhead transmission and distribution lines are dominated by their series inductance. Most power-system loads are inductive. The combination of an inductive load with an inductive source impedance leads to possible low-voltage conditions. Shunt capacitors are commonly applied to correct power factor, reduce var flow, and improve voltage. Capacitors may be permanently installed, switched by time, or switched by voltage control.

Shunt reactors are used on the highest voltage (500 or 765 kV) transmission lines to control overvoltages resulting from shunt capacitance. Shunt reactors are also common on underground transmission systems to control var flow problems resulting from the large cable capacitance.

Synchronous condensers are synchronous motors that drive no mechanical load but act as an adjustable shunt impedance that can be either capacitive (over-excited) or inductive (under-excited). The continuously variable voltage control together with the rotating inertia of the machine makes synchronous condensers attractive, but cost, durability, and maintenance problems are making them less common.

Static var compensators (SVCs) use thyristors and static impedances to mimic synchronous condensers as an adjustable shunt impedance for voltage and var control. Rapid, precise control make SVCs very attractive voltage control devices.

3.3 Protection

Power-system protection (also called power-system relaying) is essential for both lines and equipment. Protective relaying has three fundamental requirements: sensitivity, selectivity, and speed (El-Hawary, 1983). The protection must be sufficiently sensitive to detect any fault within its zone of protection, sufficiently selective to ignore faults outside its zone of protection, and sufficiently fast to remove the faulted component before damage is done to equipment or the system becomes unstable (see Sec. 3.4). Because of the importance of immediate fault removal, backup protection is provided in the event that primary relays fail to detect the fault or the circuit breaker fails to clear. A major concern in relaying is proper coordination between the relays so that only the proper relays operate in the pròper sequence. Types of relays used for power transmission include the following:

- Inverse time overcurrent relays. These respond to excessive current as a function of time. The relay responds in less time to higher currents, as shown in Fig. 5, hence the inverse time name. The time-versus-current response allows coordination between different relays.
- Distance relays. These respond to apparent impedance looking down a line. The typical characteristic of a distance relay is a circle, as shown in Fig. 6. The straight line represents impedance of the transmission line as a function of distance along the line. The relay circle is set to cross the impedance of the transmission line at about 90% of the length of the line. When the apparent impedance (voltage divided by current) seen by the relay enters the circle, the relay senses a fault and initiates a trip signal. Distance relays are more selective in their response than overcurrent relays and frequently are applied with three zones of protection with different circle sizes and time delays for backup purposes.
- Phase comparison relays. These and similar types compare current at two ends of the line to detect a fault. They are sensitive and selective, but allowance must be made in application for capacitive current on the line.

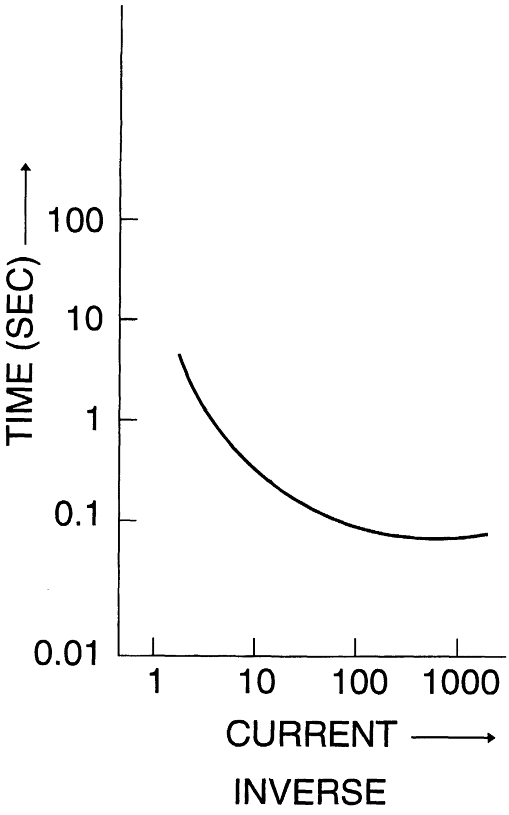

FIG. 5. Inverse time characteristic.

While it is possible to design a protection system without communication between the line ends, some form of communication is desirable for maximum protection. Phase comparison schemes require communication to compare the currents at both ends of the line. A distance relay transfer trip scheme may be used to initiate an immediate trip when the relays at both ends simultaneously see an indication. This communication may be power-line carrier, microwave, fiber optics, or leased telephone wire.

Protection must detect phase-to-phase and phase-to-ground faults. Sometimes a combination of relay types is used (e.g., distance relays for phase-to-phase and overcurrent for phase-to-ground). Other types of relays are often added—for example, directional relays to prevent tripping for faults on adjacent circuits. Where double circuit lines are involved, compensation is required to prevent ground faults on one circuit from tripping the other. System protection studies are based on load flow and fault computer pro-

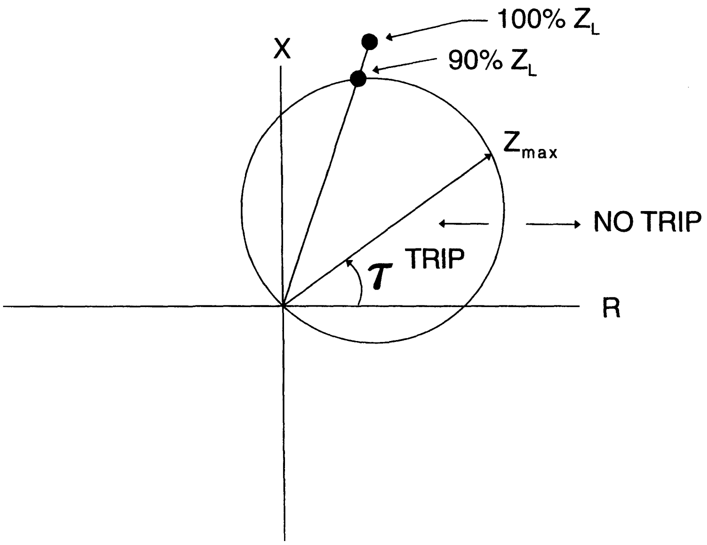

FIG. 6. Distance relay characteristic.

grams, which can model the system for normal and contingency conditions.

3.4 Stability

The classical power-flow Eq. (9) shows that any transmission circuit at its rated voltage has a maximum power flow, which cannot be exceeded without instability. This is an illustration of steady-state stability of a power system. A second stability problem is transient stability, which is a consideration whenever there is a fault or other switching of transmission lines or substation buses.

During a transmission-line fault, low system voltages instantaneously reduce power flow according to Eq. (9). The mechanical power input to the generators remains constant, but flows on the transmission lines are reduced. By conservation of energy, the mechanical power goes into stored energy in the system by speeding up generators and motors. At the same time, reduced system flows causes motors on the load side to slow down. The effect is to increase the angle δ in the milliseconds following the fault. The system is said to "swing." The detailed behavior is a function of the prefault power flow, the reactances of the transmission lines, inertia in rotating machinery, response of generation excitation and governors, and response of other equipment, such as static var compensators. If the fault is not cleared within 0.05 to 0.1 seconds, the system may swing so that δ exceeds 90°. When this happens, the system continues to swing until δ passes 180°, at which point the system conditions are mathematically identical to transmission-line faults. The system protection then properly operates, transmission lines are switched out, and the system separates into smaller isolated areas, referred to as islands. If the system separates, emergency measures must be taken by automated equipment to prevent a blackout.

Figure 7 shows an example of swing curves for a transmission-system fault where the system becomes unstable; the relative angle increases over time without bound. The two curves represent the rotor angles of two

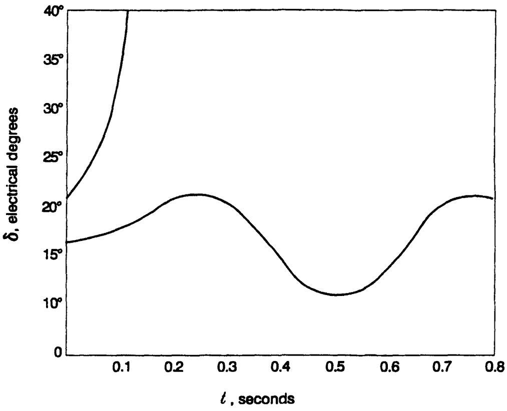

FIG. 7. Swing curves showing transient instability.

different generators relative to a common reference. One generator is speeding up with respect to the other, and the relative angle between them increases until the system separates. Because of the complexity of the transient stability problem, analysis is performed with transient stability computer programs, which represent the transmission system over a wide area and accurately model the dynamic performance of rotating machinery and response of loads to changing voltage.

3.5 Reliability

The discussion on stability points to the overall problem of power transmission reliability. Reliability involves minimization of faults and limitation of the effect of faults that do occur. Reliability considerations permeate the design of overhead and underground transmission lines, as described in Secs. 4 and 5.

Electric utilities have formed reliability councils to set reliability criteria for the bulk power system; for example, stability of the bulk power system shall be maintained for the following cases, including the effect of high-speed reclosing:

- permanent three-phase fault on any transmission circuit (as opposed to a transient fault such as a lightning trip, which causes no permanent damage);
- transformer or bus section cleared in normal time;
- simultaneous permanent phase-to-ground faults on different phases of each of two adjacent transmission circuits on a multiple circuit tower cleared in normal time; and
- permanent phase-to-ground fault on a transmission circuit with delayed clearing.

None of these events would cause a cascading failure and system separation. Reliability of individual lines is expressed in terms of outage rates, frequently in events per year. The dominant cause of transmission-line outages in the United States is lightning. Other common causes of outages are contamination on the insulator surface, trees or other objects contacting the line, and wind or ice storm damage.

3.6 Economics

Economics is a major factor in the design of transmission facilities. Selection of conductor size and type, structure type and height, foundations, span length, and other variables is a complex optimization process. The present worth of cost of losses and maintenance of the line (including all appropriate interest rates and other financial factors) must be balanced against the initial cost of construction for the overall least-cost design. Details of overhead and underground line components are given in Secs. 4 and 5. Some of the factors that enter into overhead transmission line economics are these:

- Larger conductor size results in lower losses but costs more initially and requires more massive costly structures to support.
- Longer span length requires fewer structures per kilometer, but individual structures are taller and more costly.
- Higher conductor tension results in less sag and structure height but increases mechanical loading on dead-end and angle structures.

Cost of right of way is an increasingly important economic consideration and is driving the quest for more compact lines with increased power-transfer capacity.

4. OVERHEAD ac TRANSMISSION LINES

4.1 Line Parameters

The transmission-line parameters, as shown in Sec. 2.3, may be divided into two parts: series impedance and shunt admittance. The series impedance consists of a resistance and an inductive reactance, while the shunt admittance consists of a conductance (inverse of resistance) and a capacitive reactance.

Skin effect is inherent in the conductor itself; hence when the ac resistance of a conductor is stated, what is meant is the dc resistance plus an increment that reflects the increased apparent resistance of the conductor caused solely by the skin-effect inequality of current density. Skin effect results in a decrease of current density toward the center of the cylindrical conductor (the current tends to crowd to the surface).

The per kilometer resistance, reactance, and capacitance can be determined from conductor characteristic data found in handbooks and manufacturers' literature (Aluminum Association, 1982; EPRI, 1982) and the spacing factors X_d and X'_d. The spacing factors X_d and X'_d represent the inductive reactance and capacitive reactance per conductor at a 0.3-m (1-ft) spacing, respectively. The positive-sequence resistance is listed as the 60-Hz value at 50 °C. The expression for inductive reactance per kilometer is

$$X_L = 0.001419 f \log (D/\mathrm{GMR}), \tag{11}$$

where D is the geometric mean of the three distances between phase conductors in meters, GMR is the geometric mean radius of the phase conductor in meters (as given in the conductor tables), and f is the frequency in hertz. GMR for ACSR conductor is given at 60 Hz; however, 60-Hz values of GMR can be used at other commercial power-system frequencies with small error. The expression for capacitive shunt reactance per kilometer is

$$X_c = \frac{13.45 \times 10^6}{f} \log \frac{D}{r_c}, \tag{12}$$

where r_c is the conductor radius in meters.

4.2 Conductor Types and Selection

A conductor of electricity is any substance or material that will afford continuous passage to an electric current when subjected to a difference of electric potential. The greater the density of current for a given potential difference, the more efficient the conductor.

Electrical conductors are manufactured in a variety of forms and shapes for various purposes. These may be wires, cables, flat straps, square or rectangular bars, angles, channels, or special designs for particular requirements. The most extensive use of conductors, however, is in the form of round solid wires and stranded conductors. Materials commonly used in conductors are aluminum, copper, and steel. Galvanized steel wires are combined with aluminum in the most common type of overhead conductor—aluminum conductor, steel reinforced (ACSR). The use of copper is uncommon on modern transmission lines since it usually costs and weighs considerably more than aluminum conductor of the same resistance.

Standard bare overhead conductors consist of round strands helically laid about a core in one or more layers. In a homogeneous conductor—all-aluminum conductor (AAC), hard-drawn copper conductor (CU), or all-aluminum alloy conductors (AAAC5005 or AAAC6201)—the core consists of a single strand identical to the outer strands. In a nonhomogeneous conductor—aluminum conductor, steel reinforced (ACSR), aluminum conductor, alumoweld steel reinforced (ACSR/AW), hard-drawn copper conductor, copperweld steel reinforced (CU/CW), or aluminum conductor, aluminum alloy reinforced (ACAR)—the strands in the core may or may not be of the same diameter.

In addition, there are several nonstandard overhead conductors for special-purpose applications. Self-damping ACSR conductors (ACSR/SD) are used to limit aeolian vibration to safe levels regardless of conductor tension or span length. ACSR/TW is similar to ACSR in its use of trapezoidal-shaped strands but does not have annular gaps between layers. ACSR/TW has a smaller diameter and smoother surface than conventional round-wire ACSR of the same area and thus may have reduced wind loading. Steel-supported aluminum conductors (SSAC) are similar to conventional ACSR but employ annealed aluminum alloy strands on the outside layers. The annealed aluminum has increased electrical conductivity, and the conductor has improved sag–tension characteristics for high-temperature service. T2 conductors are fabricated by twisting two conventional conductors together. Severity of wind-induced galloping when the conductor is coated with ice is reduced with T2 conductors. In conjunction with advanced line design techniques, one can consider the value of using the novel conductors for lower electrical resistance, lower thermal elongation, higher annealing temperatures, and reduced aeolian vibration.

The choice of a conductor for a transmission line, as with structure type, depends on the specific application. Once the mechanical strength requirement of the conductor is satisfied, the conductor choice considers the total costs associated with the conductor, and corona-related electrical environmental effects of radio and audible noise. Costs associated with the conductor include the cost of the conductor, support structures, and present worth of the future power losses and maintenance. Corona is a result of the electrical stress on the surface of the conductor and is a function of the voltage on the conductor, diameter and surface condition of the conductor, and the spacing between conductors and/or grounded objects. Corona also causes power loss, particularly during wet weather.

The equivalent size of a conductor can be increased either by using a larger single conductor or several smaller conductors electrically and physically connected together (bundled conductors). Typical spacing between parallel conductors for a two-conductor bundle is 47 cm. Compared with a single very large conductor, a bundle of several smaller conductors results in lower series reactance and significantly less corona and associated noise. Bundled conductors are necessary at the higher transmission voltages to limit corona to acceptable levels. They are sometimes used at lower transmission voltages to reduce reactance and provide for greater current capability.

At voltages of 345 kV and above, the minimum conductor size or the minimum number of conductors in a bundle is normally determined by the corona-related electrical environmental effects. At voltages below 345 kV, the minimum size is normally based only on conductor economics.

Since a limiting design criterion is minimum conductor height above ground (for safety reasons), the maximum sags during operation determine structure heights in terms of span lengths. Similarly in certain areas, ice can form on the conductors of sufficient weight to limit the structure heights and span lengths to maintain ground clearance. The conductor sag in the span between structures will depend on conductor materials, conductor weight, conductor strength, conductor tension, conductor temperature, and ice accumulation on the conductor. As the current in the conductor increases, the losses increase with a resultant increase in conductor temperature, causing the sag to increase. If the conductor is carrying heavy electrical load on a hot day, very significant increases in sag can occur.

4.3 Insulation Designs and Considerations

The electrical operating performance and reliability of a transmission line depend primarily on the ability of the insulation to withstand the voltage under all operating conditions. An insulator not only must have sufficient mechanical strength to support the greatest loads of ice and wind that may be reasonably expected, with an ample margin, but must be so designed as to withstand severe mechanical abuse, lightning, and power arcs without mechanically failing. It must prevent a flashover for practically any power-frequency operating condition and many transient voltage conditions, under any conditions of humidity, temperature, rain, or snow and with such accumulations of dirt, salt, and other contaminants as are not periodically washed off by rain (Kaminski, 1963).

The majority of present insulators are made of glazed porcelain. Porcelain is a ceramic product formed by the high-temperature vitrification of clay, finely ground feldspar, and silica. Insulators of high-grade electrical porcelain of the proper chemical composition free from laminations, holes, and cooling stresses have been available for many years. The insulator glaze seals the porcelain surface and is usually dark brown, but other colors such as gray and blue are used. Porcelain insulators for transmission may be disks, posts, or long rod types. Porcelain insulators have been used at all transmission-line voltages and, if correctly manufactured and applied, have high reliability.

Glass insulators have been used on a significant number of transmission lines, particularly in Europe. These are made from toughened glass and are usually clear and colorless or light green. For transmission voltages, they are available only as disk types. Most glass disk insulators will shatter when damaged but without mechanically releasing the conductor. This provides a simple method of inspection.

Synthetic insulators, originally pioneered by the General Electric Company in 1963 for high-voltage transmission lines (Nichols and Vose, 1963) and subsequently introduced by several manufacturers, are finding increasing acceptance. Most consist of a fiberglass rod covered by weather sheds of skirts of polymer (silicon rubber, polytetrafluoroethylene, cycloaliphatic resin) (Abilgaard *et al.*, 1976). Improvements in design and manufacture have made synthetic insulators increasingly attractive since their strength-to-weight ratio is significantly higher than that of porcelain and can result in reduced tower costs, especially on EHV and UHV transmission lines. Polymer insulators are usually manufactured as long rod or post types. The light weight of most designs and resistance to damage aids construction. In addition, their performance under contaminated conditions may be significantly better than that of porcelain (Karady and Lamontagne, 1976). It has been found necessary to use grading rings on some types at higher voltages to prevent damage to the sheds, and a very small number of insulators have experienced "brittle fractures," in which the fiberglass core breaks close to the end fitting. Despite these problems, it appears that reliable synthetic insulators are presently available.

The criteria for power-frequency insulation design is usually that flashover shall not occur for normal operating conditions, including reduced clearance to the structure from high wind. A typical wind design limit is the 50- or 100-year return period wind, i.e., wind velocity that occurs only once in 50 or 100 years. This velocity is obtained from local wind records and may be typically 130 to 160 km/h. In clean conditions, power-frequency voltage is not a controlling parameter for insulator design (as distinct from air-gap clearance). Design for contamination is usually expressed as centimeters of creepage per kilovolt, where the creepage distance is the length of the shortest path for a current over the insulator surface, and ranges up to 5 cm per phase-to-ground kilovolt or more for heavy contamination. Standard insulator disks (25.4 × 13 cm) have a typical creepage length of 29.2 cm per disk. To avoid very long insulator strings for contamination, disks with additional creepage distance are made. The creepage can be extended by use of lengthened skirts and deeper grooves in the underside. Fog type disks have up to 54.6 cm of creepage per 34.3 × 20.3-cm disk.

Operation of a circuit breaker on a transmission line can cause transient overvoltages, although flashovers due to such switching surges are rare in conventionally spaced lines below 500 kV. If the breaker is opening, this may be due to restrikes across the breaker contacts as they separate, although restriking has been nearly eliminated with present breaker technology. If the breaker is closing, the cause may be unequal voltage on the two sides of the breaker, including the effect of residual charge on the line from recent de-energization. The crest magnitudes of switching surges are normally defined in per unit of nominal power-frequency crest phase-to-ground voltage. The criterion for switching surge insulation design is usually that flashover shall not occur for most or all switching events.

Impulse surges on a line are caused by lightning strokes to or near the line. At transmission insulation levels, only strokes that directly intercept the line are capable of causing flashovers. It is unusual for line insulation to be determined by lightning performance alone. More typically, insulation is determined by other requirements, and the lightning performance is then verified. If this performance is unsatisfactory, it is often more efficient to change other design parameters such as shield wires or grounding than to add additional insulation.

The controlling paths for flashovers on most presently installed transmission lines are phase to ground, since there are usually grounded structure components between phases. However, compact transmission lines that do not utilize grounded support structures between the phases can employ phase-to-phase insulators. Design methods for phase-to-phase insulation are essentially the same as for phase-to-ground insulation (EPRI, 1978, 1980; Souchereau *et al.*, 1978).

4.4 Ampacity

Power lines are limited in their ability to deliver electricity. The two most important limits can be understood by considering thermal effects and stability. When current flows in the conductors, there are I^2R losses and heat is generated. This loss of power reduces transmission efficiency. The heat generated by the line losses causes a temperature rise. Since line temperature of overhead lines must be kept within safe limits to prevent excessive line sag between transmission towers (minimum ground clearances must be maintained) and to prevent irreversible stretching (at about 100 °C), this imposes limitations on the maximum safe current a line can carry. Clearly, the current-carrying capability of the line depends on the line design (conductor size, phase geometry, and spacing) and operating conditions (ambient temperature, wind velocity).

Thermal considerations impose a current-handling limitation for a given line, and, hence, lines are given current ratings that provide for safe operation. Operating the line above the rating for an extended period of time is not recommended. The thermal limitations of the terminating equipment (i.e., transformers) may be more restrictive than the ratings pertaining to the line itself.

4.5 Electrical Environmental Considerations

There are two categories of electrical environmental effects of power transmission lines. Corona effects are those caused by electrical stresses at the conductor surface that result in air ionization ("corona") and include radio, television, and audible noise. Field effects are those caused by induction to objects in proximity to the line. While the generic term is electromagnetic effects, within the electric power industry the fields are divided into two types: electric field effects and magnetic field effects. Electric fields, related to the voltage of the line, are the primary cause of induction to vehicles, buildings, and objects of comparable size. Magnetic fields, related to the current in the line, are the primary cause of induction to long objects, such as fences and pipelines.

In an electrical environmental analysis, it is important to determine the proper criteria for assessment of the impact. For example, the audible noise criterion in a commercial or industrial area would be inappropriate in a quiet residential neighborhood (Keast, 1980). Likewise, ground-level electric field criteria on a parking lot would be much more strict than these in terrain inaccessible by motor vehicles. For audible noise, the only concern is annoyance, but for electric fields, safety, annoyance, and perception levels all may need to be considered.

Corona-produced audible noise during foul weather, particularly during or following rain, can be an important design parameter for high-voltage ac transmission lines. Audible noise has two components, a random noise component and a low-frequency hum, each produced by different physical mechanisms. While the hum component is closely correlated with corona loss on the line, the random noise is not. Of these two, the most frequent cause of annoyance is the random noise, and it is this that is calculated and compared with acceptance criteria. Analyses to predict levels of audible nose consider A-weighted sound level [dB(A)] during rain including

- L_{50}, which is the level exceeded 50% of the time during rain,
- L_5, which is the level exceeded 5% of the time during rain,
- average, which is the average level of noise expected during rain, and
- heavy rain, which is the level expected during heavy rain.

One formula for calculating L_5 is given by (IEEE Task Force, 1982)

$$\begin{aligned} AN_5 = {} & -665/g + 20 \log n + 44 \log d \\ & - 10 \log D - 0.02D + AN_0 \\ & + K_1 + K_2, \end{aligned} \tag{13}$$

where g = average maximum surface gradient of conductor, kV/cm; n = number of subconductors in a phase bundle; d = diameter of subconductors, cm; D = distance from line to point at which noise level is to be calculated, m; $AN_0 = 75.2$ for $n < 3$, 67.9 for $n \geq 3$; $K_1 = 7.5$ for $n = 1$, 2.6 for $n = 2$, 0 for $n \geq 3$; $K_2 = 0$ for $n < 3$, $22.9(n - 1)d/B$ for $n \geq 3$ (B is bundle diameter in cm). The L_{50} level for each phase is obtained from

$$AN_{50} = AN_5 - \Delta A, \tag{14}$$

where $\Delta A = 14.2g_c/g - 8.2$ for $n < 3$, $14.2g_c/g - 10.4 - 8[(n - 1)d/B]$ for $n \geq 3$; $g_c = 24.4d^{-0.24}$ for $n \leq 8$, $24.4d^{-0.24} - 0.25(n - 8)$ for $n > 8$.

Radio and television interference from overhead power lines is caused by two phenomena: complete electrical discharges across small gaps (microsparks) and partial electrical discharges (corona). Gap-type sources occur at insulators, line hardware, and defective equipment and are a construction and maintenance problem rather than a design consideration. They are responsible for about 90% of noise complaints and can be located and eliminated as they occur (Loftness, 1992). Conductor and hardware corona is considered during the design phase of the line. On a properly designed line, conductor corona rarely results in complaints except perhaps in weak-signal fringe areas.

The specification of corona-free hardware is important to eliminate that source of electromagnetic interference and is especially important as lines are constructed with closer spacings and resulting higher electric fields on the hardware. Conductor clamps and other fittings that were formerly acceptable at traditional phase spacing may not be adequate for compact lines.

Two families of computation methods are available for radio noise: those based on conductor laboratory tests and analytical propagation theory (semianalytical methods) and those based on empirical formulas using data from long-term tests on operating lines (comparative methods). The comparative method is useful for conventional geometries and designs (Chartier, 1981):

$$RI = -150.4 + 120\log g + 40\log d + 20\log\left(\frac{h}{D^2}\right) + 10[1 - (\log 10f)^2], \tag{15}$$

where g = average maximum surface gradient of conductor or conductor bundle, $\mathrm{kV_{peak}/cm}$; d = subconductor diameter, mm; h = height of phase, m; D = radial distance to observer, m; f = frequency, MHz; and RI = fair-weather radio noise, dB. The term RI is calculated for each phase, and the maximum value is used as the RI of the line. There are no generally accepted RI limits in the United States, because of the impossibility of setting universal criteria for all land-use and local conditions. A Canadian standard exists for RI limits and is a useful guide (CSA, 1975).

Ground-level electric field effects of overhead power transmission lines relate to the possibility of exposure to electric discharges from objects in the field of the line. These may be steady currents or spark discharges. Other areas that have received attention are the possibility of fuel ignition and interference with individuals wearing pacemakers. The resultant electric fields in proximity to a transmission line are the superposition of electric fields due to the three phase conductors. The conducting earth must be represented by image charges located below the conductors at a depth equal to the conductor height. For a single conductor, the total ground-level electric field is given by

$$E = \frac{Q_1}{\pi\epsilon}\frac{h}{h^2 + L^2} \tag{16}$$

where Q_1 = charge on each conductor as a function of the voltage on all conductors, ϵ = permittivity, h = height of conductor above ground, and L = lateral distance to the measuring point. At ground level, the horizontal components of the electric fields of the conductor and its image cancel, and the resultant field is purely vertical. For a three-phase line, the fields of the three conductors and their images are computed separately and added.

Magnetic field coupling affects objects that parallel the line for a distance, such as fences and pipelines, and is generally negligible for vehicle- or building-sized objects. As opposed to electric field coupling, magnetic field coupling is a low-voltage, low-impedance source with relatively high short-circuit currents. Single grounds are ineffective in preventing magnetically coupled voltages, and multiple low-resistance grounds are needed. A consideration in the calculation of magnetic fields that is different from electric field calculation concerns the images. A perfectly conducting earth can be assumed for the electric field problem, even for realistic values of earth resistivity. The assumption of a transmission line in free space (no earth at all) gives a closer approximation to the ground-level magnetic fields than does the assumption of a perfectly conducting earth for measurements near the line. For a single conductor, without its image, the magnetic field may be represented by

$$B = \frac{\mu I}{2\pi r} = \frac{\mu I}{2\pi\sqrt{h^2 + L^2}}, \tag{17}$$

where I is the current in the single conductor and μ is the permeability. The magnetic field is then separated into vertical and horizontal components by multiplying by $\sin\theta$ and $\cos\theta$, where θ is the angle between the observer and the phase conductor. In general, both components must be retained. For a three-phase line, all conductors must be computed. Horizontal and vertical components of the magnetic field from the three conductors must then be combined individually as phasors, considering the angles of the different currents. The combined horizontal and vertical components in general have different time angles, causing their resultant to trace an ellipse in time. Single-axis magnetic field meters with the sensing coil oriented for a maximum reading give the magnitude of the semimajor axis of the field ellipse. A three-axis meter computes the square root of the sum of the squares of the three orthogonal field components (the "resultant" field). The resultant field can be as much as 41% greater than the major axis of the field ellipse for a circularly polarized field that results from symmetrical line configurations.

4.6 Support Structures: Mechanical and Civil Engineering Considerations

Numerous types of structures are used for supporting transmission-line conductors—for example, self-supporting steel towers, guyed steel towers, self-supporting aluminum towers, guyed aluminum towers, self-supporting steel poles, flexible and semiflexible steel towers and poles, rope suspension, wood poles, wood H frames, and concrete poles. The type of supporting structure to use depends upon such factors as the location of the line, importance of the line, desired life of the line, money available for initial investment, cost of maintenance, and availability of material. A line built with self-supporting steel towers is very satisfactory in all respects, as it requires less inspection and has a maximum life with minimum maintenance costs. Self-supporting steel poles are frequently used in congested districts where right of way is limited and short spans are necessary.

In determining the maximum forces acting on towers or poles, it is necessary to combine the transverse forces, longitudinal forces (including torsion), and vertical forces so that they act simultaneously. Other factors that may enter into the determination of the maximum forces acting on supporting structures include the horizontal and vertical components of tensions in guy wires and the addition of pole-top transformers, switches, and working platforms.

Stresses in towers can be computed analytically by the historic graphical methods or by use of one of the available computer programs for tower analysis and design. Most of the design procedures assume that the foundations are rigid. In actual practice, an uneven settlement of the foundations may produce excess stresses that must be considered and taken care of in the overload factors provided against failure. Some flexible lattice-type towers and most pole-type structures will undergo sufficiently large horizontal displacements that the nonlinear stresses due to the vertical loads acting in conjunction with these displacements must be considered.

5. UNDERGROUND ac TRANSMISSION LINES

5.1 Line Parameters

The electrical model of an underground cable is the pi-equivalent circuit described in Sec. 2. Several differences mark underground cable as compared to overhead lines:

- R is lower for an underground cable, because of the necessity to limit losses to keep the insulation temperature within limits. Conductor diameter is generally greater for an underground cable than for an overhead line, increasing the cost.
- L is lower for an underground cable, because of the smaller phase spacing.
- G is higher for an underground cable, because of dielectric losses in the solid and liquid insulation. G is not significant for the overall electrical system, but is important for considering the losses and temperature rise of the cable.
- C is higher for an underground cable, because of the higher dielectric constant of the insulation and the small spacing between the conductor and sheath.

The lower inductance and higher capacitance of an underground cable have significant system implications, as subsequently discussed in Sec. 5.6.

5.2 Types of Underground Installations

Four cable systems can be considered for application at transmission voltage levels above 69 kV (EPRI, 1992):

- High-pressure pipe-type cable; paper insulated, fluid or nitrogen filled, and pressurized to 1400 kPa (fluid filled above 135 kV). Available to 550 kV, but commercial experience to date is limited to 345 kV. This type of cable is dominant in the United States. The complete cable system includes cables, pipes, splices, terminals, oil, pumping stations, cooling stations, numerous valves, etc. The pipe is first laid in the trench, then the cables pulled in and spliced, and the pipe is filled with oil and pressurized. Distances between splices range from 460 to 1220 m.
- Self-contained fluid-filled cable, also called *low-pressure fluid-filled cable;* available in voltages through 550 kV. Instead of the pipe, the individual phase cables are sheathed with lead or aluminum. This system has evolved from the original ionization-free design developed in Italy in the 1920s and dominates underground usage in Europe, Asia, and South America.
- Extruded (solid) dielectric cable systems with polyethylene (PE), cross-linked polyethylene (XLPE), or ethylene propylene rubber (EPR) insulation.
- Compressed SF_6 gas-insulated rigid cable; available up to 500 kV for very high power levels and short (300 m) circuits. This type is an adaption of isolated phase bus developed for substations and the rigid coaxial line used for high-power UHF antenna feeds.

5.3 Insulation Considerations

At voltages above about 1.5 kV (the normal threshold of ionization), cable insulation systems fall into two categories: ionization-proof insulating materials (porcelain and other inorganic insulation such as silicone rubber and some epoxy resins) or ionization-tolerant insulations (paper-oil, varnished cloth, etc.), and ionization-free designs (XLPE cables) or ionization-suppression dielectric strength enhancement techniques (oil or gas pressurization). A power transmission cable is more complex than simple insulation over the conducting material. It is necessary to protect the insulation from water and mechanical damage, and it is especially important to grade the electric field in the insulation properly to prevent localized high fields and corona. Components of a power transmission cable (see Fig. 8) are the following:

- Conductor, aluminum or copper, stranded in segments carefully designed to minimize electrical losses to carry the load current.
- Conductor shield, a conducting or semiconducting material depending on the cable type to round out the strand conductor's irregular surface by filling or bridging the interstices between strands or segments. The purpose of the conductor shield is to make as nearly as cylindrical an electrode as possible to eliminate localized high electric field spots. A second purpose is to eliminate ionizable voids between conductor and insulation and reduce the intensity of any discharge that may occur.
- Insulation, the main insulating material to withstand the cable's voltage.

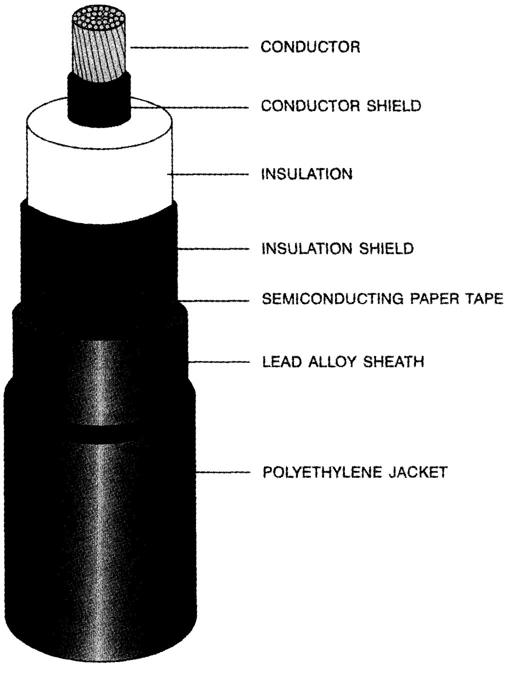

FIG. 8. Cutaway view of underground power cable.

- Insulation shield, a conducting layer over the cable with three functions: to ensure a radial electric field in the cable insulation, to carry the cable's capacitive charging current continuously, and to carry fault current.
- Sheath, in self-contained paper-insulated cables, an impermeable lead or aluminum cover to keep out water.
- Jacket, a coating layer to provide mechanical protection to the cable, additional barrier against entrance of chemicals or moisture, and sometimes a measure of electrical insulation.
- Skid wire, on cables to be installed in a pipe, a spiral-wrapped stainless steel wire on top of the sheath to protect the cable as it is pulled into the pipe and to reduce the friction during the pull.

In addition to the cable insulation, careful attention must be paid to attachments, splices, and terminations. A cable is terminated in an insulating bushing called a pothead whose function is to grade the electrical stress to prevent flashover across the outside of the insulation. If the insulating covering were merely stripped off without attention to the electric field distribution, surface flashovers could occur. Terminations have skirts to extend the leakage distance, much like the insulators on an overhead transmission line.

5.4 Cable Ampacity

An overhead electrical conductor dissipates heat directly to the adjacent air. Heat generation in an underground cable must pass through the thermal resistance of the cable insulation, pipe (if any), air space and duct (if any), and earth before being released to the atmosphere. The thermal circuit of an underground cable is significantly more complicated than for an overhead line, and the ability to dissipate heat is correspondingly reduced for an underground cable. Conversely, the thermal time constant for an underground cable is much longer than for an overhead line, allowing thermal storage to be a consideration in setting emergency loading levels. Cable losses and sources of heat fall in three categories:

- Conductor, proportional to I^2R. Shield/sheath losses are proportional to I^2R for current and resistance of the shield. Conductor losses are reduced by increasing conductor diameter, and properly stranding and segmenting the conductor. Shield/sheath losses are sometimes reduced in a three-phase cable by cross-bonding, that is, insulating the three shields from each other and transposing the connections to them along the cable length to cancel inductively coupled circulating currents.
- Dielectric, proportional to $V^2C \tan \delta$, where $C \tan \delta$ is the insulation loss factor.
- Magnetic, a function of the permeability of the pipe (if any).

Thermal resistances are the cable insulation itself, the insulating fluid (if any), the pipe and its coating (if any), and the earth (this is the dominant factor). An electrical analog of the thermal circuit of a high-pressure fluid-filled cable is given in Fig. 9. Forced cooling of the circulated insulating fluid in pipe-type cables has been employed to increase heat dissipation by controlling the ambient temperature of the cable and by lowering the thermal resistance. Additional losses are incurred by the circulating pumps and mechanical cooling equipment.

The classic reference that is still the basis of cable ampacity calculations is Neher and

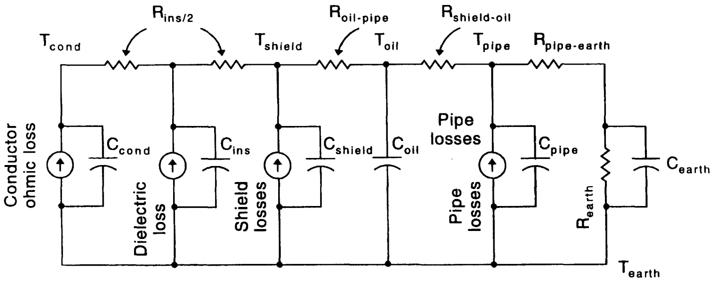

FIG. 9. Electrical analog of high-pressure fluid-filled cable thermal circuit.

McGrath (1957). This work has been extended for larger cable sizes (Katz *et al.*, 1978) and for self-contained cables (IEC, 1969).

5.5 Environmental Considerations

Underground power transmission involves several environmental considerations: opening a trench for installation and maintenance, and the location, repair, and consequences of leaks of insulating fluid. Because of the cable shield, there is no external electric field from an underground cable, and so electric fields are not an environmental factor.

Earth is not a shield for magnetic fields from underground cables. Figure 10 shows a magnetic field lateral profile for a solid dielectric cable compared with an overhead line of the same voltage and current. (Magnetic field at 60 Hz is a function of line current, not voltage. Voltage is included in this comparison to ensure comparable transmission capability.) The magnetic field of the underground cable falls off with distance more rapidly than the magnetic field of the overhead line, but the maximum values closest to the lines are comparable. The underground circuit's phase conductors have closer spacing and, hence, greater field cancellation. However, the closest distance from the observer to the underground cable is closer than that to the overhead line. These relative distances account for the difference in profiles.

The magnetic field profile of an underground circuit depends on several variables: cable geometry, sheath connections, and effects of the cable pipe. The geometry depends on the installation, whether direct buried side by side, in ducts, constrained by spacers, or in a pipe. Generally, the closer and more symmetrical the arrangement, the lower the magnetic field. When sheaths are cross-bonded to reduce losses and improve ampacity, they have no circulating current and do not affect the magnetic field profile. When the sheaths are multigrounded, allowing inductive circulating current to flow, the net magnetic field is reduced by the amount of the magnetic field from the sheath currents. Cables installed in a pipe are constrained in their geometry, have magnetic shielding from the ferromagnetic behavior of the pipe, and have shielding from the circulating currents induced in the pipe. The overall effect is difficult to predict exactly, but generally, the magnetic field of a pipe-type cable is a factor of 25 below that of a comparable cable of the same geometry without the pipe.

5.6 Specific System Considerations

System considerations of underground cables mainly result from the large capacitance compared to an overhead line. The overhead system mainly appears as a series inductance, while an underground cable system is dominated by the shunt capacitance. A capacitive current fed from an inductive source results in a voltage rise, as shown in Fig. 11. This voltage rise is significant, especially un-

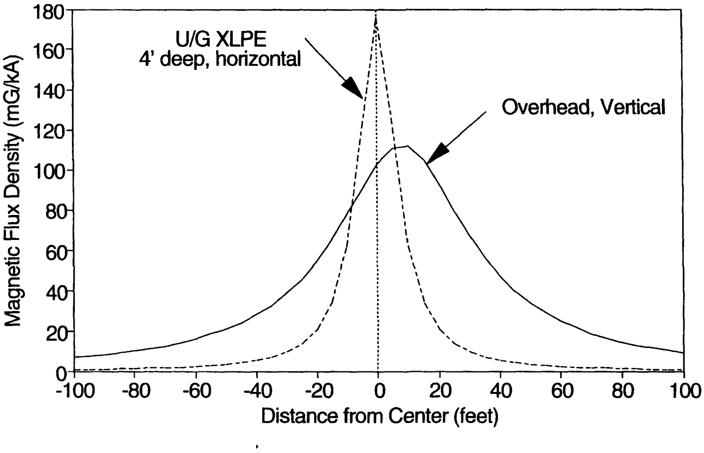

FIG. 10. Comparison of magnetic fields produced by overhead (solid line) and underground (dashed line) 230-kV transmission lines.

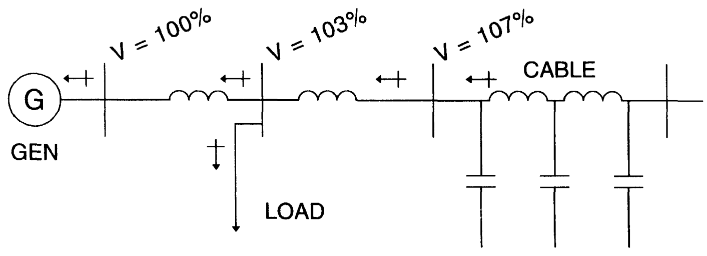

FIG. 11. Voltage rise due to cable capacitance.

der two operating conditions: light load hours when system load current is small and excessive voltage is possible and abnormal situations such as restoration of power following a blackout. During restoration, the supply system may be "weak," that is, high reactance. Energizing cable circuits with a weak source can result in overvoltages. Both problems are serious for utilities that have extensive underground transmission.

There is a fundamental limit to the length of a cable circuit. Beyond a certain length, the entire ampacity of the cable is taken by the capacitive charging current. At shorter distances, capacitive current may impair the ability of the cable to carry load current.

Overvoltages and capacitive current limitations are controlled by addition of shunt reactors to absorb the capacitive current. Placement and sizing of shunt reactors must be done in conjunction with a digital-computer power-flow study to ensure proper voltage and var control under all operating conditions. Switching and system restoration considerations may dictate more smaller reactors, sometimes switched with the cables. The comparatively low series reactance of underground cables presents a problem of distribution of power in parallel paths with overhead circuits. Section 3 addresses practical matters of real and reactive power control.

Overvoltage and surge protection is especially important for underground cable applications. Where a flashover on an overhead line may disrupt the line operation but causes no permanent damage, a fault on an underground cable damages the insulation and may require a considerable time (days or more) to repair. Thus, it is necessary to provide surge arrester and lightning protection sufficient to prevent surge damage to the cables.

Reliability of underground transmission is a misunderstood topic. Frequently it is assumed that reliability is improved by placing transmission lines underground, out of sight. While it is true that underground cables have fewer tripouts per year than overhead lines, when a failure does occur on an underground cable, the repair time is sufficiently long that a prolonged outage may result. For this reason, underground cable systems are frequently designed with more redundancy (another cost factor) than overhead lines.

6. HIGH-VOLTAGE DIRECT-CURRENT TRANSMISSION

High-voltage direct-current (HVDC) transmission has a number of significant benefits, including lower costs for long distances, aid in system stability during disturbances, controllable power transfer, and more power transfer across a given right of way than alternating current. HVDC overhead transmission has been in commercial operation in the United States since 1969 when an 800-mile, ±400 kV line was energized. This line, the "Pacific Intertie," runs from The Dalles in Oregon to near Los Angeles in California.

6.1 Line Parameters

dc lines may be overhead or underground. The electrical model of an HVDC line is the pi-equivalent circuit described in Sec. 2. Several differences mark dc lines as compared to ac lines:

- R modeling is required for steady-state and transient performance
- L modeling is needed for the transient analysis.
- C modeling will demonstrate the very high-frequency characteristics during transient conditions. The capacitance also be-

comes important in underground dc cables, as discussed in Sec. 5.

6.2 Types of dc Installations

In HVDC transmission, ground return may be used as one conductor. Based on this fundamental principle, the following basic circuit arrangements may be considered: monopolar, bipolar, or homopolar. With monopolar transmission, only one transmission pole (or "phase") is installed. Ground return is permanently used. Monopolar transmission is used in systems of comparatively low power rating, primarily with underground or underwater transmission. A bipolar dc transmission line consists of two poles: positive and negative. A ground return is not necessary in bipolar transmission, but is normally installed to provide additional reliability in case one pole fails, and the line will temporarily operate as a monopolar line. A homopolar dc transmission lines consists of two poles with the same polarity. This is applicable for an overhead line feeding a monopolar cable.

HVDC transmission systems can be classified into three major categories: back-to-back systems; two-terminal, or point-to-point, systems; and multiterminal systems. In back-to-back HVDC systems, the rectifier (conversion of ac to dc) and the inverter (conversion of dc to ac) are located in the same substation and usually in the same building. The rectifier and inverter are normally joined through a reactor. A back-to-back dc system is used to connect two asynchronous ac systems (e.g., one system operating at 50 Hz and one operating at 60 Hz, or two ac systems operating at the same frequency but not synchronized).

Two-terminal dc systems can be either bipolar or monopolar. A bipolar configuration is commonly used with overhead lines and consists of two distinct "phase" locations, one for each polarity (positive and negative), which carry equal currents. A monopolar dc system will have only one "phase," either positive or negative polarity, utilizing the earth or another metallic conductor as the return path. The monopolar, ground-return configuration has been used for underwater dc installations where the return path is the water. In a monopolar, metallic return system, the return current flows through the metallic return conductor. The monopolar mode of operation may be used on a bipolar installation under contingency conditions, such as a partial converter failure.

Multiterminal dc installations may operate in either parallel or serial configuration. Parallel configurations can be either radial or mesh where all converters operate at the same dc voltage, similar to ac installations. In the parallel operation mode, one converter determines the operating voltage, while the other converters control the current flow. In a series operation of multiterminal dc lines, all converters operate at the same current where one converter sets the current, while the other converters operate in a voltage control mode. The power output of the noncurrent-controlling converter is varied by adjusting the voltage.

6.3 Converter Stations

Since generation and most of the transmission and distribution systems are ac, HVDC transmission requires conversion from ac to dc (rectification) and from dc to ac (inversion). Rectification and inversion are accomplished by converter stations. The converter terminal comprises the following major components: solid-state valves and controls, converter transformer, reactors, filters, and reactive power supplies.

A three-phase, full-wave bridge converter (Graetz circuit or three-phase, six-pulse converter) may be used for conversion from ac to dc and from dc to ac. The dc output voltage of a six-pulse bridge contains harmonics of orders multiples of six, i.e., 6, 12, 18, . . . , $6n$, where $n = 1, 2, 3, \ldots$. Unless the harmonic voltages are filtered, telephone interference along the dc line may result. The ac current from a six-pulse bridge contains current harmonics of orders 5, 7, 11, 13, 17, 19, . . . , $6n \pm 1$. If the current harmonics are not filtered, voltage distortion and telephone interference will result on the ac system.

A three-phase, 12-pulse converter that is composed of two three-phase, six-pulse converters may also be used for conversion from ac to dc and back again. The two six-pulse bridges are identical except that the ac supply voltages of the two are shifted in phase by 30°. As a result of the 30° phase shift, certain harmonics listed above are cancelled, thus leaving voltage harmonics on the dc side of orders 12, 24, 36, . . . , 12*n*, and current harmonics on the ac side of orders 11, 13, 23, 25, . . . , $12n \pm 1$. This reduction in harmonic filter requirements is one of the major reasons why most solid-state HVDC systems operate with twelve-pulse converters.

6.4 Electrical Environmental Considerations

HVDC systems environmentally are often more compatible and provide less operational difficulties than comparable ac systems. Similar to ac lines, the two categories of dc line electrical environmental considerations are corona effects and field effects. With an HVDC line, the corona effects may be broken into three categories: audible noise, radio interference, and air ions. The field effects of an HVDC line are electric and magnetic fields.

The positive-polarity conductor is the primary source of dc transmission-line audible noise and radio interference. The radio interference produced by the negative pole is about one-half that from the positive pole. Rain causes a slight reduction in audible noise. dc radio interference levels are decreased by rain, wet snow, and other atmospheric conditions that thoroughly wet the conductor. However, radio interference may increase slightly during the initial wetting period. Wind also affects dc radio interference levels. The radio interference levels are increased by wind, with the greatest influence being when the direction of air flow is from the negative to the positive pole (Chartier, 1981).

Air ions are charged molecules produced by the breakdown of the air molecules adjacent to the conductor (corona). Because of the nonalternating nature of the direct-current transmission, the air ions migrate away from the conductor. Because both conductors of a dc line have an electric field, both can produce corona and therefore air ions. Most air ions are attracted to the conductor opposite the one that generated them. Neutralization occurs when air ions combine with those of opposite polarity. Most air ions from HVDC lines are neutralized; approximately 10% of the ions escape and migrate away from the transmission line. The migrating air ions are carried away by wind, much like dust particles or pollen. Therefore, few air ions produced by the dc line are present on the upwind side of the line (Maruvada *et al.*, 1984; Johnson, 1983).

HVDC lines produce static (or constant) electric and magnetic fields. A typical electric field for a 500-kV dc transmission line is about 15 kV/m, and the magnetic field is about 100 mG at the edge of the right of way. The earth also has static electric and magnetic fields on the order of 0.09–0.13 kV/m and 480–600 mG, respectively.

6.5 Specific System Considerations

The decision to select a dc transmission system instead of an ac system may be summarized with one question: "Will taps or new substations be needed along the route in the future to supply additional loads or incorporate additional power sources?" dc will compete with ac systems where long distances are involved, charging current limits the ampacity, asynchronous interconnection is feasible, right-of-way availability demands a higher power density, controllability of dc enhances system stability, or lower short-circuit currents are desired.

Long cable circuits are a natural application for dc. With ac, the charging current utilizes part of the cable ampacity, whereas with dc, the full ampacity is available for power transfer. Underground (or underwater) cable lengths greater than 15–25 km require shunt reactors for ac installation. Higher dc voltages than ac voltages can be tolerated by a given cable design. Hence, a dc project will require fewer cables or less costly cables.

During steady-state operation, a rectifier can be considered as a load and the inverter as a generator. Power across a dc line can be set anywhere within line rating by simply requesting the desired power level. Loss of a converter is similar to load rejection or generator tripping or, in the case of a dc line between two points in the same synchronous system, the loss of an ac line carrying the same power. A dc line can be built to move a specified amount of power.

Dynamic operation of a dc line or back-to-back converter is very different from the operation of a comparable ac system. There are three capabilities that dc can provide that make it unique:

- The transfer over the line can be reduced almost instantaneously to a lower power-transfer level or all the way to zero, if necessary.
- If equipped with temporary overload capability, the dc line can be ramped very quickly to a power level that exceeds the normal operating level.
- The real and/or reactive power level can be smoothly varied or "modulated."

GLOSSARY

A-Weighted Sound Level [dB(A)]: Measured sound pressure level adjusted to correspond approximately to the sensitivity of human hearing according to a specified frequency response curve.

Ampacity: Current-carrying capacity of a wire or cable under specified thermal conditions.

Bundled Conductor: An assembly of two or more conductors used as a single conductor and employing spacers to maintain a predetermined configuration.

Bus: A heavy conductor in a substation used to connect substation components at a specific voltage level.

Coupling Capacitor: A capacitive voltage divider used to connect communications signals to power transmission conductors.

Current Transformer: A transformer designed and applied to maintain a specific ratio of current from primary to secondary for metering and protective relay applications.

Distribution: The part of an electric power system that transports power from high-voltage substations to the end users.

Geometric Mean Radius (GMR): The equivalent radius of a single conductor that gives the same impedance as a bundled conductor.

Grading Ring: A metallic ring (e.g., mounted at the end of an insulator) to lower the electric field on some component.

Line Trap: A coil mounted in a substation to isolate communications signals to a specific power transmission line.

Positive Sequence: The sequence resulting from the symmetrical component transformation that represents normal balanced operation of a three-phase system.

Quasistatic: Low-frequency approximation where static (dc) electric and magnetic field equations adequately represent time-varying fields.

Reactive Power: The product of the voltage, current, and sine of the phase angle between them in a sinusoidal circuit. Unit of measure is volt-ampere reactive (var).

Relaxation Time: The time required for the deviation from equilibrium of some system parameter to diminish to $1/e$ of its initial value.

Shield Wire: A wire employed for the purpose of reducing the effects on electric supply or communication circuits from extraneous sources; in overhead power transmission, a grounded wire situated above the phase conductors for lightning protection.

Subconductor: One of the individual conductors constituting a bundled conductor.

Substation: A power station used to interconnect transmission and/or distribution lines, often at different voltages.

Subtransmission: A term sometimes used for that part of the power transmission system connecting bulk high-voltage substations and distribution substations.

Symmetrical Components: A matrix transformation for a three-phase system that decomposes the phase voltages, currents, and impedances into three sequences called positive, negative, and zero sequence.

Transmission: The part of an electric power system devoted to bulk transport of power.

Transverse Electromagnetic (TEM): An electromagnetic field mode whose electric and magnetic field vectors are both normal to the direction of propagation.

Voltage (Potential) Transformer: A transformer designed and applied to maintain a specific ratio of voltage from primary to secondary for metering and protective relay applications.

Zero Sequence: The sequence resulting from the symmetrical component transformation that represents the average current of the three phases that returns somewhere other than through the phase conductors themselves.

1. INTRODUCTION

The mathematical theory of probability provides a systematic approach to the study of random mass phenomena, that is, experiments that can be performed any number of times under identical conditions. This theory was initiated by B. Pascal (1623–1662) and P. Fermat (1601–1665) in 1654. The pioneering results were achieved by Ch. Huygens (1629–1695), Jakob Bernoulli (1654–1705), P. R. Montmort (1678–1719), and A. De Moivre (1667–1754). In the early nineteenth century, great progress was made by P. S. Laplace (1749–1827) and J. Lagrange (1736–1813). At the end of the nineteenth century and at the beginning of the twentieth century, P. L. Chebyshev (1821–1894) and A. A. Markov (1856–1922) contributed significantly to the theory. The foundations of modern probability theory were laid down by P. Lévy (1886–1971), A. Ya. Khintchine (1894–1959), and A. N. Kolmogorov (1903–1987).

An experiment is called a *random trial* if it has several possible outcomes and the actual outcome is not determined by the given conditions. For example, the experiment may be the tossing of a balanced coin, and the result may be either heads or tails, but we cannot predict which one. The various outcomes of a random trial are called *events* (simple or compound) and are frequently denoted by Latin capital letters. We speak about a simple event if it can occur only in one way, and a compound event if it can occur in more than one way. In the example of the coin, let

A denote the event that the coin shows heads and B, the event that it shows tails. Both A and B are simple events.

Let us suppose that we toss a coin repeatedly n times and we obtain $k_n(A)$ heads and $k_n(B)$ tails. The ratio $k_n(A)/n$ is called the *frequency* of A in the n trials, and $k_n(B)/n$, the frequency of B in the n trials. It is an empirical observation that in repeated trials the frequency of any event shows stability if the number of trials increases. If n increases, then, in a random way, $k_n(A)/n$ approaches a real number p, and $k_n(B)/n$ approaches a real number q. By an approach in a random way, we mean that as n increases, in an overwhelming majority of the trials the deviations

$$\left|\frac{k_n(A)}{n} - p\right| \quad \text{and} \quad \left|\frac{k_n(B)}{n} - q\right|$$

are very small. The numbers $\mathbf{P}\{A\} = p$ and $\mathbf{P}\{B\} = q$ are called the *probabilities* of the events A and B respectively.

Since

$$0 \le \frac{k_n(A)}{n} \le 1, \quad 0 \le \frac{k_n(B)}{n} \le 1,$$

and

$$k_n(A)/n + k_n(B)/n = 1,$$

for every $n = 1, 2, \ldots$, we must have $0 \le p \le 1$, $0 \le q \le 1$, and $p + q = 1$.

In general, if in a random trial an event A has probability p where $0 \le p \le 1$, and if we repeat the trial n times, we expect that the observed frequency of A will be close to p, provided that n is sufficiently large.

We cannot determine the probability of an event by theoretical reasoning. The probability of any event is a physical constant, like the mass of an atom. Relying on our experience with random trials, we accept the existence of such a constant, and our aim is to build up a mathematical theory that reflects this fact and makes it possible to give predictions about the nature of the outcomes of repeated random trials. Thus we can define a mathematical model for the trial of tossing a coin. If the probability of heads is p where $0 \le p \le 1$, then the probability of tails is necessarily $q = 1 - p$. By the theory of probability, we can derive several general results for the coin-tossing trials. Let us suppose that the coin is tossed n times under identical conditions, and denote by ν_n the number of heads observed, that is, $\nu_n = k_n(A)$ in our previous notation. As usual, ν_n is called a *random variable* (random quantity), which may take on the values $0, 1, \ldots, n$. The probability of the event $\nu_n = k$, that is, the probability that we obtain exactly k heads, is

$$\mathbf{P}\{\nu_n = k\} = \binom{n}{k} p^k q^{n-k}$$

for $k = 0, 1, \ldots, n$. Denote by

$$\delta_n = \nu_n/n - p$$

the deviation between the frequency and the probability of heads in the n trials. For any positive real number a, we have

$$\mathbf{P}\{|\delta_n| \le a\sqrt{pq/n}\} = \sum_{|k-np| \le a\sqrt{npq}} \mathbf{P}\{\nu_n = k\}.$$

This probability is arbitrarily close to

$$P(a) = \frac{1}{\sqrt{2\pi}} \int_{-a}^{a} e^{-x^2/2}\, dx$$

if n is sufficiently large. If $a = 3$, then $P(3) = 0.9973 \cdots$. If in our trial we use a balanced coin, then by symmetry we expect that both heads and tails have the same probability, that is, $p = q = \frac{1}{2}$. In this case, it is reasonable to choose the model for which $p = \frac{1}{2}$. Then by the above general results we can draw the conclusion that if n is sufficiently large, in n trials, the deviation between the frequency and the probability of heads is $\le 3/2\sqrt{n}$ with probability $0.9973 \cdots$. If the coin is loaded, then we should select another model for which $p \ne \frac{1}{2}$. If p is unknown, then we can still use the theory of probability to design tests that make it possible to estimate p within a prescribed error with high accuracy.

2. RANDOM TRIALS

In order to study random trials mathematically, we associate a *probability space* $(\Omega,\mathcal{B},\mathbf{P})$ with every random trial considered. Here Ω is the *sample space*, the set of all the possible simple outcomes of the random trial, and $\mathcal{B}$ is the class of events with which we desire to associate probabilities. If A is an event belonging to $\mathcal{B}$, then $\mathbf{P}\{A\}$ is the probability of A.

Let us consider the example of throwing a six-sided die. We observe the number of points showing on the top face of the die. This number may be 1, 2, 3, 4, 5, or 6. Let us define the sample space as $\Omega = \{1,2,3,4,5,6\}$. Each sample point represents a simple event. We also want to consider compound events, such as A = the result is an even number, B = the result is an odd number, and C = the result is a prime number. We also include Ω, the sure event that always occurs, and $\varnothing$, the impossible event, which never occurs. There are $2^6 = 64$ admissible events associated with the trial considered. We can describe every event as a subset of Ω. Each simple event is represented by a single sample point. A compound event contains more than one sample point. The events $A = \{2,4,6\}$, $B = \{1,3,5\}$, $C = \{2,3,5\}$, and $\Omega = \{1,2,3,4,5,6\}$, the sure event, are compound events. The impossible event, $\varnothing$, is represented by the empty set.

Now let us consider various possible relations among events. If the occurrence of an event A implies the occurrence of an event B, then we write $A \subset B$ (A is a subset of B). The complementary event of A will be denoted by $\bar{A}$ (A does not occur). If we have two events A and B, then we can define a new event by the condition "both A and B occur." This event, the simultaneous occurrence of A and B, will be denoted by AB or by $A \cap B$ (the intersection of the two sets A and B). The event "at least one of the two events A and B occurs" will be denoted by $A + B$ or by $A \cup B$ (the union of the two sets A and B). More generally, $ABC \cdots$ or $A \cap B \cap C \cap \cdots$ means the simultaneous occurrence of $A, B, C, \ldots$ (the intersection of $A, B, C, \ldots$), and $A + B + C + \ldots$ or $A \cup B \cup C \cup \cdots$ means that at least one event occurs among $A, B, C, \ldots$ (the union of the sets $A, B, C, \ldots$). Two events are mutually exclusive if they cannot occur simultaneously, that is, if $AB = \varnothing$. More generally, any number of events $A, B, C, \ldots$ are mutually exclusive if among them no two events can occur simultaneously.

A class of events (some subsets of Ω) $\mathcal{B}$ is called an *algebra* if it is closed under any finite number of set operations (forming intersection, union, and complementary sets). Equivalently, $\mathcal{B}$ is an algebra of some subsets of Ω if and only if (a) $A \in \mathcal{B}$ implies that $\bar{A} \in B$, and (b) $A \in \mathcal{B}$ and $B \in \mathcal{B}$ imply that $A + B \in \mathcal{B}$.

If Ω, the sample space, is finite, we always assume that $\mathcal{B}$, the class of random events, is an algebra. If $\mathcal{B}$ contains all the possible subsets of Ω, then $\mathcal{B}$ is obviously an algebra.

First, let us assume that Ω is finite, say, $\Omega = \{\omega_1,\omega_2,\ldots,\omega_m\}$, consisting of m sample points, and $\mathcal{B}$ is an algebra of some subsets of Ω. With every event $A \in \mathcal{B}$, we want to associate a nonnegative real number, $\mathbf{P}\{A\}$, the probability of A. Since there are various relations among events, we expect that the probabilities of the different events cannot be chosen freely; they are subject to some restraints. These restraints are expressed by the following system of axioms: (i) $\mathbf{P}\{A\} \geq 0$ for $A \in \mathcal{B}$, (ii) $\mathbf{P}\{\Omega\} = 1$, and (iii) if $A \in \mathcal{B}$, $B \in \mathcal{B}$, and $AB = \varnothing$, then

$$\mathbf{P}\{A + B\} = \mathbf{P}\{A\} + \mathbf{P}\{B\}.$$

These are obvious requirements. They are based on our intuitive interpretation of the probability of an event.

The system of axioms implies that the probability is finitely additive; that is, if A_1, $A_2, \ldots, A_n$ are mutually exclusive events, then we have

$$\mathbf{P}\{A_1 + A_2 + \cdots + A_n\} = \mathbf{P}\{A_1\} + \mathbf{P}\{A_2\} + \cdots + \mathbf{P}\{A_n\}$$

for $n = 2, 3, \ldots$.

If Ω, the sample space, is finite, then every probability space $(\Omega,\mathcal{B},\mathbf{P})$ that satisfies the above requirements provides a mathematical model for a random trial.

If Ω contains m sample points, that is, $\Omega = \{\omega_1,\omega_2,\ldots,\omega_m\}$, if $\mathcal{B}$ contains all the 2^m subsets of Ω, including the empty set and the whole set, and if the event $A_i = \{\omega_i\}$ ($i = 1,2,\ldots,m\}$ has probability $\mathbf{P}\{A_i\} = p_i$ ($i = 1,2,\ldots,m$), then it follows from the system of axioms that $p_i \geq 0$ for all $i = 1, 2, \ldots, m$ and

$$p_1 + p_2 + \cdots + p_m = 1.$$

If A is a subset of Ω that contains k sample points, namely, $A = \{\omega_{i_1},\omega_{i_2},\ldots,\omega_{i_k}\}$, then by the system of axioms,

$$\mathbf{P}\{A\} = p_{i_1} + p_{i_2} + \cdots + p_{i_k}.$$

In this case to every choice of the nonnegative real numbers $p_1, p_2, \ldots, p_m$ whose sum is $p_1 + p_2 + \cdots + p_m = 1$, there corresponds a probability space $(\Omega,\mathcal{B},\mathbf{P})$ that describes a random trial. The case where p_i does not depend on i has special importance. Then necessarily $p_i = 1/m$, and if A is defined as above, then

$$\mathbf{P}\{A\} = k/m.$$

This is a simple rule for calculating the probabilities of various events. If there are m possible cases, if they are equally probable, and if an event A can occur in k different ways (i.e., the number of cases favorable for A is k), then the probability of A is simply the ratio of the number of favorable cases to the total number of cases. In the age of classical probability theory, this model was almost exclusively the only one considered, and the above rule served as the definition of probability.

If Ω, the sample space, contains infinitely many sample points, then, in defining the associated probability space, $(\Omega,\mathcal{B},\mathbf{P})$, we impose some further restrictions on $\mathcal{B}$ and $\mathbf{P}$. We require that $\mathcal{B}$, the class of random events, be closed not only for finite, but also for countably infinite numbers of set operations. If this is satisfied, then we say that $\mathcal{B}$ is a σ-algebra. We can see that $\mathcal{B}$ is a σ-algebra of some subsets of Ω if and only if (a) $A \in \mathcal{B}$ implies that $\bar{A} \in B$, and (b) $A_n \in \mathcal{B}$ for $n = 1, 2, \ldots$ implies that

$$\sum_{n=1}^{\infty} A_n \in \mathcal{B}.$$

We require that the probability be not only finitely additive, but also countably additive. In this case, the system of axioms is as follows: (i) $\mathbf{P}\{A\} \geq 0$ for $A \in \mathcal{B}$, (ii) $\mathbf{P}\{\Omega\} = 1$, and (iii) if $A_i \in \mathcal{B}$ for $i = 1, 2, \ldots$ and $A_iA_j = \emptyset$ for $i \neq j$, then

$$\mathbf{P}\left\{\sum_{i=1}^{\infty} A_i\right\} = \sum_{i=1}^{\infty} \mathbf{P}\{A_i\}.$$

Briefly, the probability $\mathbf{P}\{A\}$ is a finite, nonnegative, countably additive (σ-additive) set function on a σ-algebra $\mathcal{B}$ of subsets of Ω.

3. GENERAL THEOREMS

Let $(\Omega,\mathcal{B},\mathbf{P})$ be a probability space describing a random trial. Let $A, B, A_1, A_2, \ldots$ be random events belonging to $\mathcal{B}$. It is always assumed that $\mathcal{B}$ is a σ-algebra of subsets of Ω and $\mathbf{P}\{A\}$ is a probability defined for $A \in \mathcal{B}$, which satisfies the system of axioms.

From the system of axioms, we can deduce several general theorems for $\mathbf{P}\{A\}$, $A \in \mathcal{B}$. Here are a few theorems.

If $A \subset B$, then $\mathbf{P}\{A\} \leq \mathbf{P}\{B\}$. The probability of the impossible event is $\mathbf{P}\{\emptyset\} = 0$. The probability of the complementary event of A is $\mathbf{P}\{\bar{A}\} = 1 - \mathbf{P}\{A\}$.

Boole's inequality: For an arbitrary sequence of events A_i ($i = 1,2,\ldots$) we have

$$\mathbf{P}\{A_1 + A_2 + \cdots\} \leq \mathbf{P}\{A_1\} + \mathbf{P}\{A_2\} + \cdots.$$

Let us consider n events $A_1, A_2, \ldots, A_n$. Define $S_0 = 1$ and

$$S_j = \sum_{1 \leq i_1 < i_2 < \cdots < i_j \leq n} \mathbf{P}\{A_{i_1}A_{i_2} \cdots A_{i_j}\}$$

for $j = 1, 2, \ldots, n$. Here S_j is the sum of $\binom{n}{j}$ probabilities. Then we have *Poincaré's theorem:* The probability that at least one event occurs among $A_1, A_2, \ldots, A_n$ is

$$\mathbf{P}\{A_1 + A_2 + \cdots + A_n\} = \sum_{j=1}^{n} (-1)^{j-1} S_j.$$

We also have *Jordan's theorem:* The probability that exactly k events occur among $A_1, A_2, \ldots, A_n$ is

$$P_k(A_1,A_2,\ldots,A_n) = \sum_{j=k}^{n} (-1)^{j-k}\binom{j}{k}S_j$$

for $k = 0, 1, \ldots, n$.

If $A_1, A_2, \ldots, A_n, \ldots$ is an infinite sequence of events, then

$$A^* = \limsup_{n\to\infty} A_n := \prod_{n=1}^{\infty}\sum_{i=n}^{\infty} A_i$$

is the event that infinitely many events occur in the sequence $A_1, A_2, \ldots, A_n, \ldots$, and

$$A_* = \liminf_{n\to\infty} A_n := \sum_{n=1}^{\infty}\prod_{i=n}^{\infty} A_i$$

is the event that all but a finite number of events occur in the sequence $A_1, A_2, \ldots, A_n, \ldots$. If $A_n \in \mathcal{B}$ for $n = 1, 2, \ldots$, then $A^* \in \mathcal{B}$ and $A_* \in \mathcal{B}$, and

$$\mathbf{P}\{A^*\} = \lim_{n\to\infty} \mathbf{P}\left\{\sum_{i=n}^{\infty} A_i\right\}$$

and

$$\mathbf{P}\{A_*\} = \lim_{n\to\infty} \mathbf{P}\left\{\prod_{i=n}^{\infty} A_i\right\}.$$

Obviously, $A_* \subset A^*$ and $\mathbf{P}\{A_*\} \le \mathbf{P}\{A^*\}$.

A remark about notations: We can use interchangeably the notations $A + B$ and $A \cup B$, and likewise AB and $A \cap B$. In this article, the notations $A + B$ and AB are used for a finite or a countably infinite number of events, and the notations $\cup$ and $\cap$ are used for nondenumerable events. It is ambiguous to write, for example, $\mathbf{P}\{A \cup B \cap C\}$. The notation $\mathbf{P}\{A + BC\}$ indicates immediately the hierarchy of operations. Multiplication (intersection) has preference over addition (union) just like in arithmetic.

4. COMBINATORIAL METHODS

In Sec. 2, we have already mentioned an important model for random trials in which the sample space Ω contains m sample points, $\mathcal{B}$ contains all the possible 2^m subsets of Ω, and if an event $A \in \mathcal{B}$ contains exactly k sample points, then

$$\mathbf{P}\{A\} = k/m,$$

that is, the probability of A is the number of favorable cases divided by the number of possible cases. We can write also that $\mathbf{P}\{A\} = |A|/|\Omega|$ where $|A|$ is the number of elements of the set A, and similarly $|\Omega|$ is the number of elements of the set Ω. It is usual to apply combinatorial methods for the determination of $|A|$ and $|\Omega|$.

Let us consider a few examples.

Example 1. We have n boxes, and each box contains a white balls and b black balls. We draw a ball from each box. What is the probability that among the n balls drawn there will be k white balls and $n - k$ black balls? If all the possible $(a + b)^n$ cases are equally probable, then the probability in question is

$$P_k = \binom{n}{k}\frac{a^k b^{n-k}}{(a + b)^n} = \binom{n}{k} p^k q^{n-k},$$

where $p = a/(a + b)$, $q = b/(a + b)$, and $k = 0, 1, \ldots, n$. The answer is the same if we have only one box that contains a white balls and b black balls, and we draw n times with replacement, that is, after each drawing we put back into the box the ball drawn.

Example 2. We have a box that contains a white balls and b black balls, and we draw n times without replacement, that is, we do not put the balls drawn back into the box. What is the probability that among the n balls drawn there will be k white balls and $n - k$ black balls? If $n \le a + b$ and if all the possible $(a + b)(a + b - 1) \cdots (a + b - n + 1)$ cases are equally probable, then the probability in question is

$$Q_k = \binom{n}{k}\frac{a(a-1)\cdots(a-k+1)b(b-1)\cdots(b-n+k+1)}{(a+b)(a+b-1)\cdots(a+b-n+1)} = \frac{\binom{a}{k}\binom{b}{n-k}}{\binom{a+b}{n}}$$

for $k = 0, 1, \ldots, n$. We obtain the same probability if we take all the n balls simultaneously out of the box and assume that all the possible $\binom{a+b}{n}$ cases are equally probable.

Example 3. A box contains m cards marked $1, 2, \ldots, m$. We draw n cards with replacement. There are m^n possible results. If all these m^n cases are equally probable, then the probability that the sum of the n numbers drawn is k is given by

$$P_k = \frac{1}{m^n}\sum_{j=0}^{[(k-n)/m]} (-1)^j \binom{n}{j}\binom{k - 1 - jm}{n - 1}$$

for $n \le k \le mn$. This formula was discovered by P. R. Montmort in 1710 and A. De Moivre in 1711.

Example 4. A box contains n cards marked $k_1, k_2, \ldots, k_n$ where $k_1, k_2, \ldots, k_n$ are nonnegative integers with sum $k_1 + k_2 + \cdots + k_n = k$ where $k \le n$. We draw all the n cards without replacement. Let us assume that all the $n!$ outcomes are equally probable. Then the probability that the sum of the first r numbers drawn is less than r for every $r = 1, 2, \ldots, n$ is given by

$$P(n,k) = (n - k)/n.$$

This problem is a generalization of the classical ballot problem of J. Bertrand from 1887.

Example 5. We distribute n balls in m boxes. All the m^n arrangements are assumed to be equally probable. The probability that the ith box contains k_i balls for $i = 1, 2, \ldots, m$ is

$$P(k_1,k_2,\ldots,k_m) = \frac{n!}{k_1!k_2!\cdots k_m!}\left(\frac{1}{m}\right)^n$$

if $k_1 + k_2 + \cdots + k_m = n$. In statistical mechanics the Maxwell–Boltzmann statistics is based on the above model.

5. GEOMETRIC METHODS

First, let us say a few words about Borel sets and the Lebesgue measure in finite-dimensional Euclidean spaces. In one dimension, an elementary set is defined as the union of a finite number of disjoint intervals. Let us consider the smallest class of sets that contains all the elementary sets and that is closed under any finite or countably infinite number of intersections and unions. If a set belongs to this class, then the set is called a Borel set. With every Borel set S, we can associate a nonnegative real number $\mu(S)$, the measure of S. If S is an interval, then $\mu(S)$ is simply the length of S. If an interval S is the union of a finite or countably infinite number of disjoint intervals $S_1, S_2, \ldots$, then the length of S satisfies the following property:

$$\mu(S) = \mu(S_1) + \mu(S_2) + \cdots.$$

The Lebesgue measure of a Borel set S is simply an extension of the notion of length to more general sets than intervals in such a way that above-mentioned additive property is preserved. It can be proved that there is a unique extension. Accordingly, if S is a Borel set and if S is the union of a finite or countably infinite number of disjoint Borel sets S_i, $i = 1, 2, \ldots$, then

$$\mu(S) = \mu(S_1) + \mu(S_2) + \cdots.$$

In higher dimensions, we define Borel sets and the Lebesgue measure in a similar way. In two dimensions, we start with the area of a rectangle; in three dimensions, with the volume of a parallelepiped, and so on.

Let Ω be a Borel set with a finite, positive Lebesgue measure $\mu(\Omega)$. We choose a point at random in Ω. We can describe this random trial by the probability space $(\Omega,\mathcal{B},\mathbf{P})$ where $\mathcal{B}$ is the σ-algebra of Borel subsets of Ω, and if $A \in \mathcal{B}$, then $\mathbf{P}\{A\} = \mu(A)/\mu(\Omega)$ where $\mu(A)$ is the Lebesgue measure of A. In this case, we say simply that the random point has a uniform distribution over the set Ω. The problem of finding the probabilities of various events can be reduced to the problem of finding the measures of various sets in one, two, three, or higher dimensions.

Here are a few examples.

Example 1. We choose a point at random in the interval $(0,t)$. Suppose that the point has a uniform distribution over $(0,t)$. Let $0 \le x \le t$. What is the probability that the random point belongs to the interval $(0,x)$? The answer is evidently x/t.

Example 2. Let us choose two points at random in the interval $(0,t)$. The outcome of this random trial can be described by an ordered point pair (u,v) where $0 \le u \le t$ and $0 \le v \le t$. It is obvious to define the sample space as $\Omega = \{(u,v):0 \le u \le t, 0 \le v \le t\}$, that is, Ω is a square in the plane. Let us assume that the point pair (u,v) has a uniform distribution over Ω. In this case, we define $\mathcal{B}$ as the σ-algebra of Borel subsets of Ω, and the probability of an event $A \in \mathcal{B}$ is $\mathbf{P}\{A\} = \mu(A)/\mu(\Omega)$ where now $\mu(A)$ is the two-dimensional Lebesgue measure of A and $\mu(\Omega) = t^2$, the area of Ω. If we want to find the probability that both points belong to the interval $(0,x)$ where $0 \le x \le t$, then the answer is $\mathbf{P}\{A\}$ where now $A = \{(u,v):0 \le u \le x, 0 \le v \le x\}$. In this case, A is a square and its area is x^2. Thus $\mathbf{P}\{A\} = x^2/t^2$.

Example 3. What is the probability that in the preceding example the distance between the two points is $\leq x$ where $0 \leq x \leq t$? The answer is simply $\mathbf{P}\{B\}$ where now $B = \{(u,v):|u - v| \leq x\}$. We can easily see that the area of B is $t^2 - (t - x)^2 = 2tx - x^2$ and so the probability in question is $(2tx - x^2)/t^2$.

Example 4. In 1733, Comte de Buffon (G. L. Leclerc) proposed the following problem in geometric probability. A plane is ruled with a series of parallel lines a distance of $2a$ apart. A needle of length $2l (l < a)$ is thrown at random on the plane. Determine the probability that the needle will touch or intersect one of the lines. We can describe the outcome of this random trial by a pair of numbers (x,α), where x is the distance from the center of the needle to the closest line and α is the angle that the needle forms with this line. We have $0 \leq x \leq a$ and $0 \leq \alpha \leq \pi$. In this case, we can define the sample space as $\Omega = \{(x,\alpha):0 \leq x \leq a, 0 \leq \alpha \leq \pi\}$, that is, Ω is a rectangle in the plane and its area is $\mu(\Omega) = a\pi$. If we assume that the point pair (x,α) has a uniform distribution over Ω, then the probability in question is $\mathbf{P}\{C\} = \mu(C)/\mu(\Omega)$ where now C is the subset of Ω that contains the point pairs (x,α) for which the needle touches or intersects one of the lines. This happens if and only if $0 \leq x \leq l \sin\alpha$, that is, $C = \{(x,\alpha):0 \leq x \leq l \sin\alpha, 0 \leq \alpha \leq \pi\}$. The area of C is

$$\mu(C) = l \int_0^\pi \sin\alpha \, d\alpha = 2l,$$

and consequently, $\mathbf{P}\{C\} = 2l/(a\pi)$. In 1850, a Swiss astronomer, J. R. Wolf, performed 5000 trials in the case where $l/a = 0.8$ and estimated π empirically. He found that $\pi \sim 3.159 \cdots$.

6. CONDITIONAL PROBABILITIES

The following consideration leads in a natural way to the notion of conditional probability. Let us consider a random trial with probability space $(\Omega,\mathcal{B},\mathbf{P})$. Let $A \in \mathcal{B}$ and $B \in \mathcal{B}$ be two given events. Let us perform the random trial n times under identical conditions and observe the number of occurrences of A, B, and AB. Suppose that in n trials A occurs $k_n(A)$ times, B occurs $k_n(B)$ times, and AB occurs $k_n(AB)$ times. If n increases, $k_n(A)/n$, $k_n(B)/n$, and $k_n(AB)/n$ approach in a random way the probabilities $\mathbf{P}\{A\}$, $\mathbf{P}\{B\}$, and $\mathbf{P}\{AB\}$ respectively.

The frequency of A in the $k_n(B)$ trials in which B occurs is

$$\frac{k_n(AB)}{k_n(B)} = \frac{k_n(AB)/n}{k_n(B)/n}.$$

If $\mathbf{P}\{B\} \neq 0$, then $k_n(AB)/k_n(B)$ will approach $\mathbf{P}\{AB\}/\mathbf{P}\{B\}$ in a random way. We can interpret $\mathbf{P}\{AB\}/\mathbf{P}\{B\}$ as the probability of A given that B occurs. We shall denote it by $\mathbf{P}\{A|B\}$ and call it the *conditional probability* of A for given B (or if it is known that B occurred, or on the hypothesis B.) If $\mathbf{P}\{B\} > 0$, then for an arbitrary event A we define

$$\mathbf{P}\{A|B\} = \mathbf{P}\{AB\}/\mathbf{P}\{B\}.$$

The conditional probability $\mathbf{P}\{A|B\}$ remains undefined when $\mathbf{P}\{B\} = 0$. Then necessarily $\mathbf{P}\{AB\} = 0$.

Let us suppose that the random trial consists in throwing a symmetric die and we assume that each side has the same probability of being the top face. Denote by A the event that the result is an even number, that is, $A = \{2,4,6\}$, and B, the event that the result is ≤ 3, that is, $B = \{1,2,3\}$. Then $\mathbf{P}\{A\} = \mathbf{P}\{B\} = \frac{3}{6}$ and $\mathbf{P}\{AB\} = \frac{1}{6}$. The conditional probability

$$\mathbf{P}\{A|B\} = \tfrac{1}{3}.$$

By the definition of the conditional probability, it follows that

$$\mathbf{P}\{AB\} = \mathbf{P}\{A|B\}\mathbf{P}\{B\}$$

if $\mathbf{P}\{B\} \neq 0$, and by symmetry

$$\mathbf{P}\{AB\} = \mathbf{P}\{A\}\mathbf{P}\{B|A\}$$

if $\mathbf{P}\{A\} \neq 0$. More generally, for any n events $A_1, A_2, \ldots, A_n$ we have the so-called chain rule,

$$\mathbf{P}\{A_1A_2 \cdots A_n\} = \mathbf{P}\{A_1\}\mathbf{P}\{A_2|A_1\}\mathbf{P}\{A_3|A_1A_2\} \cdots \mathbf{P}\{A_n|A_1 \cdots A_{n-1}\},$$

provided that the conditional probabilities on the right-hand side are meaningful.

6.1 The Theorem of Total Probability

Let $\{A_i, i \in I\}$ be a complete system of events, that is, a sequence of mutually exclusive and exhaustive events. By this, we mean that $A_iA_j = \varnothing$ for $i \neq j$ and $\Sigma_{i \in I} A_i = \Omega$. Then for any event B we have

$$\mathbf{P}\{B\} = \sum_{i \in I} \mathbf{P}\{A_i\}\mathbf{P}\{B|A_i\}.$$

If it happens that for some i the probability $\mathbf{P}\{A_i\} = 0$, then in the sum the ith term should be interpreted as 0. This formula is useful because the evaluation of the conditional probabilities $\mathbf{P}\{B|A_i\}$ is sometimes easier than a direct evaluation of $\mathbf{P}\{B\}$.

Example 1. Let us consider $m + 1$ boxes numbered $i = 0, 1, \ldots, m$. In box i, there are i white balls and $m - i$ black balls. We choose a box at random. We may choose any of the $m + 1$ boxes with the same probability. We draw n balls with replacement from the box chosen. What is the probability that we get k white balls and $n - k$ black balls?

Let A_i denote the event of choosing box i. Then $\mathbf{P}\{A_i\} = 1/(m + 1)$ for $i = 0, 1, \ldots, m$. Denote by B the event of drawing k white balls and $n - k$ black balls. Then

$$\mathbf{P}\{B|A_i\} = \binom{n}{k} \frac{i^k(m - i)^{n-k}}{m^n}$$

for $i = 0, 1, \ldots, m$, and

$$\mathbf{P}\{B\} = \sum_{i=0}^{m} \mathbf{P}\{A_i\}\mathbf{P}\{B|A_i\}$$
$$= \binom{n}{k} \frac{1}{(m + 1)m^n} \sum_{i=0}^{m} i^k(m - i)^{n-k}.$$

6.2 Bayes's Theorem

In 1763, an important theorem was discovered in the manuscripts of the Rev. Thomas Bayes, who had died two years earlier. By this theorem if $\mathbf{P}\{B\} > 0$ and $\{A_i, i \in I\}$ is a complete system of events, then

$$\mathbf{P}\{A_i|B\} = \frac{\mathbf{P}\{A_iB\}}{\mathbf{P}\{B\}} = \frac{\mathbf{P}\{A_i\}\mathbf{P}\{B|A_i\}}{\Sigma_{j \in I}\mathbf{P}\{A_j\}\mathbf{P}\{B|A_j\}}.$$

This theorem can be applied in the following situation. We perform a random trial and observe the occurrence of an event B. If $\{A_i\}$ is a complete system of events, then one and only one event necessarily occurs. Here $\mathbf{P}\{A_i\}$ is the *a priori* (before observation) probability of A_i. The conditional probability $\mathbf{P}\{A_i|B\}$ is the *a posteriori* (after observation) probability of A_i, that is, the probability of A_i calculated under the hypothesis that we observe the occurrence of B.

Example 2. Let us suppose that we have $m + 1$ boxes. For each $i = 0, 1, \ldots, m$ there is one box that contains i white balls and $m - i$ black balls. We choose a box at random. We may choose any of the $m + 1$ boxes with equal probability. From it we draw n balls with replacement. We get k white balls and $n - k$ black balls. What is the probability that we have chosen the box that contains i white balls and $m - i$ black balls? If we use the same notations as in example 1, then the answer is

$$\mathbf{P}\{A_i|B\} = \frac{\mathbf{P}\{A_i\}\mathbf{P}\{B|A_i\}}{\Sigma_{j=0}^{m} \mathbf{P}\{A_j\}\mathbf{P}\{B|A_j\}} = \frac{i^k(m - i)^{n-k}}{\Sigma_{j=0}^{m} j^k(m - j)^{n-k}}$$

for $i = 0, 1, \ldots, m$.

Example 3. A box contains m balls, white balls and black balls in unknown proportion. We draw n balls with replacement. Among the n balls, we get k white balls and $n - k$ black balls. What is the probability that in the box there are i white balls and $m - i$ black balls?

Let A_i $(i = 0,1,\ldots,m)$ be the event that there are i white balls and $m - i$ black balls in the box, and denote by B the event that in the n drawings with replacement we get k white balls and $n - k$ black balls. Then

$$\mathbf{P}\{B|A_i\} = \binom{n}{k} \frac{i^k(m - i)^{n-k}}{m^n}$$

and write $\mathbf{P}\{A_i\} = \omega_i$ $(i = 0,1,\ldots,m)$. By Bayes's theorem

$$\mathbf{P}\{A_i|B\} = \frac{\mathbf{P}\{A_i\}\mathbf{P}\{B|A_i\}}{\Sigma_{j=0}^{m}\mathbf{P}\{A_j\}\mathbf{P}\{B|A_j\}}$$
$$= \frac{\omega_i i^k(m - i)^{n-k}}{\Sigma_{j=0}^{m}\omega_j j^k(m - j)^{n-k}}$$

for $i = 0, 1, \ldots, m$. Now $\omega_i = \mathbf{P}\{A_i\}$ denotes the *a priori* probability that there are i white and $m - i$ black balls in the box, and $P_i(n) = \mathbf{P}\{A_i|B\}$ $(i = 0,1,\ldots,m)$ is the *a posteriori* (conditional) probability of the event that there are i white balls and $m - i$ black balls in the box. To find this probability, we must accept some hypothesis as to how the box was filled with balls. For example, we may suppose that all possible proportions of the white balls to the black balls are equally probable. Then $\omega_i = 1/(m + 1)$ for $i = 0, 1, \ldots, m$ and

$$P_i(n) = \frac{i^k(m - i)^{n-k}}{\sum_{j=0}^{m} j^k(m - j)^{n-k}}$$

for $i = 0, 1, \ldots, m$. This hypothesis is justified, for example, if we know that the box was chosen among the $m + 1$ boxes considered in example 2 and all the $m + 1$ possible choices were equally probable. There are many other possible hypotheses. For example, the box may contain as many white balls as the number of heads obtained in tossing m balanced coins, and as many black balls as the number of tails obtained. If we know that the box was filled with balls in that way, then we should choose

$$\omega_i = \binom{m}{i}\frac{1}{2^m}$$

for $i = 0, 1, \ldots, m$.

7. INDEPENDENT EVENTS AND TRIALS

The conditional probability $\mathbf{P}\{A|B\}$ generally does not equal the probability $\mathbf{P}\{A\}$. The information as to whether B has occurred changes the probability of the occurrence of the event A. Only when $\mathbf{P}\{A|B\} = \mathbf{P}\{A\}$ does this information not permit any inference as to the occurrence of A. In this case we say that A is *independent* of B. The notion of independence in probability theory is interpreted in a stochastic or statistical sense. Since $\mathbf{P}\{AB\} = \mathbf{P}\{A|B\}\mathbf{P}\{B\}$, the condition $\mathbf{P}\{A|B\} = \mathbf{P}\{A\}$ can be expressed in the following form: $\mathbf{P}\{AB\} = \mathbf{P}\{A\}\mathbf{P}\{B\}$. This equation is symmetric in A and B, and shows that whenever A is independent of B so is B of A.

Definition: Two events A and B are said to be independent if

$$\mathbf{P}\{AB\} = \mathbf{P}\{A\}\mathbf{P}\{B\}.$$

This definition is accepted also if $\mathbf{P}\{A\} = 0$ or $\mathbf{P}\{B\} = 0$, although in these cases $\mathbf{P}\{B|A\}$ and $\mathbf{P}\{A|B\}$ are not defined.

If A and B are independent, then $\bar{A}$ and B, A and $\bar{B}$, and $\bar{A}$ and $\bar{B}$ are similarly independent.

More generally, we say that n events $A_1, A_2, \ldots, A_n$ are mutually independent if any event and the simultaneous occurrence of any other events are independent. This definition is equivalent to the following: The events $A_1, A_2, \ldots, A_n$ are mutually independent if for any $i_1, i_2, \ldots, i_r$ satisfying the inequalities $1 \le i_1 < i_2 < \cdots < i_r \le n$ we have

$$\mathbf{P}\{A_{i_1}A_{i_2}\cdots A_{i_r}\} = \mathbf{P}\{A_{i_1}\}\mathbf{P}\{A_{i_2}\}\cdots\mathbf{P}\{A_{i_r}\}.$$

The above requirements mean $\binom{n}{r}$ conditions for any $r = 2, 3, \ldots, n$. The total number of conditions is

$$\binom{n}{2} + \binom{n}{3} + \cdots + \binom{n}{n} = 2^n - (n + 1).$$

If $\mathbf{P}\{A_{i_1}A_{i_2}\} = \mathbf{P}\{A_{i_1}\}\mathbf{P}\{A_{i_2}\}$ for $1 \le i_1 < i_2 \le n$, then we say that $A_1, A_2, \ldots, A_n$ are pairwise independent. Pairwise independence does not imply mutual independence. This fact will be illustrated by the following example. Two dice are thrown simultaneously. Let us suppose that all the 36 possible outcomes are equally probable. Three events A, B, and C are defined as follows: A means odd number with the first die, B means odd number with the second die, and C means odd sum. In this case, $\mathbf{P}\{A\} = \mathbf{P}\{B\} = \mathbf{P}\{C\} = \frac{18}{36} = \frac{1}{2}$ and $\mathbf{P}\{AB\} = \mathbf{P}\{AC\} = \mathbf{P}\{BC\} = \frac{9}{36} = \frac{1}{4}$. Consequently, A, B, and C are pairwise independent: $\mathbf{P}\{AB\} = \mathbf{P}\{A\}\mathbf{P}\{B\}$, $\mathbf{P}\{AC\} = \mathbf{P}\{A\}\mathbf{P}\{C\}$, and $\mathbf{P}\{BC\} = \mathbf{P}\{B\}\mathbf{P}\{C\}$. But A, B, C are not mutually independent: $\mathbf{P}\{ABC\} \neq \mathbf{P}\{A\}\mathbf{P}\{B\}\mathbf{P}\{C\}$. For $\mathbf{P}\{ABC\} = 0$. The three events cannot occur simultaneously; $ABC = \varnothing$, the impossible event that has probability 0.

An infinite sequence of events $A_1, A_2, \ldots, A_n, \ldots$ is said to be mutually independent if for any $n = 2, 3, \ldots$, the events $A_1, A_2, \ldots, A_n$ are mutually independent.

Our next aim is to introduce the notion of *independent trials*. Previously, we defined the notion of independent events concerning a random trial. That is, we considered a probability space $(\Omega, \mathcal{B}, \mathbf{P})$ and defined the notion of independence for events in $\mathcal{B}$.

Now let us consider a *compound random*

trial (e.g., random trials performed simultaneously, a succession of random trials, or, in particular, repeated random trials). If any outcome of a constituent random trial is independent of the simultaneous occurrence of any outcomes of any other constituent trials in the compound random trial, we say that the constituent random trials are independent. Conversely, if we consider random trials whose outcomes do not interact on each other, then we suppose that they are independent, that is, the compound random trial has the property that the outcomes of the constituent random trials are independent. Clearly, ordinary independence, defined in terms of occurrences, implies stochastic independence defined in terms of probability alone. The only problem is to show that there always exists a compound trial with the described property. In 1933, A. N. Kolmogorov and in 1939, more generally, B. Jessen proved that there always exists a so-called product probability space that possesses the indicated properties.

For example, let us suppose that we perform two random trials and in each trial we choose a point at random in the interval $(0,t)$. Assume that each point has a uniform distribution over $(0,t)$. Let us associate with the compound random trial the probability space defined in example 2 of Sec. 5. In this case, the two constituent trials are independent in the compound trial. Conversely, if the two trials do not interact on each other, we define the compound trial in the same way as in example 2 of Sec. 5.

8. RANDOM VARIABLES

So far, we have dealt with random events occurring in random trials, and our aim has been to determine the probabilities of various events. However, in many cases it is more convenient to work with random variables. Intuitively, a random variable is a random quantity whose value depends on the outcome of a random trial. The outcome of a random trial is completely determined by one, and only one, sample point. Consequently, the value of a random variable is determined if it is known which simple event occurs. We shall consider mostly real random variables and denote them by lowercase Greek letters such as ξ, η, ζ, χ, ν, τ. For example, let us suppose that the random trial consists in throwing a die. The number of points on the top face of the die is a random variable ξ that may assume the values 1, 2, 3, 4, 5, 6. If the sample space is $\Omega = \{1,2,3,4,5,6\}$, then $\xi = \xi(\omega) = \omega$ for $\omega \in \Omega$. Accordingly, a random variable is a function defined on the sample space. Many random variables can be defined on the same sample space. For instance, let us suppose that there are two players P_1 and P_2 and one of them throws a die. If the score is even, then P_2 pays one dollar to P_1, and if the score is odd, then P_1 pays one dollar to P_2. Denote by η_1 the gain of P_1 and η_2 the gain of P_2. Then $\eta_1(\omega)$, $\omega \in \Omega$, and $\eta_2(\omega)$, $\omega \in \Omega$, are random variables. Another example: Denote by A the event that in throwing the die the result is an even number. Define a random variable χ such that $\chi = 1$ if A occurs and $\chi = 0$ if A does not occur. Such a random variable is called an *indicator random variable.* It has only two possible values, 0 and 1. Table 1 illustrates the above-mentioned random variables.

Let $(\Omega,\mathcal{B},\mathbf{P})$ be a probability space and $\xi(\omega)$, a function defined on the sample space. We shall not consider arbitrary functions $\xi(\omega)$, but only those for which probability questions can be answered. An example of such questions is "what is the probability that $\xi \in S$ where S is a linear Borel set?" In order for all such questions to be answerable, it is necessary and sufficient that the set $\{\omega: \xi(\omega) \in S\}$ belong to $\mathcal{B}$. This is assured by the following definition:

A real, single-valued function $\xi(\omega)$, defined on the sample space Ω, is called a real random variable, if for every choice of the real number x $(-\infty < x < \infty)$ the set $\{\omega: \xi(\omega) \le x\}$ [the set of all $\omega \in \Omega$ for which the inequality $\xi(\omega) \le x$ is satisfied] belongs to $\mathcal{B}$. Briefly, a real random variable is a measurable function on the sample space (measurable with respect to $\mathcal{B}$).

The function

Table 1. Random variables.

ω	1	2	3	4	5	6
ξ	1	2	3	4	5	6
η_1	-1	1	-1	1	-1	1
η_2	1	-1	1	-1	1	-1
χ	0	1	0	1	0	1

$$\mathbf{P}\{\xi \le x\} = F(x)$$

defined for every real x is called the *distribution function* of the random variable ξ. The event $\xi \le x$ is described by the set of sample points $\omega \in \Omega$ for which $\xi(\omega) \le x$. We define $F(\infty) = \lim_{x\to\infty} F(x)$ and $F(-\infty) = \lim_{x\to-\infty} F(x)$. If $\xi(\omega)$ is finite for every $\omega \in \Omega$, then $F(\infty) = 1$ and $F(-\infty) = 0$. If we know the distribution function $F(x)$ of a random variable ξ, and if S is any linear Borel set, then the probability $\mathbf{P}\{\xi \in S\}$ is uniquely determined by $F(x)$.

A distribution function $F(x)$ is a nondecreasing function of x. If $F(x)$ is an absolutely continuous function of x, then there exists a function $f(x)$ such that $f(x) \ge 0$, $f(x)$ is integrable over $(-\infty,\infty)$ and

$$F(x) = \int_{-\infty}^{x} f(u)du$$

for all x. Such an $f(x)$ is called a *density function* of a real random variable. The density function is not determined uniquely by $F(x)$, but any two versions are equal almost everywhere. They can differ only on a set of measure 0. If $f(x)$ is a density function of ξ, then

$$\frac{dF(x)}{dx} = f(x)$$

for almost every $x \in (-\infty,\infty)$. The derivative $dF(x)/dx$ exists for every $x \in (-\infty,\infty)$ except perhaps for a set of measure 0.

If $\mathbf{P}\,\{\xi = a\} = F(a) - F(a - 0) > 0$, then $\xi = a$ is a possible value of the random variable ξ and $F(x)$ has a jump of magnitude $F(a) - F(a - 0)$ at $x = a$. The set of possible values of a real random variable is always countable (empty, finite, or countably infinite). If $F(x)$ increases only in jumps, then we say that $F(x)$ is a step function and ξ is a discrete random variable.

If in a random trial $(\Omega,\mathcal{B},\mathbf{P})$ we consider n random variables $\xi_1, \xi_2, \ldots, \xi_n$, that is, n functions $\xi_1(\omega), \xi_2(\omega), \ldots, \xi_n(\omega)$ defined on Ω and measurable with respect to $\mathcal{B}$, then for every choice of the real numbers $x_1, x_2, \ldots, x_n$ the events $\{\omega\colon \xi_i(\omega) \le x_i\} \in \mathcal{B}$. The simultaneous occurrence of these n events also belongs to $\mathcal{B}$ and thus the following function is well defined:

$$F(x_1,x_2,\ldots,x_n) = \mathbf{P}\{\xi_1 \le x_1, \xi_2 \le x_2, \ldots, \xi_n \le x_n\}.$$

It is called the *joint distribution function* of the random variables $\xi_1, \xi_2, \ldots, \xi_n$. The function $F(x_1,x_2,\ldots,x_n)$ is an n-dimensional distribution function.

If there exists a nonnegative, integrable function $f(x_1,x_2,\ldots,x_n)$ such that

$$F(x_1,x_2,\ldots,x_n) = \int_{-\infty}^{x_1}\int_{-\infty}^{x_2}\cdots\int_{-\infty}^{x_n} f(u_1,u_2,\ldots,u_n) \times du_1 du_2 \cdots du_n,$$

then we say that $f(x_1,x_2,\ldots,x_n)$ is a *joint density function* of the random variables $\xi_1, \xi_2, \ldots, \xi_n$. If such a function exists, then

$$\frac{\partial^n F(x_1,x_2,\ldots,x_n)}{\partial x_1 \partial x_2 \cdots \partial x_n} = f(x_1,x_2,\ldots,x_n)$$

for almost every $(x_1,x_2,\ldots,x_n)$. For any n-dimensional Borel set S we have

$$\mathbf{P}\{(\xi_1,\xi_2,\ldots,\xi_n) \in S\} = \int\int\cdots\int_S f(x_1,x_2,\ldots,x_n) \times dx_1 dx_2 \cdots dx_n.$$

If

$$\mathbf{P}\{\xi_1 \le x_1,\ldots,\xi_n \le x_n\} = \mathbf{P}\{\xi_1 \le x_1\} \cdots \mathbf{P}\{\xi_n \le x_n\}$$

for every choice of $x_1, \ldots, x_n$, then we say that the random variables $\xi_1, \xi_2, \ldots, \xi_n$ are *mutually independent*. If $\xi_1, \xi_2, \ldots, \xi_n$ are mutually independent, then for any linear Borel sets $S_1, S_2, \ldots, S_n$ we have

$$\mathbf{P}\{\xi_1 \in S_1, \xi_2 \in S_2, \ldots, \xi_n \in S_n\} = \mathbf{P}\{\xi_1 \in S_1\}\mathbf{P}\{\xi_2 \in S_2\} \cdots \mathbf{P}\{\xi_n \in S_n\}.$$

If each variable ξ_i $(i = 1,2,\ldots,n)$ has a density function $f_i(x)$, then the variables $\xi_1, \xi_2, \ldots, \xi_n$ have a joint density function

$$f(x_1,x_2,\ldots,x_n) = f_1(x_1)f_2(x_2)\cdots f_n(x_n).$$

If ξ_1 and ξ_2 are independent random variables with distribution functions $\mathbf{P}\{\xi_1 \le x\} = F_1(x)$ and $\mathbf{P}\{\xi_2 \le x\} = F_2(x)$ respectively, then the distribution function of the sum, $\mathbf{P}\{\xi_1 + \xi_2 \le x\} = H(x)$, can be calculated by the following Riemann–Stieltjes integral:

$$H(x) = \int_{-\infty}^{\infty} F_1(x - u)dF_2(u).$$

We can write briefly that $H(x) = F_1(x) * F_2(x)$ and say that $H(x)$ is the *convolution* of $F_1(x)$ and $F_2(x)$. If ξ_1 has a density function $f_1(x)$ and ξ_2 has a density function $f_2(x)$, then $\xi_1 + \xi_2$ also has a density function $h(x)$ given by

$$h(x) = \int_{-\infty}^{\infty} f_1(x - u)f_2(u)du.$$

We can determine the distribution function of the sum of mutually independent random variables by forming repeated convolutions.

9. EXPECTATION OF RANDOM VARIABLES

Let us consider a random trial with which a probability space $(\Omega,\mathcal{B},\mathbf{P})$ is associated. Let $\xi = \xi(\omega)$ be a real random variable defined on Ω.

First, let us suppose that ξ is a discrete random variable with possible values a_j ($j \in I$) where I is a finite or countably infinite set and the corresponding probabilities are $\mathbf{P}\{\xi = a_j\} = p_j$ for $j \in I$. Repeat the random trial n times under identical conditions and observe the value of ξ in each trial: $X_1, X_2, \ldots, X_n$. Suppose that the value a_j is observed n_j times. Then $\Sigma_{j\in I} n_j = n$. The arithmetic mean of the observations is

$$\frac{X_1 + X_2 + \ldots + X_n}{n} = \frac{\Sigma_{j\in I} n_j a_j}{\Sigma_{j\in I} n_j} = \sum_{j\in I} a_j \frac{n_j}{n}.$$

In many cases if $n \to \infty$, the observed mean shows stability, namely, it approaches a certain constant in a random way. The frequency of the event $A_j = \{\xi = a_j\}$, that is, n_j/n, approaches p_j, the probability of A_j. Consequently, the mean value of the observations should approach

$$\sum_{j\in I} a_j p_j.$$

If

$$\sum_{j\in I} |a_j| p_j < \infty,$$

then

$$\sum_{j\in I} a_j p_j$$

is a definite number and it is called the expectation of the random variable ξ.

Definition: If ξ is a discrete random variable that assumes the values a_j ($j \in I$) with corresponding probabilities $\mathbf{P}\{\xi = a_j\} = p_j$, then the *expectation* (or mean, or average) of ξ is defined by

$$\mathbf{E}\{\xi\} = \sum_{j\in I} a_j p_j = \sum_{j\in I} a_j \mathbf{P}\{\xi = a_j\}$$

provided that the series converges absolutely. In this case, we say that ξ has a finite expectation; the expectation exists. If

$$\sum_{j\in I} |a_j| p_j = \infty,$$

then we say that ξ has no finite expectation. (The expectation does not exist: infinite or indefinite.)

If we throw a symmetric die and ξ is the number of points on the top face of the die, then $\mathbf{P}\{\xi = j\} = \frac{1}{6}$ for $j = 1,2,\ldots,6$ and the expectation of ξ is

$$\mathbf{E}\{\xi\} = \frac{1 + 2 + \cdots + 6}{6} = \frac{7}{2} = 3.5.$$

If we repeat the trial n times and in each trial we observe the number of points obtained, then we expect that the arithmetic mean of the observations will be approximately 3.5 if n is large enough.

If $\mathbf{P}\{\xi \le x\} = F(x)$ and ξ has a density function $f(x)$, then the expectation of ξ is defined by

$$\mathbf{E}\{\xi\} = \int_{-\infty}^{\infty} xf(x)dx,$$

provided that

$$\int_{-\infty}^{\infty} |x| f(x)dx < \infty.$$

In the general case when $\mathbf{P}\{\xi \le x\} = F(x)$, the expectation of ξ is defined by

$$\mathbf{E}\{\xi\} = \int_{-\infty}^{\infty} xdF(x),$$

provided that

$$\int_{-\infty}^{\infty} |x| dF(x) < \infty.$$

Here the integrals are Riemann–Stieltjes integrals.

If ξ is a nonnegative real random variable with finite expectation $\mathbf{E}\{\xi\}$, then *Chebyshev's inequality* states that

$$\mathbf{P}\{\xi \geq a\} \leq \frac{\mathbf{E}\{\xi\}}{a}$$

for $a > 0$.

One of the most frequently used theorems is the following: If $\xi_1, \xi_2, \ldots, \xi_n$ are real random variables and

$$\eta_n = \xi_1 + \xi_2 + \cdots + \xi_n,$$

then the expectation of η_n is

$$\mathbf{E}\{\eta_n\} = \mathbf{E}\{\xi_1\} + \mathbf{E}\{\xi_2\} + \cdots + \mathbf{E}\{\xi_n\},$$

provided that each ξ_i ($i = 1,2,\ldots,n$) has a finite expectation.

If $\xi_1, \xi_2, \ldots, \xi_n$ are mutually independent random variables having finite expectations, then

$$\mathbf{E}\{\xi_1\xi_2 \cdots \xi_n\} = \mathbf{E}\{\xi_1\}\mathbf{E}\{\xi_2\} \cdots \mathbf{E}\{\xi_n\}.$$

10. MOMENTS, VARIANCE, AND COVARIANCE

If ξ is a real random variable and $g(x)$ is a continuous function, or more generally a Borel-measurable function, then $\eta = g(\xi)$ is also a random variable. If $\mathbf{P}\{\xi \leq x\} = F(x)$, then the expectation of η is

$$\mathbf{E}\{\eta\} = \int_{-\infty}^{\infty} g(x) dF(x)$$

provided that

$$\int_{-\infty}^{\infty} |g(x)| dF(x) < \infty.$$

If ξ is a discrete random variable with possible values a_j ($j \in I$) and corresponding probabilities $\mathbf{P}\{\xi = a_j\} = p_j$, then

$$\mathbf{E}\{\eta\} = \sum_{j \in I} g(a_j) p_j,$$

provided that the series is absolutely convergent. If ξ has a density function $f(x)$, then

$$\mathbf{E}\{\eta\} = \int_{-\infty}^{\infty} g(x) f(x) dx,$$

provided that

$$\int_{-\infty}^{\infty} |g(x)| f(x) dx < \infty.$$

If, in particular, $g(x) = x^m$ where $m = 0, 1, 2, \ldots$, then $\mathbf{E}\{\xi^m\}$ is called the mth *moment* of the random variable ξ. If $\mathbf{E}\{\xi\} = a$ exists, and $g(x) = (x - a)^m$ where $m = 0, 1, 2, \ldots$, then $\mathbf{E}\{(\xi - a)^m\}$ is called the mth *central moment* of ξ.

The second central moment plays an important role. It is called the *variance* of ξ and is denoted by

$$\mathrm{Var}\{\xi\} = \mathbf{E}\{(\xi - a)^2\} = \mathbf{E}\{\xi^2\} - [\mathbf{E}\{\xi\}]^2.$$

The positive square root of the variance is called the *standard deviation.*

The variance measures the spread of the values of ξ around the expectation. If $\mathbf{E}\{\xi\} = a$ and $\mathrm{Var}\{\xi\} = \sigma^2$ where σ is the standard deviation, and if we apply Chebyshev's inequality to the random variable $\eta = (\xi - a)^2$, then we obtain that

$$\mathbf{P}\{|\xi - a| \geqq \lambda\sigma\} = \mathbf{P}\{(\xi - a)^2 \geqq \lambda^2\sigma^2\} \leq 1/\lambda^2$$

for any $\lambda > 0$.

If $\mathbf{E}\{\xi\} = a$ and $\mathrm{Var}\{\xi\} = \sigma^2$, where $\sigma > 0$, then the random variable

$$\xi^* = (\xi - a)/\sigma$$

is called the *standardized random variable* corresponding to ξ. It has expectation 0 and variance 1.

If $\xi_1, \xi_2, \ldots, \xi_n$ are real random variables with finite expectations $\mathbf{E}\{\xi_i\} = a_i$ ($i = 1,2,\ldots,n$) and finite variances $\mathrm{Var}\{\xi_i\} = \sigma_i^2$ ($i = 1,2,\ldots,n$), then

$$\mathrm{Var}\{\xi_1 + \xi_2 + \cdots + \xi_n\} = \sum_{i=1}^{n} \mathrm{Var}\{\xi_i\} + 2 \sum\sum_{1 \leq i < j \leq n} \mathrm{Cov}\{\xi_i, \xi_j\},$$

where the *covariance* of ξ_i and ξ_j is defined by

$$\begin{aligned}\operatorname{Cov}\{\xi_i,\xi_j\} &= \mathbf{E}\{(\xi_i - a_i)(\xi_j - a_j)\}\\ &= \mathbf{E}\{\xi_i\xi_j\} - \mathbf{E}\{\xi_i\}\mathbf{E}\{\xi_j\}.\end{aligned}$$

If the random variables $\xi_1, \xi_2, \ldots, \xi_n$ are pairwise independent, then $\operatorname{Cov}\{\xi_i,\xi_j\} = 0$ for $1 \le i < j \le n$, and

$$\operatorname{Var}\{\xi_1 + \xi_2 + \cdots + \xi_n\} = \sum_{i=1}^{n} \operatorname{Var}\{\xi_i\}.$$

10.1 The Correlation Coefficient

Let ξ_1 and ξ_2 be two real random variables with finite expectations a_1 and a_2 and finite positive variances σ_1^2 and σ_2^2, respectively. The covariance of the standardized random variables $\xi_1^* = (\xi_1 - a_1)/\sigma_1$ and $\xi_2^* = (\xi_2 - a_2)/\sigma_2$ is called the *correlation coefficient* of ξ_1 and ξ_2 and is denoted by

$$\rho(\xi_1,\xi_2) = \operatorname{Cov}\{\xi_1^*,\xi_2^*\} = \operatorname{Cov}\{\xi_1,\xi_2\}/\sigma_1\sigma_2.$$

The correlation coefficient measures the linear dependence of the two random variables ξ_1 and ξ_2. We have always $|\rho(\xi_1,\xi_2)| \le 1$, and $\rho(\xi_1,\xi_2) = \pm 1$ if and only if $\xi_2 = a\xi_1 + b$ where a and b are constants. If ξ_1 and ξ_2 are independent, then $\rho(\xi_1,\xi_2) = 0$.

11. GENERATING FUNCTION, CHARACTERISTIC FUNCTION, AND LAPLACE–STIELTJES TRANSFORM

If ξ and η are real random variables, then $\zeta = \xi + i\eta$ is a complex random variable. If both ξ and η have finite expectations, then we say that the expectation of ζ exists and is defined by

$$\mathbf{E}\{\zeta\} = \mathbf{E}\{\xi\} + i\mathbf{E}\{\eta\}.$$

If $\zeta_1, \zeta_2, \ldots, \zeta_n$ are complex random variables and $\mathbf{E}\{\zeta_k\}$ exists for $k = 1, 2, \ldots, n$, then

$$\begin{aligned}\mathbf{E}\{\zeta_1 + \zeta_2 + \cdots + \zeta_n\} = \mathbf{E}\{\zeta_1\} &+ \mathbf{E}\{\zeta_2\}\\ &+ \cdots + \mathbf{E}\{\zeta_n\}.\end{aligned}$$

We say that $\zeta_k = \xi_k + i\eta_k$ $(k = 1,2,\ldots,n)$ are mutually independent random variables if the n events $(\xi_k,\eta_k) \in S_k$ $(k = 1,2,\ldots,n)$ are mutually independent for any choice of the two-dimensional Borel sets S_k $(k = 1,2,\ldots,n)$. If $\zeta_k = \xi_k + i\eta_k$ $(k = 1,2,\ldots,n)$ are mutually independent random variables, then

$$\mathbf{E}\{\zeta_1\zeta_2\cdots\zeta_n\} = \mathbf{E}\{\zeta_1\}\mathbf{E}\{\zeta_2\}\cdots\mathbf{E}\{\zeta_n\},$$

provided that the expectations on the right-hand side exist.

If ξ is a real random variable and z is a complex number, then z^ξ is a complex random variable. If we know the distribution function $\mathbf{P}\{\xi \le x\} = F(x)$, then the expectation of z^ξ is a function of z and is given by

$$G(z) = \mathbf{E}\{z^\xi\} = \int_{-\infty}^{\infty} x^x\, dF(x),$$

provided that the expectation exists. It is called the *generating function* of ξ.

If $z = e^{it}$ where t is a real number, then the expectation of $e^{it\xi}$, that is,

$$\psi(t) = G(e^{it}) = \int_{-\infty}^{\infty} e^{itx}\, dF(x),$$

always exists and is called the *characteristic function* of ξ.

If $z = e^{-s}$ where s is a complex number and if the expectation of $e^{-s\xi}$, that is,

$$\varphi(s) = G(e^{-s}) = \int_{-\infty}^{\infty} e^{-sx}\, dF(x),$$

exists, then it is called the *Laplace–Stieltjes transform* of ξ.

The distribution function of ξ is uniquely determined by any of the aforementioned three transforms, and if the moments of ξ exist, then they can be determined by forming the derivatives of these transforms. In particular,

$$\mathbf{E}\{\xi\} = G'(1) = -i\psi'(0) = -\varphi'(0)$$

and

$$\mathbf{E}\{\xi^2\} = G''(1) + G'(1) = -\psi''(0) = \varphi''(0).$$

If $\xi_1, \xi_2, \ldots, \xi_n$ are mutually independent real random variables, then $z^{\xi_1}, z^{\xi_2}, \ldots, z^{\xi_n}$ are also mutually independent and

$$\mathbf{E}\{z^{\xi_1+\xi_2+\cdots+\xi_n}\} = \mathbf{E}\{z^{\xi_1}\}\mathbf{E}\{z^{\xi_2}\}\cdots\mathbf{E}\{z^{\xi_n}\},$$

provided that the expectations on the right-hand side exist. By this equation, we can conclude that the generating function, or the characteristic function, or the Laplace–Stieltjes transform of a sum of n mutually independent real random variables is the product of the appropriate transforms of the n random variables.

It is convenient to use generating functions for discrete random variables that take on nonnegative integer values only, and Laplace–Stieltjes transforms for nonnegative real random variables.

If $G(z)$ is the generating function of a discrete random variable ξ that takes on nonnegative integer values only, then

$$\mathbf{P}\{\xi = k\} = \frac{1}{k!}\left(\frac{d^kG(z)}{dz^k}\right)_{z=0}.$$

If a real random variable ξ has a density function $f(x)$, then its characteristic function is

$$\psi(t) = \int_{-\infty}^{\infty} e^{itx}f(x)dx.$$

Conversely, if $\psi(t)$ is the characteristic function of a real random variable ξ, and if

$$\int_{-\infty}^{\infty} |\psi(t)|dt < \infty,$$

then ξ has a density function $f(x)$ and

$$f(x) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-itx}\psi(t)dt.$$

12. DISCRETE DISTRIBUTIONS

12.1 The Bernoulli Distribution

Let us assume that in a sequence of repeated independent trials there are only two possible outcomes: "success", which has probability p, and "failure", which has probability q, where $p > 0$, $q > 0$, and $p + q = 1$. In this case, we speak about a sequence of *Bernoulli trials*. Denote by ν_n the number of successes in the first n trials and τ_n the number of trials performed up to the occurrence of the nth success. Then

$$\mathbf{P}\{\nu_n = k\} = \binom{n}{k} p^kq^{n-k}$$

for $k = 0, 1, \ldots, n$. We say that the random variable ν_n has a *Bernoulli distribution* (or binomial distribution) with parameters n and p. The expectation of ν_n is $\mathbf{E}\{\nu_n\} = np$ and its variance is $\mathrm{Var}\{\nu_n\} = npq$. Furthermore,

$$\mathbf{E}\{|\nu_n - np|\} = 2sq\mathbf{P}\{\nu_n = s\},$$

where $s = [np] + 1$. The generating function of ν_n is

$$\mathbf{E}\{z^{\nu_n}\} = (q + pz)^n$$

for any z.

12.2 The Negative Binomial Distribution

We have $\{\tau_n \leq n + k\}$ if and only if $\{\nu_{n+k} \geq n\}$, that is

$$\mathbf{P}\{\tau_n \leq n + k\} = \mathbf{P}\{\nu_{n+k} \geq n\}$$

for $n \geq 1$ and $k \geq 0$. Hence

$$\mathbf{P}\{\tau_n = n + k\} = \binom{n + k - 1}{n - 1}p^nq^k$$

for $n \geq 1$ and $k \geq 0$. We can write also that

$$\mathbf{P}\{\tau_n = n + k\} = (-1)^k\binom{-n}{k}p^nq^k$$

for $n \geq 1$ and $k \geq 0$, and say that τ_n has a *negative binomial distribution.* The expectation of τ_n is $\mathbf{E}\{\tau_n\} = n/p$ and its variance is $\mathbf{Var}\{\tau_n\} = nq/p^2$. The generating function of τ_n is

$$\mathbf{E}\{z^{\tau_n}\} = \left(\frac{p}{1 - qz}\right)^n$$

for $|z| < 1/q$.

12.3 De Moivre's Limit Theorem

In 1730, A. De Moivre proved that if

$$a \leq \frac{k - np}{\sqrt{npq}} \leq b,$$

where $[a,b]$ is an arbitrary finite interval, then

$$\mathbf{P}\{\nu_n = k\} \sim \varphi\left(\frac{k - np}{\sqrt{npq}}\right)\frac{1}{\sqrt{npq}},$$

where

$$\varphi(x) = \frac{1}{\sqrt{2\pi}}e^{-x^2/2}$$

is the *normal density function.* The symbol ~ means that the left-hand side is asymptotically equal to the right-hand side, that is, the ratio of the two sides tends to 1 as $n \to \infty$. Hence it follows that

$$\lim_{n\to\infty}\mathbf{P}\left\{a \le \frac{\nu_n - np}{\sqrt{npq}} \le b\right\} = \Phi(b) - \Phi(a)$$

for $a \le b$ where

$$\Phi(x) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{x} e^{-x^2/2}\,du$$

is the *normal distribution function.*

12.4 The Poisson Distribution

Another limit theorem for the Bernoulli distribution is the Poisson limit theorem. Let us perform n Bernoulli trials with probability $p = p_n$ for success, and denote again by ν_n the number of successes. Then $\mathbf{E}\{\nu_n\} = np_n$. If $\lim_{n\to\infty} np_n = a$ where a is a positive real number, then

$$\lim_{n\to\infty}\mathbf{P}\{\nu_n = k\} = e^{-a}a^k/k!$$

for $k = 0, 1, \ldots$.

If ν is a discrete random variable with possible values $0,1,2,\ldots$, and

$$\mathbf{P}\{\nu = k\} = e^{-a}a^k/k!$$

for $k = 0,1,2,\ldots$ where a is a positive real number, then we say that the random variable ν has a *Poisson distribution* with parameter a. Then $\mathbf{E}\{\nu\} = \mathrm{Var}\{\nu\} = a$ and

$$\mathbf{E}\{|\nu - a|\} = 2s\mathbf{P}\{\nu = s\}$$

where $s = [a] + 1$. The generating function of ν is

$$\mathbf{E}\{z^\nu\} = e^{-a(1-z)}$$

for every z.

12.5 The Hypergeometric Distribution

If ξ denotes the number of white balls in n drawings in example 2 of Sec. 4, then we have

$$\mathbf{P}\{\xi = k\} = \binom{a}{k}\binom{b}{n-k}\bigg/\binom{a+b}{n}$$

for $k = 0, 1, \ldots, n$. In this case, we say that ξ has a *hypergeometric distribution.* Now $\mathbf{E}\{\xi\} = na/(a + b)$,

$$\mathrm{Var}\{\xi\} = \frac{nab(a + b - n)}{(a + b)^2(a + b - 1)}$$

and

$$\mathbf{E}\left\{\left|\xi - \frac{na}{a+b}\right|\right\} = \frac{2s(b + s - n)}{a + b}\mathbf{P}\{\xi = s\},$$

where $s = [na/(a + b)] + 1$.

12.6 The Multinomial Distribution

Finally, we mention the *multinomial distribution.* Consider a sequence of repeated independent trials. Let $A_1, A_2, \ldots, A_m$ be a complete system of events, that is, mutually exclusive and exhaustive events. Let $\mathbf{P}\{A_i\} = p_i$ for $1 \le i \le m$. Then $p_i \ge 0$ and $p_1 + p_2 + \cdots + p_m = 1$. Let us denote by $\nu_i(n)$ the number of occurrences of A_i in the first n trials. Then

$$\mathbf{P}\{\nu_1(n) = k_1, \nu_2(n) = k_2, \ldots, \nu_m(n) = k_m\} = \frac{n!}{k_1!k_2!\cdots k_m!}p_1^{k_1}p_2^{k_2}\cdots p_m^{k_m}$$

if $k_1 + k_2 + \cdots + k_m = n$. In this case, we say that the random variables $\nu_1(n), \nu_2(n), \ldots, \nu_m(n)$ have a multinomial distribution. The binomial distribution is the special case $m = 2$. Now $\mathbf{E}\{\nu_i(n)\} = np_i$, $\mathrm{Var}\{\nu_i(n)\} = np_i(1 - p_i)$, and

$$\mathrm{Cov}\{\nu_i(n),\nu_j(n)\} = -np_ip_j$$

for $i \ne j$.

13. CONTINUOUS DISTRIBUTIONS

13.1 The Exponential Distribution

Let us consider the disintegration of radioactive atoms. Denote by ξ the lifetime of an atom. Suppose that the event that an existing atom disintegrates during a time interval of length t does not depend on the age of the atom. If we write $\mathbf{P}\{\xi > t\} = q(t)$ for $t \geq 0$, then $q(t)$ is a nonincreasing function of t and $q(t + u) = q(t)q(u)$ for $t \geq 0$ and $u \geq 0$. The only solution of this functional equation is $q(t) = e^{-\mu t}$ for $t \geq 0$ where μ is a positive real constant. Accordingly, $\mathbf{P}\{\xi \leq x\} = F(x)$ where

$$F(x) = 1 - e^{-\mu x}$$

for $x > 0$ and $F(x) = 0$ for $x \leq 0$. We say that the random variable ξ has an *exponential distribution function* with parameter μ. Now ξ has a density function $f(x)$ and

$$f(x) = \mu e^{-\mu x}$$

for $x > 0$ and $f(x) = 0$ for $x \leq 0$. We have $\mathbf{E}\{\xi\} = 1/\mu$ and $\mathrm{Var}\{\xi\} = 1/\mu^2$. The characteristic function of ξ is

$$\mathbf{E}\{e^{it\xi}\} = \mu/(\mu - it)$$

for any real t.

13.2 The Gamma Distribution

The gamma function $\Gamma(a)$ is defined for $a > 0$ by the integral

$$\Gamma(a) = \int_0^\infty e^{-x}x^{a-1}dx.$$

We have $\Gamma(a) = (a - 1)\Gamma(a - 1)$ for $a > 1$. In particular, $\Gamma(1) = 1$ and $\Gamma(\frac{1}{2}) = \sqrt{\pi}$.

If a random variable η_a has the distribution function

$$G_a(x) = \frac{1}{\Gamma(a)}\int_0^x e^{-u}u^{a-1}du$$

for $x > 0$ and $G_a(x) = 0$ for $x \leq 0$, then we say that η_a has a *gamma distribution function* with parameter a. Then η_a has a density function

$$g_a(x) = \frac{1}{\Gamma(a)}e^{-x}x^{a-1}$$

for $x > 0$ and $g_a(x) = 0$ for $x \leq 0$. We have $\mathbf{E}\{\eta_a\} = \mathrm{Var}\{\eta_a\} = a$. The characteristic function of η_a is

$$\mathbf{E}\{e^{it\eta_a}\} = (1 - it)^{-a}$$

for any real t.

The gamma distribution has the following important property:

$$G_a(x) * G_b(x) = G_{a+b}(x).$$

Accordingly, if we add mutually independent random variables each having a gamma distribution, then the sum also has a gamma distribution. In particular, if we add n independent random variables each having the same exponential distribution function $G_1(x) = 1 - e^{-x}$ for $x > 0$, then the sum has a gamma distribution function with parameter n, that is,

$$G_n(x) = 1 - \sum_{j=0}^{n-1} e^{-x}\frac{x^j}{j!}$$

for $x > 0$, and $G_n(x) = 0$ for $x \leq 0$.

13.3 The Beta Distribution

The beta function $B(a,b)$ is defined for $a > 0$ and $b > 0$ by the integral

$$B(a,b) = \int_0^1 x^{a-1}(1 - x)^{b-1}dx = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a + b)}.$$

If a random variable $\eta_{a,b}$ has the distribution function

$$F_{a,b}(x) = \frac{1}{B(a,b)}\int_0^x u^{a-1}(1 - u)^{b-1}du$$

for $0 \leq x \leq 1$, $F_{a,b}(x) = 1$ for $x > 1$ and $F_{a,b}(x) = 0$ for $x < 0$, then we say that the random variable $\eta_{a,b}$ has a *beta distribution function* with parameters a and b. We have $\mathbf{E}\{\eta_{a,b}\} = a/(a + b)$ and $\mathbf{E}\{\eta_{a,b}^2\} = a(a + 1)/(a + b)(a + b + 1)$.

13.4 The Normal Distribution

If $\mathbf{P}\{\xi \le x\} = \Phi(x)$ where

$$\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-u^2/2} du,$$

then we say that ξ has a *standard normal distribution function.* We have $\mathbf{E}\{\xi\} = 0$ and $\operatorname{Var}\{\xi\} = 1$. If $\eta = \sigma\xi + a$ where $\sigma > 0$, then we say that η has a normal distribution of type $N(a,\sigma^2)$. The first parameter is $\mathbf{E}\{\eta\} = a$ and the second parameter is $\operatorname{Var}\{\eta\} = \sigma^2$. The distribution function of η is

$$\mathbf{P}\{\eta \le x\} = \Phi\left(\frac{x-a}{\sigma}\right),$$

and the characteristic function of η is

$$\mathbf{E}\{e^{it\eta}\} = \exp(ita - \sigma^2 t^2/2).$$

If we add n mutually independent random variables having normal distributions of types $N(a_i,\sigma_i^2)$ $(i = 1,2,\ldots,n)$ respectively, then the sum has a normal distribution of type $N(a_1 + a_2 + \cdots + a_n, \sigma_1^2 + \sigma_2^2 + \cdots + \sigma_n^2)$.

13.5 The χ^2 Distribution

[F. R. Helmert (1876) and K. Pearson (1900)]. Let $\xi_1, \xi_2, \ldots, \xi_n$ be mutually independent random variables each having the same standard normal distribution $N(0,1)$. Define

$$\chi_n^2 = \xi_1^2 + \xi_2^2 + \cdots + \xi_n^2.$$

Then $\mathbf{P}\{\chi_n \le x\} = H_n(x)$ is given by

$$H_n(x) = \frac{1}{2^{(n-2)/2}\Gamma(n/2)} \int_0^x e^{-u^2/2}\, u^{n-1}\, du$$

for $x > 0$ and $H_n(x) = 0$ for $x \le 0$. Since $\mathbf{P}\{\xi_i^2/2 \le x\} = G_{1/2}(x)$ for $i = 1, 2, \ldots, n$, we have

$$\mathbf{P}\{\xi_1^2 + \xi_2^2 + \cdots + \xi_n^2 \le x\} = G_{n/2}(x/2),$$

and consequently $H_n(x) = G_{n/2}(x^2/2)$.

13.6 The Multivariate Normal Distribution

Let

$$Q(x_1,x_2,\ldots,x_n) = \sum_{i=1}^{n}\sum_{j=1}^{n} a_{ij}x_ix_j$$

be a positive definite quadratic form with coefficient matrix

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix},$$

where $a_{ij} = a_{ji}$. We say that $Q(x_1,x_2,\ldots,x_n)$ is positive definite if $Q(x_1,x_2,\ldots,x_n) \ge 0$ and $Q(x_1,x_2,\ldots,x_n) = 0$ if and only if $x_1 = x_2 = \cdots = x_n = 0$. Then $A = \operatorname{Det}[\mathbf{A}] > 0$. The n-variate function

$$f(x_1,x_2,\ldots,x_n) = \frac{\sqrt{A}}{(2\pi)^{n/2}} e^{-Q(x_1-m_1,x_2-m_2,\ldots,x_n-m_n)/2}$$

is an n-dimensional density function for any choice of $m_1, m_2, \ldots, m_n$. We say that n random variables $\xi_1, \xi_2, \ldots, \xi_n$ have an n-dimensional normal distribution if their joint density function has the above form. In this case, we have $\mathbf{E}\{\xi_i\} = m_i$ for $i = 1, 2, \ldots, n$. If we define $\sigma_{ij} = \mathbf{E}\{(\xi_i - m_i)(\xi_j - m_j)\}$ for $i, j = 1, 2, \ldots, n$, then the covariance matrix

$$\Delta = \begin{bmatrix} \sigma_{11} & \sigma_{12} & \cdots & \sigma_{1n} \\ \sigma_{21} & \sigma_{22} & \cdots & \sigma_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{n1} & \sigma_{n2} & \cdots & \sigma_{nn} \end{bmatrix} = \mathbf{A}^{-1};$$

that is, Δ, the covariance matrix, is the inverse of $\mathbf{A}$, the coefficient matrix.

14. LAWS OF LARGE NUMBERS

Let $(\Omega,\mathcal{B},\mathbf{P})$ be a probability space and $\{\eta_n(\omega), n \ge 1\}$ be a sequence of real random variables defined on Ω. Let also $\eta(\omega)$ be a random variable defined on Ω.

We say that the sequence $\{\eta_n\}$ *converges in probability* to the random variable η if for every $\epsilon > 0$ we have

$$\lim_{n\to\infty} \mathbf{P}\{|\eta_n - \eta| < \epsilon\} = 1.$$

Define

$$C = \{\omega: \lim_{n\to\infty} \eta_n(\omega) \text{ exists}\}.$$

The set C represents a random event, that is, $C \in \mathcal{B}$ and consequently, the probability $\mathbf{P}\{C\}$ is determined. If $\mathbf{P}\{C\} = 1$, then we say that the sequence $\{\eta_n(\omega)\}$ converges with probability 1. In this case, there exists a random variable $\eta(\omega)$ such that the event $\{\lim_{n\to\infty}\eta_n(\omega) = \eta(\omega)\}$ has probability 1, and we say that the sequence of random variables $\{\eta_n\}$ *converges with probability* 1 to the random variable η. We can prove that $\eta_n \to \eta$ with probability 1 if and only if for every $\epsilon > 0$ we have

$$\lim_{n\to\infty} \mathbf{P}\{\sup_{k\geq n} |\eta_k - \eta| \geq \epsilon\} = 0.$$

14.1 The Weak Law of Large Numbers

Let $\xi_1, \xi_2, \ldots, \xi_n, \ldots$ be pairwise independent and identically distributed random variables for which $\mathbf{E}\{\xi_k\} = a$ exists. Then $(\xi_1 + \xi_2 + \cdots + \xi_n)/n$ converges in probability to a, that is

$$\lim_{n\to\infty} \mathbf{P}\left\{\left|\frac{\xi_1 + \xi_2 + \ldots + \xi_n}{n} - a\right| < \epsilon\right\} = 1$$

for every $\epsilon > 0$.

This theorem was proved by J. Bernoulli around 1680 in the case where $\mathbf{P}\{\xi_n = 1\} = p$, $\mathbf{P}\{\xi_n = 0\} = q$, and $p + q = 1$, and by P. L. Chebyshev in 1867 in the case where $\mathbf{E}\{\xi_k^2\} < \infty$. The above general theorem was proved by A. Ya. Khintchine in 1929.

14.2 The Strong Law of Large Numbers

Let $\xi_1, \xi_2, \ldots, \xi_n, \ldots$ be mutually independent and identically distributed random variables for which $\mathbf{E}\{\xi_k\} = a$ exists. Then $(\xi_1 + \xi_2 + \cdots + \xi_n)/n$ converges with probability 1 to a, that is,

$$\mathbf{P}\left\{\lim_{n\to\infty} \frac{\xi_1 + \xi_2 + \ldots + \xi_n}{n} = a\right\} = 1.$$

In the particular case where $\mathbf{P}\{\xi_n = 1\} = \mathbf{P}\{\xi_n = 0\} = \frac{1}{2}$, this theorem was proved by É. Borel in 1909. In the case where $\mathbf{P}\{\xi_n = 1\} = p$, $\mathbf{P}\{\xi_n = 0\} = q$, and $p + q = 1$, the theorem was proved by F. P. Cantelli in 1917. The above general theorem was proved by A. N. Kolmogorov in 1930.

15. LIMIT DISTRIBUTIONS

The following limit theorem, which G. Pólya (1920) named the *central limit theorem*, is one of the most frequently used theorems in probability theory.

15.1 The Central Limit Theorem

Let $\xi_1, \xi_2, \ldots, \xi_n, \ldots$ be mutually independent and identically distributed random variables such that $\mathbf{E}\{\xi_n\} = a$ and $\mathrm{Var}\{\xi_n\} = \sigma^2$ where σ is a finite positive number. Then

$$\lim_{n\to\infty} \mathbf{P}\{(\xi_1 + \xi_2 + \cdots + \xi_n - na)/\sigma\sqrt{n} \leq x\} = \Phi(x),$$

where

$$\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-u^2/2}\, du$$

is the normal distribution function.

In the particular case where $\mathbf{P}\{\xi_n = 1\} = p$, $\mathbf{P}\{\xi_n = 0\} = q$, and $p + q = 1$, the central limit theorem was proved by A. De Moivre (1730) and P. S. Laplace (1812). The above general case was proved by P. L. Chebyshev (1890) and A. A. Markov (1898).

Now let us suppose that $\xi_1, \xi_2, \ldots, \xi_n, \ldots$ are mutually independent random variables and define $\zeta_n = \xi_1 + \xi_2 + \cdots + \xi_n$ for $n \geq 1$. The problem arises under what conditions there exist constants a_n and $b_n > 0$ such that

$$\lim_{n\to\infty} \mathbf{P}\{(\zeta_n - a_n)/b_n \leq x\} = H(x),$$

where $H(x)$ is a nondegenerate distribution function. This problem was solved by B. V. Gnedenko (1939) and W. Doeblin (1941) for identically distributed random variables, and A. Ya. Khintchine (1937), P. Lévy (1937), and B. V. Gnedenko (1939) for the general case.

15.2 The Arcsine Law

In the central limit theorem, the limit distribution is independent of the distribution of the random variables $\{\xi_n\}$. This independence is sometimes described as an invariance principle. There are many other examples where the invariance principle is valid. One such example is the *arcsine law*. Let $\zeta_k = \xi_1 + \xi_2 + \cdots + \xi_k$ for $k \geq 1$ where $\xi_1, \xi_2, \ldots, \xi_k, \ldots$ are mutually independent and identically distributed random variables for which $\mathbf{E}\{\xi_k\} = 0$ and $\mathrm{Var}\{\xi_k\} = 1$. Denote by Δ_n the number of subscripts $k = 1, 2, \ldots, n$ for which $\zeta_k > 0$. Then

$$\lim_{n\to\infty}\mathbf{P}\{\Delta_n/n \leq x\} = (2/\pi)\arcsin\sqrt{x}$$

for $0 \leq x \leq 1$. In the particular case where $\mathbf{P}\{\xi_k = 1\} = \mathbf{P}\{\xi_k = -1\} = \frac{1}{2}$, the theorem was proved by P. Lévy in 1939 and in the general case by P. Erdös and M. Kac in 1947.

INTRODUCTION

In the last thirty years, amorphous materials have been developed that allow new practical applications never before realized by crystalline materials. This rapid expansion of the applicational field originates not only from epoch-making events in basic physics, but also from breakthroughs in technical developments. This article reviews three special areas of new applications: electronic and optoelectronic devices using amorphous semiconductors, functional usages with optical, mechanical, and chemical properties of glasses, and ferromagnetic functions of amorphous metals. In each section, the physical properties of each material are first briefly explained. Next, important applications and their operational principles are described. Section 1 discusses thin-film transistors for liquid-crystal display, solar cells, and imaging devices. Section 2 looks at optical fibers, laser glasses, nonlinear optical glasses, chemical and biomedical glasses, and functional polymers. Finally, in Sec. 3, magnetic cores for distribution transformers, high-frequency power device components, magnetic nonlinear uses, and high-permeability applications are reviewed. Despite recent developments, the progress in fundamental understanding of amorphous materials has been slow because of the lack of the symmetry and long-range order that is found in crystals. Many problems are still to be solved. A continuous effort in fundamental studies and in technical developments is necessary to expand the useful application areas.

1. AMORPHOUS SEMICONDUCTORS

Recently amorphous materials have been receiving a great deal of attention for possible application in various devices as well as for their interesting physical properties. Of particular significance are amorphous thin-film semiconductors such as amorphous Se (*a*-Se) and hydrogenated amorphous Si (*a*-Si:H), which are now opening useful new fields of application in electronics. Liquid-crystal displays (LCD), solar cells, and image-sensing devices are the most important applications for electronic devices at this time.

Thirty years ago, amorphous semiconductors were mainly studied as interesting materials from the purely scientific viewpoint. Great applicative efforts on amorphous semiconductors have taken place since the decade of the 1950s. Pioneer work on an image-sensing device using amorphous Se was done by Weimer and Cope (1951), and the commercial use of image pickup tubes using amorphous Se-based material was successfully reported by Maruyama *et al.* (1974).

In 1975, successful conductivity control over ten orders of magnitude and conduction-type control (of p and n types) using boron and phosphorus doping into amorphous Si prepared by glow-discharge decomposition of a monosilane (SiH_4) source gas were reported by Spear and LeComber (1975, 1976). After the publication of this key report, various applications were attempted that dramatically increased in parallel with studies on basic material properties.

Spear and LeComber also demonstrated that this material could be used in thin-film transistors (TFT) (LeComber *et al.*, 1979). Currently, liquid-crystal displays driven by *a*-Si TFTs are widely used, for example, in flat-panel televisions, laptop computers, car navigation systems, and so on.

The application of hydrogenated amorphous Si to solar calls was first demonstrated by Carlson and Wronski (1976). Over 50% of electronic pocket calculators selling throughout the world are powered by amorphous Si solar cells. Applications are expanding mainly into various wireless and limited-power appliances such as electric power sources for wrist watches, car ventilation fans, and so on.

The high dark resistivity and high photoconductivity of amorphous Si and Se are useful for the photoreceptors in copy machines or laser-beam printers and also for photosensors.

Amorphous semiconductors can be classified into two material groups: tetrahedrally coordinated materials and chalcogenide materials. Almost all the applications for amorphous semiconductors are listed in Table 1. The device applications italicized in the table are major commercial products that are discussed later.

1.1 Advantages and Disadvantages of Amorphous Materials

Amorphous materials have great advantages compared with crystalline semiconductor materials. These are as follows:

1. Readily controlled electronic properties of films over a wide range. In the chalcogenide amorphous group, Se is the principal material and S, Te, Si, Ge, Sb, and As are used mainly as alloying elements to control electronic properties. In tetrahedrally coordinated materials such as hydrogenated amorphous *a*-Si:H, optical and electrical properties can be varied widely by alloying with Ge, C, Sn, N, or O. B or P doping into *a*-Si:H and related alloys allows *p*- or *n*-type control similar to crystalline Si (*c*-Si).
2. Production of the films at low temperatures. In contrast to the growth temperatures over 1000 °C required for *c*-Si, only deposition temperatures up to about 500 °C are required for amorphous Si. Typically, deposition temperature is lower than 100 °C for *a*-Se and 300 °C for *a*-Si:H. Low-temperature deposition permits low interdiffusion of compositional elements and impurities between multilayers, allowing precise control of compositional and doping profiles; the use of various kinds of substrate materials such as glass (Ohnishi *et al.*, 1984), flexible polymer (Okaniwa *et al.*, 1982), and stainless steel (Okamoto *et al.*, 1979; Haruki and Uchida, 1983); and the conservation

Table 1. Electronic-device application of amorphous semiconductors.

Phenomena	How to use the phenomenon	Materials: Chalcogenide	Materials: Tetrahedral	Device applications
Photoconducting effect	Conductivity change by optical absorption	Se, Se–Te, Se–As, Se–As–Te	Si:H, SiC:H, SiN:H, SiO:H, Si:H(B)	*Image pickup tube,*[a] *photoreceptor* for copy machine or laser-beam printer, *linear photosensor,* color sensor, *solid-state imager*
Nonlinear effect	Nonlinear response by light or electric field	Se, Te–Ge–Sb–S, Te–As–Si–Te		*Avalanche-multiplication device,* varistor
Electric-field effect	Conductivity change by varying electric field		Si:H	*Thin-film transistor,* charge-coupled device, static-induction device
Carrier-injection effect	Interaction and/or recombination of electrons and holes		Si:H	Bipolar transistor, light-emitting diode, injection-type photosensor
Photovoltaic effect	Photoinduced carrier separation by *p-i-n,* Schottky, MIS junctions		Si:H, SiGe:H, Si:H(B), μc-Si:H	*Solar cell,* photosensor, pattern sensor
Quantization effect	Tunneling, quantum confinement, Coulomb blockade, carrier separation, low-dimensional effect, etc.		Si:H, SiC:H, SiN:H, SiO:H, μc-Si:H	Solar cells, thin-film transistor, light-emitting diode, Coulomb-blockade device

---

[a] The italicized devices, which are commercially used in specific application fields, are explained in this section.

of heating-up energy required for substrates during deposition.

3. Easily produced thin and multilayered films over a large area. Nonepitaxial deposition of amorphous films can be achieved on various foreign materials. Deposition is typically undertaken by using the thermal or plasma chemical vapor-deposition method [see CVD (CHEMICAL VAPOR DEPOSITION)] from gas-phase materials, or conventional resistive or electron-beam heating evaporation method from solid source materials. Large-area deposition to the order of 0.5 × 0.5 m^2 is now standard technology on commercial production lines.
4. Materials conservation. Amorphous thin-film semiconductors are directly prepared on substrates by using various deposition methods that conserve materials.

Amorphous materials have some disadvantages compared with crystalline materials. These are as follows:

1. Instability of structural and electronic properties. The unstable physical properties of amorphous materials, which have nonequilibrium metastable structures, affect the reliability of devices. With chalcogenide amorphous materials, thermal structural change such as crystallization readily occurs even at temperatures of less than 100 °C. With tetrahedrally coordinated materials, light-induced structural changes brought about by the Staebler–Wronski effect (Staebler and Wronski, 1977, 1980) still remain a problem that needs to be solved. The present reliability of devices is greatly increased through the effective choice of device structures and preparation conditions for materials. Materials having these instabilities are primarily used in new functional devices such as nonvolatile memories.
2. Low carrier mobility. Carrier mobilities of amorphous semiconductors are several orders of magnitude lower than those for crystalline materials, as shown for *a*-Si:H and *c*-Si in Table 2. Although it is difficult to expect these to achieve realizing high speed in electronic devices, amorphous semiconductors are suitable for high-impedance and low–power-dissipation devices such as the switching elements for liquid-crystal displays. With optoelectronic applications such as solar cells and photosensors, the high optical-absorption coefficient compensates for disadvantages of low mobility and short minority-carrier diffusion length.

Table 2. Electronic properties of *c*-Si and *a*-Si:H.

Electronic properties	*c*-Si	*a*-Si:H
Character of optical absorption	Indirect	Quasidirect
Band/optical gap (eV)	1.1	1.65–1.8
Refractive index	3.42	3.6

Minority-carrier diffusion length (μm)	~1000	~1
Minimum gap state density (cm^{-3} eV^{-1})	~0	$>10^{15}$

1.2 Structural, Electrical, and Optical Properties of Amorphous Semiconductors

From the viewpoint of electronic applications, the most important materials are *a*-Si:H and its related alloy group. In addition to this, chalcogenide materials such as *a*-Se and its alloys play an important role for those purposes. We concentrate on these materials in this section. The main physical properties of *a*-Se and *a*-Si:H are listed in Table 3.

1.2.1 Amorphous Si and Tetrahedrally Coordinated Materials The local atomic-bonding structure or the so-called short-range order (SRO) of *a*-Si is based on the covalent bonding of an sp^3-type configuration. The hybridized eightfold sp^3 valence-electron orbitals of a Si atom are split into four occupied bonding and four unoccupied antibonding orbitals in a solid, having strong directionality and making valence and conduction bands, respectively. The lack of a long-range order (LRO) in the atomic-bonding structure erases the sharp Van Hove singularities and eliminates the wave vector as a good quantum number in the material. The strong directionality of four sp^3 covalent bonds and the lack of LRO induce bond-length and -angle deviations, and dangling bonds. In other words, medium-range order

Table 3. Physical properties of *a*-Se and *a*-Si:H.

	a-Se	*a*-Si:H
Chemical bonding structure	Twofold coordinated chainlike structure	Fourfold coordinated three-dimensional structure
Hardness (Vickers, kg/mm^2)	~30	~2000
Optical gap (eV)	~2.0 (nonbonding–antibonding)	~1.7 (bonding–antibonding)

Mobility (cm^2/V·s) Electron	~5 × 10^{-3}	~1
Mobility (cm^2/V·s) Hole	~0.2	~10^{-2}
Maximum storage temperature (°C)	60	200–300

(MRO) characterizes the various properties of amorphous materials. The bond-length and -angle deviations induce band-edge tails, in which carrier mobilities are very low. The dangling bonds introduce midgap states, which act as traps and recombination centers. This prevents Fermi-level control by impurity doping.

In contrast to *a*-Si, *a*-Si:H contains hydrogen from 5 to 20 at.% bonded to Si. The Si–H bonds primarily relax strain in the material and passivate the dangling bonds. The reduction of strain reduces band-edge tailing. The midgap nonbonding states vanish on account of the passivation of dangling bonds. Namely, passivation pushes the antibonding states up above the conduction-band edge and the bonding states down below the valence-band edge, because of the strong bonding energy of Si–H compared with that of Si–Si. As a result, sharper band edges, wider band gap, and lower gap-state density are achieved in an *a*-Si:H network.

The electronic structure of *a*-Si:H is schematically shown in Fig. 1. Since *a*-Si:H has a lower gap-state density (down to 10^{15} cm^{-3} eV^{-1}), Spear and LeComber (1975) were able to achieve *p*-type or *n*-type valence control by PH_3 and B_2H_6 gas-phase doping during deposition, as shown by Fig. 2. Figure 2(a) shows room-temperature conductivity as a function of doping gas ratio, and Fig. 2(b) plots the activation energy of conductivity. Undoped *a*-Si:H shows weak *n*-type characteristics. Consequently, a small amount of B doping creates an electronically intrinsic *a*-Si:H.

In highly doped *p*- and *n*-*a*-Si:H, the state density around the Fermi level and the gap-state density increase greatly. Good *p*-*n* junction characteristics have not been obtained yet. The *p*-*i*-*n* junction shows fine rectifying characteristics as illustrated in Fig. 3.

Even with *a*-Si:H, the effect of wave vector **k**, which is not a good quantum number, appears during the interband optical-absorption and emission processes. The optical-absorption coefficient in the indirect transition region between 1.8 and 3.4 eV of *c*-Si is in the order of ~10^4/cm. The *a*-Si:H, however, has direct transition characteristics in which the optical-absorption coefficient is about one order higher than that of the *c*-Si shown in Fig. 4.

In order for *c*-Si to be used in optoelectronic devices such as solar cells and photosensors in the visible region, a thickness of 10 μm is necessary to absorb incident photons. However, an *a*-Si:H thickness of about 1 μm is sufficient to absorb incident photons. Figure 5 shows the Si-content dependence of optical gaps for *a*-Si(Ge or C):H al-

loys (Anderson and Spear, 1977; Shimada *et al.*, 1979; Morimoto *et al.*, 1982), which exhibit quasidirect optical-transition characteristics. Alloying with Ge or C allows us to achieve systematic control of optical gaps.

1.2.2 Amorphous Se and Chalcogenide Materials The local atomic-bonding structure of amorphous Se is based on covalent bonding in the p^4 valence-electron configuration. This has a chainlike structure. The hybridized six *p* orbitals are split into two occupied bonding and two occupied nonbonding orbitals and two unoccupied antibonding orbitals in the solid. The occupied nonbonding and the unoccupied antibonding orbitals make valence and conduction bands, respectively. The splitting between nonbonding and antibonding states forms an energy gap.

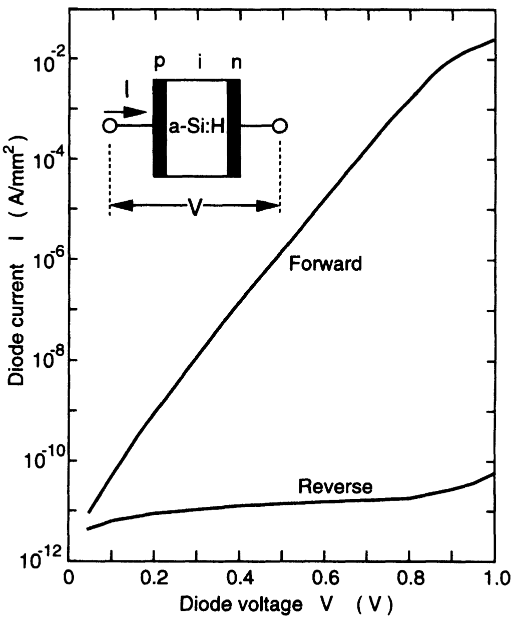

FIG. 3. Voltage vs current of an *a*-Si:H *p*-*i*-*n* diode.

The chainlike structure originating from the two occupied bonding orbitals is flexible compared with the tetrahedrally bonded structure of *a*-Si:H. As a result, very low gap-state density can be achieved in *a*-Se without the use of any strain-relaxation procedures such as the hydrogenation required for *a*-Si.

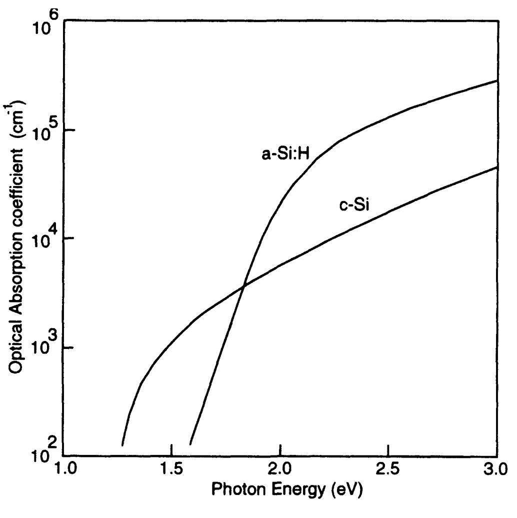

FIG. 4. Optical-absorption spectra of *a*-Si:H and *c*-Si.

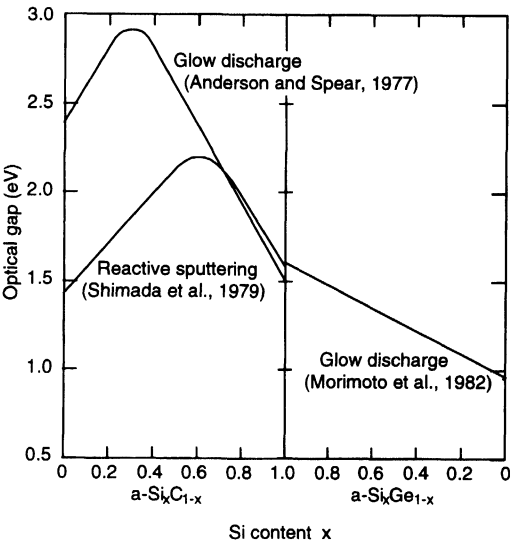

FIG. 5. Si-content dependence of optical gaps of *a*-Si(Ge or C):H alloys (Anderson and Spear, 1977; Shimada *et al.*, 1979; Morimoto *et al.*, 1982).

In contrast to *a*-Si:H, *p*, *n* doping cannot be performed in *a*-Se. This limits the various electronic applications—for example, use in solar cells, *p*-*n* or *p*-*i*-*n* photodiodes, and so on. Amorphous Se has high photoconductive yield, up to 1, and this is a solitary instance in which clear avalanche-multiplication effects have been observed in amorphous materials (Juska and Arlauskas, 1980; Tanioka *et al.*, 1987; Tsuji *et al.*, 1994). Image pickup device application by use of the avalanche-multiplication effect is one application.

1.3 Applications of Amorphous Semiconductors

1.3.1 Thin-Film Transistors In 1962, thin-film transistors (TFTs) using CdSe were reported for the first time (Weimer, 1962). Stable fabrication processes and operation of TFTs, however, could not be realized until the discovery of *a*-Si:H and the means of *p*-, *n*-doping control (Spear and LeComber, 1975, 1976). An *a*-Si:H TFT is useful to cover large areas and for use in high-impedance circuits such as the switching transistors in liquid-crystal displays (LeComber *et al.*, 1979; Powell, 1989; Tsumura *et al.*, 1991). Figure 6 shows a cross-sectional view of a typical inverted stagger-type *a*-Si:H TFT. The carrier channel is situated in the interface between the *a*-Si:H and gate insulator. Source and drain electrodes have been formed on the opposite side of the channel. This is the origin of the name "inverted stagger-type," in contrast to the *c*-Si MOSFET (metal-oxide-semiconductor field-effect transistor) structure shown in the figure for comparison.

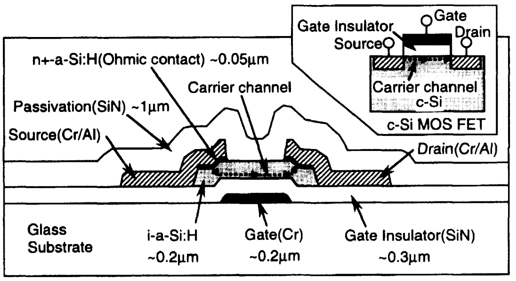

FIG. 6. Cross-sectional structure of an inverted stagger-type *a*-Si:H TFT. Inset: A *c*-Si MOSFET shown for comparison.

Figure 7 shows gate-voltage V_G vs drain-current I_D characteristics of an *a*-Si:H TFT.

FIG. 8. Cross-sectional view of a color TFT/LCD element.

On application of a weak negative bias voltage to the gate, I_D falls to on the order of 10^{-13} A. This corresponds to the estimated value of 10^{-13} A obtained from the intrinsic resistivity of *a*-Si:H in the flat-band scheme (shown by the dotted line in the inset).

The *a*-Si TFT and liquid-crystal optical switch are combined in the single pixel shown in Fig. 8. They are arranged in two dimensions as shown by Fig. 9 using an equivalent circuit. The operation of this device is as follows. White and unpolarized light arrives from the bottom and is polarized by the bottom polarizer. When the TFT is in the "off" state, molecules are aligned parallel to the alignment layers and perpendicular to one another as shown in Fig. 10(a). The direction of polarization of the incident light is rotated 90°. As a result, the light is blocked by the top polarizer [Fig. 10(a)]. When the TFT is in the "on" state, molecules are aligned vertically to the alignment layers. The polarized light can go through the top polarizer [Fig. 10(b)]. Sets of three color pixels display color dots. Each pixel is connected as shown by Fig. 9.

Initially, the first series of TFTs connected to the line of the first gate are in an "on" state. Data are sent in parallel to the series of TFTs from the data-input bus line. Next, the second series of TFTs is in an "on" state, and data are written in the same manner. The storage capacitors maintain the written data until the next scan.

A *c*-Si LSI is used for the scanning transistors at this time. To reduce the cost of TFT/LCDs, a high-mobility TFT using poly-Si is expected to be used commercially instead of the *c*-Si LSI presently used for the scanner and the *a*-Si:H TFT presently used for matrix switches.

The electron channel at the insulator–*a*-Si:H interface is opened by applying positive bias voltage to the gate. The current I_D increases exponentially and tends toward the relation $I_D = (W/2L)\mu C_{\text{INS}}(V_G - V_T)^2$. It is finally limited by the series resistance of the device. In the above, W and L are the channel width and length, respectively; μ is the field-effect electron mobility in the channel, V_T is the threshold voltage, and C_{INS} is the gate-insulator capacitance per unit area. estimated values of μ and V_T in this case are 0.42 cm^2/V·s and 0.4 V, respectively. The on-off ratio of I_D at V_G = −3 and 10 V exceeds 10^8, which is a value large enough for a high-definition LCD.

1.3.2 Solar Cells

1.3.2.1 Single-Junction Cells. Carlson and Wronski (1976) first reported on a Pt/*a*-Si:H Schottky-type solar cell with a conversion efficiency of 5%. A *p-i-n*–type *a*-Si:H solar cell, which is the standard structure for *a*-Si:H solar cells, was developed by the members of Prof. Hamakawa's group at Osaka University (Okamoto *et al.*, 1979). Their group also developed an *a*-SiC/*a*-Si heterojunction solar cell having a conversion efficiency of more than 8% (Tawada *et al.*, 1982). The Taiyoyuden and Electrotechnical Laboratory group showed that the employment of a textured transparent conductive oxide (TCO) electrode is effective in increasing conversion efficiency by means of optical confinement. The rough surface scattering of incident light by the so-called "textured surface" reduces optical-reflection loss in a wide range of light wavelength compared with an optically flat surface. Recently, conversion efficiencies of about 13% have been reported for the *a*-SiC/*a*-Si heterojunction solar cell (Miyachi *et al.*, 1992; Sawada *et al.*, 1993).

A typical *p-i-n* heterojunction solar cell with a glass/textured SnO$_2$/*p*-*a*-SiC/*i*-*a*-Si/μc-Si/Ag structure is schematically shown in Fig. 11(a), and its potential distribution is shown in Fig. 11(b). Because of the short minority-carrier diffusion length in *a*-Si:H compared with that of crystalline Si and the high gap-state density of heavily doped *a*-Si:H, a *p-i-n* junction has been used instead of a *p-n* junction.

Conversion efficiency η is defined as shown in Fig. 12, where V_{OC}, J_{SC}, V_m, and J_m are open-circuit voltage, short-circuit current density, and voltage and current at maximum power output, respectively; *FF* is fill factor, and P_{in} is incident-light power density.

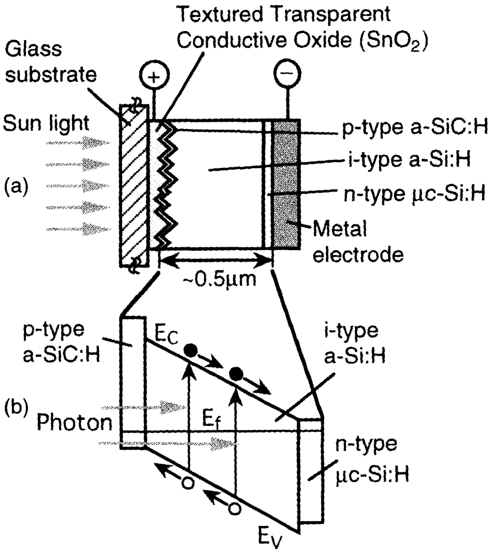

FIG. 11. (a) Cross-sectional structure of single-junction *a*-SiC:H/*a*-Si:H heterostructure solar cells and (b) potential distribution.

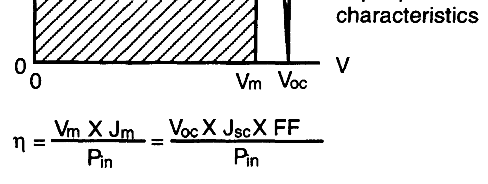
In a crystalline-material solar cell such as a *c*-Si cell, the diffusion-type photovoltaic effect is the essential operation mechanism. In contrast to this, the mechanism converting sunlight to electric power in *a*-Si:H solar cells is based on the drift-type photovoltaic effect, in which the generated photocarriers are transported by the internal field. The internal electric field in an *a*-Si:H solar cell is very sensitive to change as a function of gap-state density and photoinduced space-charge distributions.

The drift length of photogenerated carriers is strongly dependent on electric field and comparable to an *a*-Si thickness of 0.1–1 μm that absorbs sunlight effectively. The *p* and *n* layers only act as pinning for the Fermi level to establish an internal electric field, but do not contribute to photocarrier



$$\eta = \frac{V_m \times J_m}{P_{in}} = \frac{V_{oc} \times J_{sc} \times FF}{P_{in}}$$

FIG. 12. Definition of output characteristics of solar cells.

generation directly. It is very important to achieve large internal electric-potential difference and optimized internal electric-field distribution in the cell.

In this cell structure, B-doped *a*-SiC:H is used for the *p* layer, which increases the internal electric field and acts as an optical window layer for the *i* layer. The textured TCO and metal back layer are used for electrodes as well as for the optical-confinement layers of incident light.

1.3.2.2 Stacked-Junction Cells. A stacked-junction cell structure has been introduced to increase the conversion efficiency. Each cell can separately convert a certain range in the spectrum of incident sunlight. The cell is fabricated by using various optical-gap materials—for example, *a*-SiGe:H and narrow-gap *a*-Si with a low H content of less than 5 at.%. A primary concern, to obtain higher efficiency in the stacked cell, is to develop high-quality narrow–optical-gap materials.

An *a*-SiGe:H alloy is a promising candidate in the manufacture of narrow-gap materials. At this stage, however, the quality of this alloy is poor compared with that of *a*-Si:H. The preferential attachment of H to Si and Ge and the microscopic structural fluctuations of Si and Ge compositions seem to degrade the quality of the materials. In other words, structural fluctuation in the medium-range order (MRO) apparently prevents the preparation of high-quality *a*-SiGe:H.

MRO in *a*-Si:H and *a*-SiGe:H has been investigated using small-angle x-ray scattering (SAXS) measurement with the aid of the thermal-evolution measurement of hydrogen and IR spectroscopy (Muramatsu, 1989, 1991). Results obtained by SAXS suggest that hydrogenated amorphous silicon contains compositional fluctuations of Si and/or voids. In addition to this, the MRO in *a*-SiGe:H alloys is strongly affected by the clustering of Ge atoms in the alloys.

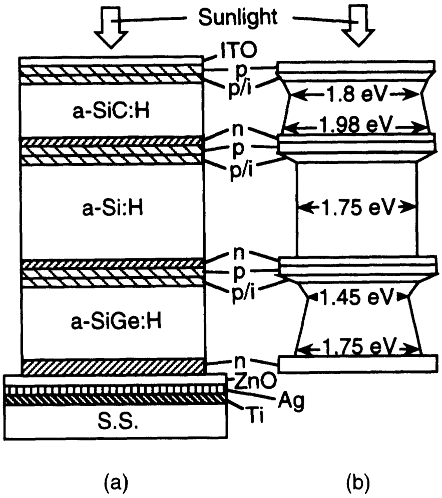


FIG. 13. (a) *a*-SiC/*a*-Si/*a*-SiGe stacked solar cell and (b) its band-gap profile (Nakata *et al.*, 1990b).

A microwave CVD method was introduced to reduce the preferential attachment of H and structural fluctuation in the medium range (Watanabe, 1987). This method has high decomposition and ionization yields for SiH_4 and GeH_4 source gases. By optimizing deposition conditions, minimum gap-state density N_d can be less than 10^{15} cm^{-3} eV^{-1} in *a*-SiGe:H with an optical gap of 1.5 eV. Such an optical gap is comparable to that realized in *a*-Si:H.

The stacked three-junction structure cell is a most promising structure with both high stability and high conversion efficiency (Nakata *et al.*, 1990a). Inside each subcell, precise band-gap profiling is useful in obtaining more efficient and more stable solar cells. By application of the band-gap profiling technique, *a*-SiC/*a*-Si/*a*-SiGe stacked cells were fabricated by Nakata *et al.* (1990b) as shown in Fig. 13(a). The band-gap profile is in Fig. 13(b). The solar-cell characteristics are shown in Fig. 14. By use of this cell structure, light-induced degradation is greatly suppressed. An expected degradation ratio of 14% in the first year was estimated from an

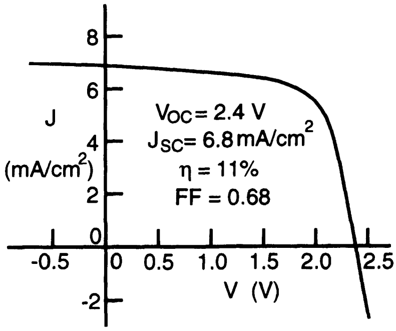

FIG. 14. Output characteristics of the stacked solar cell (Nakata *et al.*, 1990b).

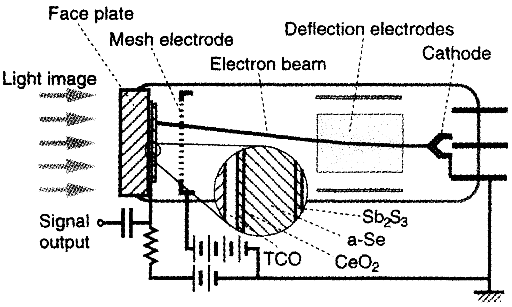

FIG. 15. Schematic illustration of Vidicon-type *a*-Se image pickup tube.

acceleration test. Ichikawa *et al.* (1992) also reported a total-area efficiency of 10.5% in a 30 × 40-cm² tandem cell with a large surface area.

1.3.3 Two-Dimensional Image Pickup Tubes

1.3.3.1 Vidicon-Type* a*-Se Image Pickup Tubes. Application of *a*-Se to image pickup tubes was first attempted by Weimer and Cope (1951). Commercial use was achieved by Maruyama *et al.* (1974). The cross-sectional structure of an *a*-Se image pickup tube is schematically shown in Fig. 15. Two-dimensional light images are converted into time-sequential electric signals by electron-beam scanning. The electric charge on a photoconductive *a*-Se film deposited by electron-beam scanning is discharged by incident light. Recharging occurs at the next electron-beam scan. Current for recharging is from electric-signal output.

Figure 16 shows the structure of a photoconductive *a*-Se film in detail (Shidara *et al.*, 1981). Elimination of Te in the first layer maintains hole-blocking characteristics, which prevents hole injection from the transparent conductive oxide (TCO) electrode. Te in the second layer enhances red-light sensitivity. Graded doping of As in the third layer provides uniform field distribution, contributing to the effective collection of photocarriers. The small amount of As in the *a*-Se prevents crystallization of the film. The fourth layer achieves small-device capacitance. The fifth layer, of porous Sb_2S_3, acts as the beam-landing layer to suppress secondary electron emission as well as acting as the electron-blocking layer to prevent injection of electrons into the *a*-Se. The thin CeO_2 layer, 20 nm, inserted between the TCO (made of indium tin oxide, ITO) and the first layer also suppresses injection of holes from the TCO and crystallization of the *a*-Se layer. Instead of *a*-Se, the use of *a*-Si:H has also been attempted for image pickup tubes (Imamura, 1979).

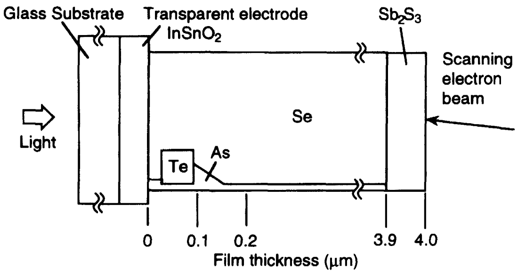

FIG. 16. Photoconductive-layer composition of an *a*-Se image pickup tube (Shidara *et al.*, 1981).

1.3.3.2 Avalanche-Multiplication–Type* a*-Se Image Pickup Tubes. In 1987, Tanioka *et al.* achieved steady and uniform avalanche multiplication of photocurrent in an *a*-Se thin film (Tanioka *et al.*, 1987). An ultrahigh-sensitive image pickup tube was successfully fabricated using this *a*-Se film as the photoconductive target. This was the first imaging device to use the avalanche multiplication of photocarriers in amorphous materials.

The avalanche-multiplication effect is very widespread in crystalline materials—for example, Si, Ge, and GaAs. An avalanche photodiode is already commercially available for high-speed photodetection in optical communication systems. However, only a few studies have been conducted on the effect in amorphous materials. Only one pioneer work suggesting this effect was reported by Juska and Arlauskas (1980), and this was studied in detail by Tsuji *et al.* (1987, 1991).

The structure of an avalanche-multiplication–type *a*-Se image pickup tube is essentially the same as that in Fig. 15. The amorphous Se-layer thickness, up to 25 μm, exceeds the 4 μm in a conventional *a*-Se vidicon tube. The applied target voltage, up to 2500 V, is extremely high compared with the approximately 50 V used in conventional ones.

The operation mechanism of this tube is shown in Fig. 17. The electron-blocking layer is charged by landed electrons when the

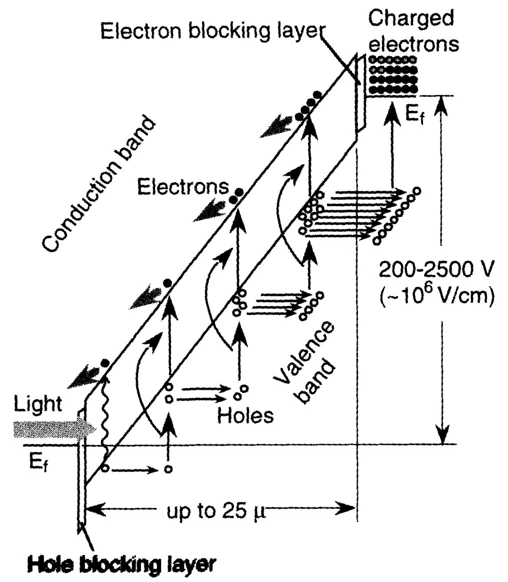

FIG. 17. Operation mechanism of avalanche-multiplication–type image pickup tube.

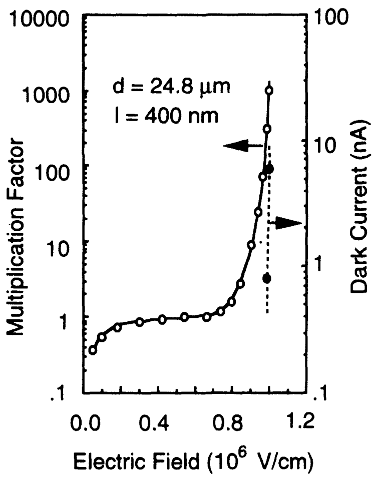

FIG. 18. Electric-field dependence of avalanche-multiplication factor and dark current in the tube (Tsuji *et al.*, 1991).

scanning electron beam just passes through this point in the target area. Incident light creates electron–hole pairs. Electrons and holes are accelerated by the electric field in opposite directions, and these create new electron–hole pairs by collision. The creation of new electron–hole pairs is called the avalanche-multiplication effect, and it happens easily with holes as compared with electrons in *a*-Se. Only avalanche-multiplication events initialized by holes are shown in the figure. The holes reaching the electron-blocking layer recombine with the charged electrons (recombined electrons are shown by gray circles), reducing the surface potential of the target. When the electron beam comes through this point during the next scanning cycle, the number of lost electrons is restored. This restoring current comes out as the signal.

Figure 18 shows the electric-field dependence of the avalanche-multiplication factor for 400-nm light in a tube with an *a*-Se thickness of 25 μm and a dark current as the reference. Ultrahigh sensitivity with an equivalent quantum efficiency larger than 1000 was obtained by Tsuji *et al.* (1991).

In addition to this, excess noise induced by avalanche multiplication is greatly reduced because of the large ratio of the creation rate of electron–hole pairs created by one hole collision to that by one electron collision. The effects of negative feedback due to the operation mode of charge storage for this device also contribute to reductions in excess noise.

This tube can have a high sensitivity to the ultraviolet or x-ray wavelength regions by changing the window material. In principle, it is also applicable to solid-state imaging devices.

1.3.4 Photoreceptors Amorphous Se and *a*-Si:H were successfully used in photoreceptors for an electrophotographic copy machine and a laser-beam printer. The photoreceptor consisted of an *a*-Se(Te) or *a*-Si:H photoconductive film deposited onto an aluminum cylinder.

Figure 19 explains the operational steps (so-called Carlson process: Carlson, 1938) for the laser-beam printer using the amorphous photoreceptor (positively charged case). Step 1: The surface of the drum is charged up to about 1000 V by the corona-discharging method. Step 2: The drum surface is scanned using laser light modulated by a pattern signal. A charge pattern is formed on the drum surface by the recombination of photocarriers with surface charges. Step 3: Fine carbon particles with thermally adhesive materials ("toner") are deposited on the surface by electrostatic force. Step 4: The patterned

toner is transferred onto plain paper electrostatically. Step 5: The patterned toner on the paper is fixed by heating. Step 6: The drum surface is cleaned up. The operation step returns to step 1.

An *a*-Se photoreceptor is used in a plain-paper copy machine. Various types of *a*-Si:H–based photoconductive layers have been reported (Oda *et al.*, 1981; Inoue and Shimizu, 1982; Yamamoto *et al.*, 1981; Kawamura *et al.*, 1983). The structure of a multilayered *a*-Si:H photoreceptor is shown in Fig. 20. Incident light is mainly absorbed in the carrier-generation layer and forms electron–hole pairs. In the case of positive charge, photoelectrons compensate for surface positive charge and holes running through the carrier-transport layer to the Al conductive substrate.

Photoconductivity gains up to 0.8 are obtained in a wavelength range of 400–800 nm. The top and bottom blocking layers prevent the injection of surface holes and electrons into the respective carrier-transport layers. The high resistivity of the top blocking layer maintains the electrostatic latent image and the toner image on the surface.

Recently, however, organic photoconductive materials have mainly been used for photoreceptors. Consequently, performance and durability have advanced remarkably and production costs have been greatly reduced. Development of a low-cost production process is desirable for amorphous photoreceptors.

1.3.5 Linear Photosensors and Solid-State Imagers Amorphous Si:H contact-type linear photosensors are widely used in facsimile machines to read documents. Cassanhiol *et al.* (1974) first reported the non-storage mode of operation of a contact-type linear photosensor using chalcogenide material. Kagawa *et al.* (1982) fabricated *a*-Si:H photosensors. The sensor consisted of 1000–6000 photoconductive elements. The elements were spaced 200–250 mm in a line for standard A4-size facsimile machines. Several thousand terminals for photoconductive elements have to be connected to addressing LSI chips.

Addressing *a*-Si:H TFTs are integrated on glass substrates using *a*-Si:H photodiodes to reduce the number of terminals. Figure 21 shows the equivalent circuit of a matrix-scanning–type integrated linear sensor with 2560 elements with 104 terminals. The 2560 elements are divided into 40 blocks. Each block operating in the parallel storage mode is read out and the readout converted into serial signals by an analog-multiplexer LSI. An analog multiplexer has been used because of the low switching speed of TFTs.

Various types of matrix-scanning integrated linear sensors have been reported (Credelle, 1988; Kobayashi *et al.*, 1991; Miyake *et al.*, 1991). These linear sensors are used mostly with lens arrays or lensless contact schemes using illumination light

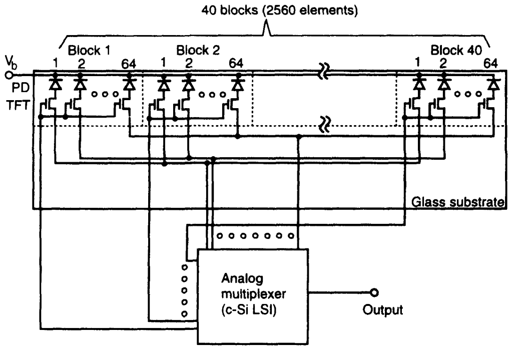

FIG. 21. Equivalent circuit of matrix-scanning line sensor (Miyake *et al.*, 1991).

sources. Current commercially available facsimile machines mainly employ this type of sensing unit.

An *a*-Se or an *a*-Si:H photoconductive film is integrated onto a *c*-Si MOS- or CCD-type two-dimensional scanner to obtain a highly sensitive and compact solid-state imager (Tsukada *et al.*, 1979; Baji *et al.*, 1982; Sasaki *et al.*, 1990; Manabe *et al.*, 1991). Recently, two-dimensional solid-state color imagers were made using *a*-Si:H photosensors and *a*-Si:H TFTs (Weisfield, 1993), and using *a*-Si:H phototransistors (Yamaguchi *et al.*, 1993). More intensive study and development, however, are expected to allow for actual commercial use.

2. FUNCTIONAL GLASSES

2.1 Fundamental Properties of Glasses

2.1.1 What Is Glass? Glass has long been defined as an inorganic product of fusion that has cooled to a rigid condition without crystallizing. This is true for the glasses used for windows, bottles, lenses, lamp bulbs, etc. However, along with other amorphous materials, glasses can now be made by deposition from the vapor phase, by sputtering in a low-pressure system, or through chemical processes—that is, by methods other than cooling a melt. So a more accurate definition of glass is an amorphous material that exhibits the glass transition. The glass transition is a phenomenon by which a solid amorphous phase exhibits a more or less sudden change in the derivative thermodynamic properties with changing temperature; these properties may include heat capacity and expansion coefficient, which change from crystal-like to liquidlike values (Rawson, 1980).

Figure 22 shows the volume change of a liquid, a supercooled liquid, glasses, and a crystal with temperature. Crystallization of the melt on cooling is usually accompanied by a marked decrease in volume at the melting point T_m. If the crystallization rate is low enough, the melt can be cooled below the melting point without crystallization taking place. This viscous liquid below the melting point is a supercooled liquid. No sudden volume change occurs when the melt is supercooled. The volume decreases along the same line with the liquid according to the change in the structure of the melt, reflecting the equilibrium configuration at a particular temperature. Further cooling results in the viscosity rising to as high a value as 10^{12} Pa s so that no further such changes are possible. Then a decrease in slope is found in the volume–temperature curve. With a further drop of temperature, the decrease in volume is due almost entirely to the decreasing amplitude of the atomic vibrations (Rawson, 1980; Boyd and Thompson, 1985).

The change in slope with temperature is characteristic of a glass as described in its definition. The temperature at which the change in slope occurs is called the glass-

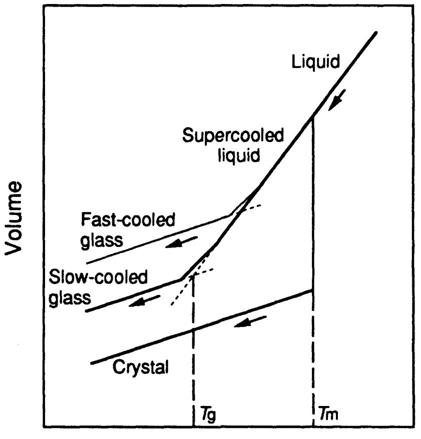

FIG. 22. Volume change of a liquid, a supercooled liquid, glasses, and a crystal with temperature. T_m, melting point; T_g, glass-transition temperature.

transition temperature T_g, and below T_g the material is described as a glass. Thus among amorphous materials, only those that exhibit the glass transition are glasses.

The change from supercooled liquid to glass is not a sudden one, and so T_g is not a well-defined temperature for any particular glass. The temperature at which the change in slope occurs decreases as the cooling rate is decreased. The structure that is frozen in during the glass transition persists at lower temperatures. Thus the structure of a glass depends on the cooling rate.

2.1.2 Structure and Features of Glasses

Most glasses are composed of metal–oxygen (or nitrogen, halogen, or chalcogen) bondings. In silicate glasses, the basic structural unit is the silicon–oxygen tetrahedron in which a silicon atom is tetrahedrally coordinated to four surrounding oxygen atoms. These tetrahedra are joined together at their corners. The structural unit is almost the same as that of crystalline silica. However, the bonding features between silicon–oxygen tetrahedra in glasses are different from those in the crystalline material, as shown in Fig. 23. Structure of glasses is treated in separate articles in the Encyclopedia in connection with experimental and theoretical techniques for structure determination (see AMORPHOUS MATERIALS, STRUCTURE OF; GLASSES).

The random-network theory of glass structure proposes that the atoms form a three-dimensional connected structure without periodic order and with energy content comparable to that of the corresponding crystalline material. The structure of silicate glasses described above is in accordance with this theory. In reality, the situation is not likely to be so simple, however, and the random-network hypothesis cannot be applied to every inorganic glass-forming material. Conceptions of chemical and structural inhomogeneities of glasses have been proposed (Porai-Koshits, 1990).

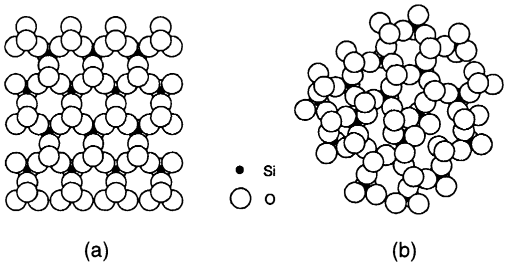

FIG. 23. Structure of SiO_2 in (a) crystalline and (b) glassy forms.

The similarity in the structural unit between the glass and crystalline forms results in similarities in optical, electrical, and magnetic properties. A glass exhibits most of the features peculiar to the crystalline form with the same composition, but less remarkably. Only in rare cases does a glass exhibit more remarkable features than the crystalline form—for example, in chemical resistance. Glasses can be made by combinations of almost any of the elements in the periodic table and with nonstoichiometric compositions. Consequently, the number of kinds of glass is infinite and many properties are controlled continuously over a wide range.

Another important feature of glass from the standpoint of practical application is that glass is more easily formed to any desired shape and to large-size components than ceramics or single crystals, resulting in lower machining costs. Moreover, glass is chemically stable compared with steel or plastics and more stable to temperature changes than plastics. The main elements constituting glass are generally among the most common elements on Earth, and suitable for industrial purposes.

2.1.3 Synthesis of Glasses

Most glass articles are manufactured by a process in which raw materials are melted at high temperatures and then formed into the articles (Boyd and Thompson, 1985). Recent demands for new high-performance glasses, however, have led to new preparation methods. Soga (1990) has reviewed many of the new glass-forming methods with an emphasis on their advantages for preparing the new types of glasses over the conventional melting method.

2.1.3.1 Unconventional Forming Method.

Rapid quenching is a new glass-forming method in which a liquid is rapidly cooled below the glass-transition temperature without the occurrence of crystallization. Rapid quenching is achieved by quenching the liquid into a bath of water, mercury, or liquid nitrogen, splat cooling onto a cold plate, smashing a molten droplet with a fast-moving cold piston, or dropping the liquid between two cold rotating rollers. In the case of two cold rotating rollers with a rotating speed of several thousand rpm, a cooling rate of 10^7 K/s can be realized. This method has allowed a variety of glasses to be gotten with new compositions, including the Bi–Sr–Ca–Cu–O system noted for its high-T_c superconducting property.

2.1.3.2 Deposition Methods. Evaporation is an old and well-established nonreactive deposition method involving only physical processes. In place of the usual electrical heating in metal boats or coils, electron-beam heating is used to vaporize a raw material. An example is deposition of antireflection coatings of Ta_2O_5 or SnO.

In the sputtering process (see SPUTTERING), atoms ejected by the starting material target when hit by energetic ions or charged particles deposit on the substrate. To obtain an amorphous film, the substrate temperature is kept low enough to avoid crystallization of the deposited film. Radio-frequency (rf) sputtering is commonly used for inorganic materials. A high-rate magnetron sputtering apparatus that combines magnetic and electric fields is effective to achieve a high sputtering rate.

Chemical vapor deposition [see CVD (CHEMICAL VAPOR DEPOSITION)] involves chemical reactions and is an effective method to produce bulk glasses. Vaporizable–decomposable organometallic or halide compounds are oxidized in a flame or a glow-discharge plasma to produce ultrafine amorphous particles, which are deposited on the solid surface, forming a high-purity glass soot. The soot is then sintered to make a solid, inclusion-free, glass body. This method has been explored extensively as a method to fabricate high-purity optical-waveguide fibers.

An advantage of deposition from a vapor phase is the possibility of making a glass that cannot be realized by any melting method. One example is aluminophosphate glass, which is difficult to make by any melting process, because Al_2O_3 and P_2O_5 have quite different melting temperatures and vapor pressures.

Finally, the thermal-oxidation process is a variation of the reactive deposition method, in which a metal surface, such as Si, is oxidized in an oxygen-containing atmosphere at elevated temperatures to form an amorphous oxide film.

2.1.3.3 Sol-Gel Method. In the sol-gel method, a glass is formed from a liquid solution. A sol of chemically polymerized organometallic compounds or a colloidal solution of metallic salts is transformed into a gel through chemical reaction at low temperatures. By heat treatment of the gel at temperatures lower than the usual melting temperature of that material, a glass with no detectable difference from the melt-driven glass is obtained.

The advantages of the sol-gel method are

1. preparation of the glass at lower temperatures than usual;
2. high homogeneity (components can be mixed at an atomic or molecular level);
3. synthesis of new kinds of multicomponent glasses with novel functions, which otherwise cannot be obtained because of crystallization and phase-separation tendencies, or the requirement of very high melting temperatures; and
4. the possibility of doping organic compounds or making organic–inorganic hybrid materials.

Long processing times are the most serious disadvantage of the sol-gel method. Photoirradiation has been proved to enhance the reaction effectively in the sol-gel process and to lower the temperature and shorten the time for the heat treatment (Ohishi *et al.*, 1992).

2.1.3.4 Solid-State Transformation Method. Extra energy given to a crystalline solid through impacting bodies or particles destroys the lattice structure at low temperatures and produces amorphous materials. This transformation occurs upon neutron bombardment in a nuclear reactor, exposure to shock waves as in a meteorite impact, and ion implantation.

2.1.4 Molecular-Dynamics Simulation

Soga (1990) has treated molecular-dynamics simulation as a virtual method for preparing glasses, because it can be a tool for determining whether some glasses can be made in a given system.

Molecular-dynamics simulation can provide a realistic model of glass structure when suitable pair potentials are used. Each atom in the system is assumed to take a random configuration corresponding to the Boltzmann distribution of velocities at a temperature high enough to form a liquid state. Then, the temperature is decreased by reducing the average kinetic energy stepwise or suddenly to room temperature. By selecting a slow cooling rate, a glass can be simulated having a real quenching rate. This requires a large number of steps and extremely long computing times. Unrealistically high quenching rates can also be simulated by this method.

2.2 Applications of Glasses

2.2.1 Function of Glasses New types of glasses with active functions completely different from those of conventional glasses, such as containers or building materials, are often called new glasses (Sakka, 1987; Tomozawa, 1987). New glasses are contributing to marked progress in advanced technologies, such as information and communications technology, electronics, energy technology, and biotechnology. Sophisticated research work is required to elucidate the mechanism involved in various functions of new glasses and to find applications for them. The development of new glasses is important also from the standpoint of glass industries. Glass containers (bottles) have been replaced by plastic, metallic, and paper containers. Their production is decreasing every year. Eyeglass lenses are also commonly plastic lenses nowadays. Glass industries have to introduce new glasses and new products in order to survive.

New glasses involve

1. glasses;
2. amorphous materials [typical elemental semiconductors (Si and Ge), metals, carbons, and high polymers are excluded];
3. crystalline materials made from glasses and amorphous materials; and
4. composite materials based on glass, amorphous materials, or crystals obtained from them.

New glasses are classified by areas of function: optical function, electronic function, thermal and mechanical function, chemical function, and biochemical function (Sakka, 1987). Examples of glasses and applications are shown in Table 4.

2.2.2 Optical Fibers Glasses have been used as a medium for transmission, reflection, refraction, absorption, and dispersion of light for centuries, and optical functions are still the most important and useful. Formability into fibers and capability to change properties such as refractive index continuously by incorporating additives into the structure are advantages of glasses over crystals for application to transmitting light. Glasses are used in the form of fibers or planar waveguides for this purpose.

Light-wave communications via glass fibers is replacing electronic message transmission on wires. The frequencies of visible or infrared radiation used in optical communications are vastly higher than those of the electronic carrier used in wire transmissions. Since the information-carrying capacity increases with the carrier frequency, the potential for light-wave communications is enormous. So optical fibers are indispensable for construction of multimedia infrastructures (see FIBER OPTICS; OPTICAL COMMUNICATIONS).

Developments have been made of low-loss glass fibers for light-wave communication systems mainly using silica glass. A glass fiber consists of a core of very high transparency and a transparent cladding layer of lower refractive index surrounding the core. The refractive-index difference between the core and cladding is about 0.01. The structures of optical fibers are classified into three types according to refractive-index profiles as shown in Fig. 24 (Pearson *et al.*, 1985; MacChesney and DiGiovanni, 1991). These fiber diameters are of the order of 100 μm. In the single-mode fiber, the core diameter is 1 to 5 μm. In the multimode fiber, the core diameter is over 30 μm, typically 60 μm. The fiber is called multimode since there are many paths the light may follow. The multimode fiber was designed for use with an incoherent light-emitting diode (LED) source, and the single-mode fiber with an injection laser emitting coherent light.

In stepped-index fibers, the core and the cladding have uniform refractive indices and the change in the refractive index at the core–cladding interface is an abrupt one. Mode dispersion broadens the light pulse injected into the core of a multimode stepped-index fiber. All the rays of different mode orders travel at the same speed, but on

Table 4. Classification of new glasses and their applications.

Glasses	Applications

Biochemical functions	
Bioactive glass ceramics	Artificial bone, tooth root

different paths with different lengths, and the time width of the pulse increases as the light travels down the fiber core. This broadening effect would cause the trailing edge of the pulse to overlap the leading edge of the next pulse, and the information being transmitted would be lost. To decrease mode dispersion of multimode fibers, the graded-index fiber configuration is used. In such a structure, the refractive index of the core in-

creases gradually from its periphery to the center as shown in Fig. 24(c), so that the speed of the light that travels a longer distance is higher and the modes can arrive at the end of the fiber almost simultaneously.

The wavelength range of the light used in light-wave communications is 0.8 to 2 μm. The most important characteristic of optical fibers is the attenuation or loss in this wavelength range. Optical loss L, measured in terms of dB/km, is expressed as $L = (10/l) \times \log(I_0/I)$, where I_0 is the input intensity and I is the intensity measured after a distance l. Low loss of 0.2 dB/km at a wavelength of 1.55 μm has been achieved by silica-glass fiber. This means attenuation of 4.5% in traveling a distance of 1 km. An example is shown in Fig. 25 (Snitzer, 1989).

Optical loss at short wavelengths is caused by ultraviolet absorption due to electronic transitions of the glass cations; at longer wavelengths it is caused by infrared absorption due to molecular vibrations. Rayleigh scattering is caused by compositional fluctuations and density fluctuations on a scale smaller than the wavelength of the light being used, and causes loss increasing at shorter wavelengths.

Other losses are superimposed on these intrinsic loss mechanisms (Pearson *et al.*, 1985). Material absorption is primarily caused by transition-metal ions: iron, cobalt, nickel, copper, chromium, manganese, and vanadium. A few tens of parts per billion of these metals dissolved in a soda-lime silicate glass will cause enough absorption to preclude lightguide use. Water can also be a serious contaminant. Macroscopic inhomogeneities such as bubbles and crystallites with dimensions that are large compared with the wavelength give rise to light scattering. The structure of the lightguide affects the lightwave transmission and becomes a cause of loss. For example, irregularities at the core–cladding interface might result in some of the light striking the interface at an angle such that it is lost into the cladding.

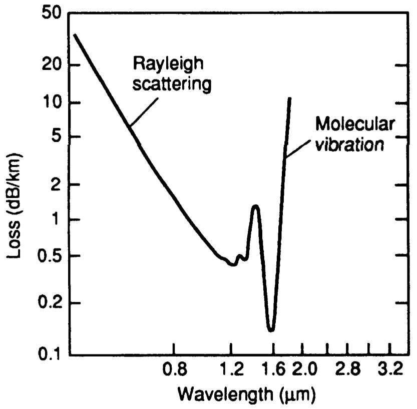

FIG. 25. Optical loss of low-loss silica fibers and its causes (Snitzer, 1989). At shorter wavelengths, loss is caused by electronic transitions.

Fiber-fabrication technologies aim at producing a fiber having the highest purity to achieve low losses and with a precise index profile to achieve low dispersion at the particular wavelength of operation (MacChesney and DiGiovanni, 1991).

Multicomponent glass fibers are fabricated by a double-crucible technique. In this process an ingenious continuous-casting system composed of concentric platinum crucibles is used. A thin stream of core glass flows from the upper crucible, passes through the reservoir of cladding glass, and is concentrically surrounded by the cladding.

Low-loss silica fibers are fabricated by vapor-deposition techniques, using oxidation of silicon tetrachloride vapor to produce submicron amorphous silica particles and of other chloride vapors such as germanium tetrachloride and phosphorus oxychloride as sources of dopants in the silica. There are inside and outside processes. For inside processes, modified chemical vapor deposition (MCVD) or plasma chemical vapor deposition (PCVD) is used to deposit doped silica layers on the inside wall of a silica tube. The tube is collapsed to a rod and drawn into fiber.

There are two versions of outside processes. One is outside vapor deposition (OVD) and the other is vertical-axial deposition (VAD). In the former, a soot of SiO_2 particles is deposited layer by layer on a horizontal, rotating mandrel. A core is deposited first, followed by a cladding. After the deposition, the mandrel is removed and the preformed tube is sintered to form vitreous silica. Then it is drawn to fiber. The central hole is collapsed during either the sintering or the fiber drawing.

In the VAD process, a porous soot cylinder without a central hole is formed by depositing the core on the end of the cylinder and cladding around the cylinder simultaneously using two torches. The core profile is controlled by precise control of the gaseous constituents in the torch flame producing the growing soot face. When the deposition is completed, the body is sintered and drawn to fiber.

Several attempts have been made to develop optical fibers with transmission characteristics superior to the silica-glass fiber. Heavy-metal fluoride glasses are expected to have lower intrinsic optical attenuation than a silica fiber (MacChesney and DiGiovanni, 1991; Lucas, 1991). Fluoride glasses based upon the ZrF_4–BaF_2 system—for example, ZBLA (ZrF_4–BaF_2–LaF_3–AlF_3) or ZBLAN (ZrF_4–BaF_2–LaF_3–AlF_3–NaF) glasses—are being developed. Fluoride glasses are unstable and not easy to fabricate. Bi_2O_3–PbO–based heavy-metal oxide glasses having high infrared transmission characteristics with better stability have been developed. Chalcogenide glasses, such as the GeSbSe system, are also expected to be low-loss glasses with high infrared transmission (Elliott, 1991). As a practical matter, however, these glasses require development of longer-wavelength light sources and detectors to take full advantage of the lowest-loss region at 2 μm, so that silica glass still holds an advantage.

2.2.3 Active Optical Devices Glass lasers are being developed and utilized for high-power applications, because it is easy to produce various shapes and sizes of laser material with high optical quality. The laser glass has been used in forms ranging from fibers to disks with diameters tens of centimeters across. Large pieces of laser glass are used for the amplifier disks in laser-induced fusion facilities. It would be enormously expensive and probably technically impossible to make those with single crystals of similar size. The function of glass lasers is based on doping with rare-earth luminescent ions. Rare-earth ions used include Nd, Yb, Ho, Er, and Tm. The Nd ion is practically useful because its light emission takes place at room temperature and the absorption bands spread over wavelengths ranging from the visible to near-IR regions.

Figure 26 shows the energy levels of the laser glass. Pumping light excites the active ions in the glass to some upper energy level. The radiative transition back to the ground state yields a photon. This radiative transition is either spontaneous or stimulated. Stimulated emission is in phase with the signal photon promoting deexcitation. A laser is made by placing semitransparent mirrors and promoting stimulated emissions all in phase continuously between them. The spectral range of glass lasers extends from about 0.5 to 3.0 μm. Wide–band-gap fluoride glasses or fused silica are used as hosts for the ultraviolet emission and heavy-metal halide or chalcogenide glasses as hosts for the infrared. Because the optical spectra of ions in glass are inhomogeneously broadened, glass lasers provide a degree of tunability ($\leq 10\%$) that is not possible in crystalline hosts (Weber, 1990, 1991; MacChesney and DiGiovanni, 1991).

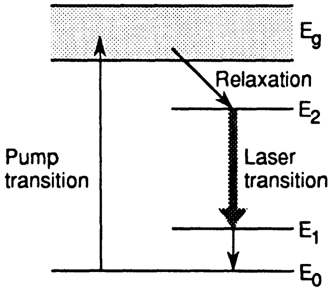

FIG. 26. Energy levels and transitions of laser glass.

New developments of rare-earth–doped glass are as fiber amplifiers and planar-waveguide optical amplifiers. A single-mode fiber core doped with ions of a rare earth and pumped with (injected by) light of an appropriate wavelength emits photons stimulated by the incident signal, and it can act as an amplifying device. Fiber amplifiers are of particular interest for applications in telecommunications, because they can amplify signal input directly without transforming it to an electrical one and reconverting it to an optical one after electrical amplifying. Optical amplification was successfully demonstrated in erbium-doped silica-fiber amplifiers, which allow amplification of signals in the range of 1.5–1.6 μm, a very important region for communication systems. Figure 27 illustrates the basic configuration of such an amplifier. See AMPLIFIERS, OPTICAL.

An Er-doped planar-waveguide amplifier was also reported (Kitagawa *et al.*, 1993). It has an Er concentration of 0.47% and exhib-

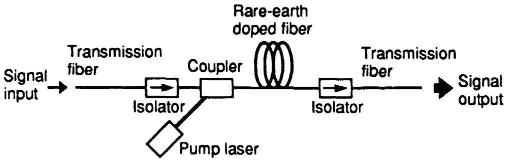

FIG. 27. Rare-earth–doped fiber amplifier configuration.

its a gain of 24 dB for signal wavelength of 1.533 μm. Planar-waveguide amplifiers should contribute to the development of planar light-wave circuits and optical integrated circuits.

The introduction of a large amount of a rare earth into the now available low-loss oxide fibers is difficult. New processes and nonoxide glasses such as fluoride fibers are being considered.

2.2.4 Nonlinear Optical Glasses Nonlinear glasses have attracted attention because of their potential application in all-optical devices.

High intensity of radiation induces a large polarization P in a medium, which is not linear in the external optical electric field E, but expressed as its power series. Nonlinear parts of this series lead to many desirable effects such as second-harmonic generation, an intensity-dependent refractive index, and optical bistability. These effects allow an optical signal to affect the medium, and thereby its own propagation or the propagation of other optical signals, so that it can be utilized for optical switches, memories, or modulators. These devices are key components of planar light-wave circuits.

Glasses with small values of the linear refractive index and dispersion generally have small nonlinearities. Simple SiO_2 has the smallest linear and nonlinear refractive indices of the oxide glasses. These values increase as modifier ions are added (Weber, 1991).

Another approach to produce highly nonlinear glasses is based upon composites with glass matrix and semiconductor dispersed particles. In semiconductor-doped glasses, the nonlinear behavior appears as intensity-dependent changes in the absorption and refractive indices. These effects originate from the generation of a short-lived free-electron plasma and band-filling effects. The size of the semiconductor microcrystals in the glass affects the linear and nonlinear optical properties through quantum confinement effects in the potential accompanying the particles. Typical semiconductor-doped glasses include I–VII [CuCl, CuBr, Ag(Cl,Br,I)] compounds, II–VI [CdS, CdSe, CdS_xSe_{1-x}, CdTe] compounds, and III–V compounds (Weber, 1991). Semiconductor-doped glasses have nonlinear refractive-index coefficient values 10^5 times higher than silicate glasses (Tomozawa, 1987).

2.2.5 Electronic Substrates Thermal, mechanical, and electronic functions of glasses allow their utilization for various kinds of substrates, which is becoming the most important usage in the electronics field. Glasses are used as substrates for flat-panel displays (liquid-crystal display, plasma display panel, electroluminescence display, and electrochromic display), for disks (magnetic disk, optical disk, and magneto-optical disk), for solar cells, for photomasks, and for microelectronics packaging.

Requirements as microelectronics packaging coming from developments in semiconductor technology are, for example, a lower dielectric constant of substrate material, low-temperature processing, a thermal-expansion rate match to silicon, improved thermal conductivity, multilayer processing, and high mechanical strength. These objectives have been achieved by the development of various low-temperature, cofirable glass ceramics and glass-plus-filler composites. Metals such as copper, gold, and silver can be used as conductors in the low-temperature cofired systems around 900 °C. These metals have approximately one-third the resistivity of the tungsten or molybdenum metals used in high-temperature alumina-based systems (Geiger, 1990).

Table 5 compares low-temperature cofired glass ceramics with high-temperature alumina ceramics. Glass ceramics are derived through glass crystallization. Glass-plus-filler composites are formed by admixing filler materials such as granular ceramics and metals into a glass. The filler acts not only to toughen the material or to increase the strength, but also to control physical properties such as thermal expansion (Nishigaki and Fukuta, 1989; Niwa *et al.*, 1989).

Figure 28 shows a schematic diagram of a

Table 5. Comparison of low-temperature cofired glass ceramics with high-temperature alumina ceramics.

Property	Glass ceramics	Alumina
Sintering temperatures (°C)	800–1100	1500–1600
Cofired conductors	Cu, Ag, Ag/Pd, Au	W, Mo, Mo–Mn
Flexural strength (MPa)	150–300	280–420
Thermal conductivity (W/m·K)	2–10	20–40
Dielectric constant (at 1 MHz)	4–8	9–10
Thermal expansion ($\times 10^{-7}$/°C)^a	30–80	65–75

^{a}Si: 35

typical low-temperature cofired multilayer process using the green-sheet technology. A three-dimensional electrical circuit is formed inside the multilayer substrate with layer-to-layer conductive connections through via holes (Geiger, 1990). Several tens of layers are laminated and as many as 100 LSI chips are mounted for multilayer substrate modules used in mainframe computer systems (Tummala, 1992).

2.2.6 Chemically Durable Glasses Glasses are relatively inactive chemically compared with plastics and metals. For applications such as physicochemical apparatus and medical appliances, the chemical durability of glasses is sufficiently high.

Long-term chemical durability is the major concern in high-level radioactive-waste management (Tomozawa, 1987). The most popular waste-solidification method is vitrification. Glass for the high-level radioactive-waste solidification is required to be stable in structure at 500–600 °C under high radiation exposure and resistant against leaching to water or, when used with cement, to alkaline aqueous solution formed by reaction between water and cement, which causes migration of nuclides from the glass to the underground water. Glass compositions including borosilicate glass, aluminosilicate glass, and phosphate glass have been investigated, and, currently, borosilicate glass is being most widely investigated. Borosilicate glasses for this application have 40–50 mass % SiO_2 and melt at 1100–1200 °C, because several toxic materials volatilize during melting above 1300 °C.

2.2.7 Biomedical Glasses Some glasses and glass ceramics can be used as implants for hard tissue (bones and teeth). Desirable properties of glass and glass ceramics as biomaterials are these:

1. bioactivity, i.e., the property to bond with hard tissue (bones) of the human body;
2. biocompatibility, i.e., the biologically compatible intergrowth of the biomaterial and the tissue of the human body without a rejection reaction or possible toxic effect;
3. higher mechanical strength than living bones and long-term stability in living bodies;
4. ease of forming and machining;
5. ease of sterilization.

The hard tissue of human bodies is constituted of apatite [$Ca_{10}(PO_4)_6(OH)_2$]. An example of bioactive glass is based on the $Na_2O–CaO–P_2O_5–SiO_2$ system. This glass forms calcium-phosphate layers and apatite

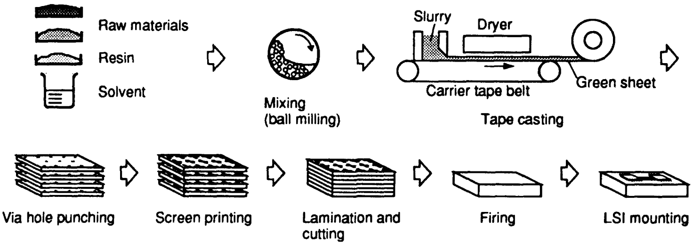

FIG. 28. Schematic diagram of the typical fabrication process for a low-temperature cofired multilayer substrate.

in the living body in reaction with the fluid and bonds to the bones.

On the other hand, bioactive glass ceramics are based on parent glasses yielding apatite on a suitable crystallization treatment, so that they contain apatite crystals already in the base material. It is possible in glass ceramics to control the apatite crystallization and the formation of other crystal phases in order to develop materials having a combination of special properties. Vogel and Höland (1990) developed glass ceramics in the SiO_2–Al_2O_3–MgO–CaO–Na_2O–K_2O–F–P_2O_5 system. This system precipitates apatite and mica/phlogopite crystals simultaneously and, consequently, bioactive and machinable glass ceramics are produced. They have long-term stability and can be machined with standard metal-working tools by a surgeon, if necessary during an operation. Living bones and apatite crystals have flexural strength of 100–200 MPa, and bioactive glass ceramics of 100–600 MPa.

Bioactive machinable glass ceramics have widely and successfully been applied in the middle ear, nose, and jaw and have been implanted as thoracic vertebra substitutes or cervical spine substitutes and as tooth root implants.

2.3 Polymeric Materials

2.3.1 Features of Polymers There are two types of polymers: thermoplastic polymers and thermosetting polymers. Thermoplastic polymers melt on heating. Cooling of the melt causes crystallization in some polymers (crystalline polymers) such as polyethylene. Some regions remain amorphous, however, and further cooling reduces these regions to glass states through the glass-transition temperature. Other polymers such as polystyrene cannot be crystallized even partially and form amorphous solids through glass transition upon cooling from the melt (noncrystalline or amorphous polymers). Properties of polymers change drastically at the glass-transition point in the same manner as with inorganic-glass materials.

Thermosetting polymers have a network structure with a large number of cross-linking points on the polymer chains. Prepolymers are the materials before the cross-linking reaction and they are liquid at room temperature. They become hard glassy plastics through cross-linking reactions upon heating and do not melt with further heating, but proceed to harden until decomposed.

2.3.2 Applications of Polymers Some polymers resemble inorganic-glass materials in properties such as hardness, transparency of light, electrical insulation, and ease of forming. Others have completely different features from glasses. For example, a wide range of ductility and elasticity allows several hundred percent of stretching and restoration. The variation in dynamic properties of polymers comes from differences in the states of aggregation and thermal agitation of molecular chains as well as in the molecular structure of the polymer chains themselves. This variety in characteristics has made polymers very useful in many fields. Only a part of electronics and photonics applications is outlined below.

The main application of electrical properties of polymers is as insulators. Polymers such as phenol resin have been used as insulators for a long time, and polymers are now indispensable to the development of new microelectronics.

In the fabrication of integrated circuits, polymers sensitive to UV light, electrons, x-rays, and ions are used as resists in the lithographic process. The change in solubility rate with exposure allows developer to remove either the exposed (positive tone) or unexposed (negative tone) areas of the resist and a developed image is produced. The developed image is transferred into the semiconductor substrate by using resists as etching masks. Solubility characteristics, thermal stability, and chemical-etch resistance of the materials are key requirements (Watts, 1987). Polyimides and polyimidelike materials are widely used for photoresists.

A continuing increase in the scale of integration in microelectronics requires line-width control of smaller than 1 μm. In place of conventional photolithography, which lacks the resolution to meet these requirements, alternative lithographic technologies, such as electron-beam lithography, short-wavelength (deep UV) photolithography, and x-ray and ion-beam lithography are under development. Each technology requires resist materials specifically designed and optimized for the particular radiation being applied.

Polyimides are also used as a protective overcoat (passivant), providing a barrier for transport of chemical species that could attack the underlying device, and as an interlevel insulator film for multilevel interconnecting systems. For these usages, the material must be an excellent electrical insulator and must adhere well to the substrate. In addition, planarity and a good etching property to form fine via holes for reliable interconnections between the metal layers above and beneath the film (the "via contact") are required of interlevel insulator films (Senturia, 1987).

Plastic packaging of microelectronics devices provides lower-cost, nonhermetic packages. Epoxy encapsulation compounds are used to protect chips during handling and subsequent assembling. Multilayer printed circuit boards are manufactured by laminating circuitized epoxy laminates containing glass fabric (Oka *et al.*, 1992; Higgins, 1992).

Conducting polymers have been developed and are expected to find application as electrodes or electromagnetic interference shielding (Baker, 1987).

In the application field of photonic process and devices, polymers are used as protective coatings for silica optical fibers. The coating affects the fiber strength and transmission loss. UV-curable epoxy acrylates or urethane acrylates are used for in-line application processes as the fiber is drawn and nylon or polyester elastomers are used for off-line application processes (Blyler *et al.*, 1987). Polymeric optical fibers such as those of deuterated polymethyl methacrylate (PMMA) are useful for local communication loops and links. In optical-disk technology, polymers are not only applied as inexpensive substrates, but also used as passive layers (e.g., antiscratch, defocusing overcoats) and as recording layers. PMMA and polycarbonate (PC) are used for disk substrates. Moreover, polymer glasses, such as PMMA and polystyrene, have potential use as nonlinear optical materials for integrated optics (Sohn *et al.*, 1987).

3. AMORPHOUS METALS

The pioneers in the development of rapidly quenched metals were Pol Duwez and his group in 1960 (Klement *et al.*, 1960). They obtained an Au–Si alloy in an amorphous state by plunging a droplet of it onto a Cu substrate. The first product was in the form of a flake. A prototype method for producing an amorphous ribbon continuously was developed by Pond and Maddin (1969). This technology, called centrifugal melt spinning, contributed greatly to accelerating progress in the study of amorphous metals. The most refined method is planar flow casting (PFC), developed by Narasimhan (1980). In PFC, the molten alloy is ejected onto the outer surface of a rotating wheel through a slotted nozzle placed close to the top of the wheel. Today, most wide ribbons are produced by this method.

The characteristic features of amorphous metals stem from the random structures in atomic arrangement, similar to that in liquids. The lack of long-range order endows amorphous metals with various unique properties, such as soft magnetic behavior, high mechanical strength, high corrosion resistance, and combinations of these, which have not been easily realized in crystalline metals.

These unique properties provide a variety of applications. This section focuses on the magnetic properties, because most applications of amorphous metals currently are connected with the magnetic properties. In respect to types of materials, only rapidly quenched amorphous-metal ribbons are dealt with. Even though amorphous metals can also be produced by other techniques, such as gaseous-phase deposition, electrodeposition and electroless deposition, and ion implantation, the rapid quenching from the liquid phase is the most mass productive and therefore the least expensive. Nanocrystalline metals are also discussed as among the rapidly quenched metals, because they are obtained by annealing of amorphous metals.

3.1 Magnetic Properties of Rapidly Quenched Metals

The amorphous metals are commonly very soft magnetically. The magnetic softness—that is, low coercivity and high permeability—results from the absence of magnetocrystalline anisotropy, grain boundaries, and secondary phases. Also, their high electrical resistivity and thinness of the ribbon contribute to reducing energy wasted when they are used in connection with an alternating field.

On the other hand, amorphous metals have a deficiency of low-saturation magnetic induction. In this respect, the addition of alloying elements and the change in electronic structure are concerned. Amorphous metals made by rapid quenching generally contain 1–25 at.% metalloid elements—B, Si, P, and C—or transition-metal elements, typically like Zr, Ti, or Hf. These elements are added to enhance glass-forming ability and to stabilize amorphous phases. However, the addition of glass formers not only dilutes the concentration of ferromagnetic atoms, but also reduces the magnetic moment per atom because of a change in electronic structure, so-called charge transfer. As a result, the saturation magnetization and Curie temperature of amorphous metals are greatly decreased compared with those of crystalline metals. The decrease in magnetization acts unfavorably in power applications, giving rise to an increase in the size of cores.

An additional advantage of amorphous magnetic metals is that one can expect to realize a desirable combination of several properties. For instance, one can attain soft magnetic and hard mechanical properties simultaneously; in traditional crystalline materials, soft magnetic materials are also mechanically soft. These features not only improve performance through use of amorphous metals, but also allow the development of unique applications.

Figure 29 shows the composition dependence of saturation induction, coercivity, and magnetostriction in an amorphous $(Fe,Co,Ni)_{78}Si_8B_{14}$ alloy system. This figure combines the experimental results of Ohnuma *et al.* (1977) and Jagielinsky *et al.* (1977). The Fe-rich region has high saturation induction and high magnetostriction, and the compositions along the line from Co-rich toward Ni-rich regions exhibit zero magnetostriction, resulting in very low coercivity. Figure 29 also indicates that the magnetic properties change continuously with chemical composition. Hence it is easy to find the best composition to meet given requirements. This is another characteristic of amorphous metals. On change in composition, crystalline materials often encounter phase transformations where many properties change drastically.

Nowadays, commercial amorphous magnetic materials are largely classified into Fe-based and Co-based alloys, both of which contain B and Si as glass formers. Fe-based alloys have core losses approximately 70% lower than that of 3% silicon steel, whereas the saturation induction is 20% less than

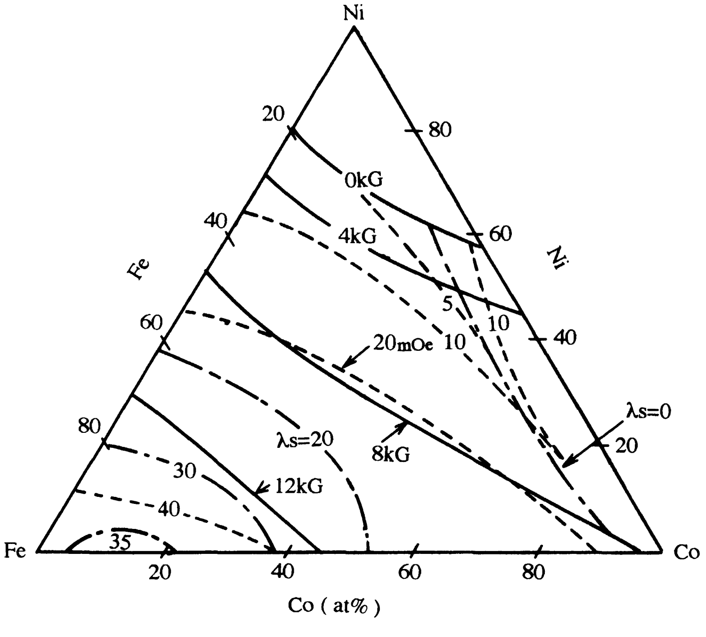

FIG. 29. Composition dependence of several magnetic properties in amorphous $(Fe–Co–Ni)_{78}Si_8B_{14}$ quasi-ternary system. Solid lines denote saturation magnetic induction in kG, dashed lines coercivity in mOe, and chained lines saturation magnetostriction in 10 times.

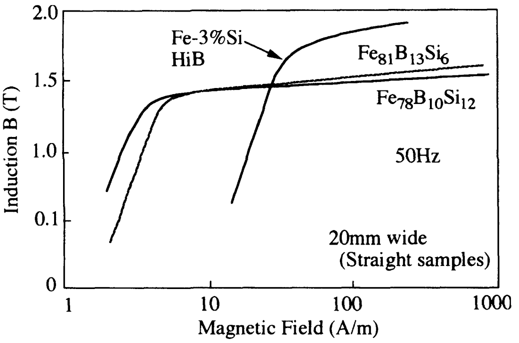

FIG. 30. Typical ac magnetic induction curves as a function of magnetic field for amorphous alloys and silicon-steel HiB.

that of silicon steel. Examples of the magnetization curves and core-loss characteristics of Fe-based alloys are given in Figs. 30 and 31 (Sato, 1983). The amorphous $Fe_{78}B_{13}Si_9$ alloy was proposed by DeCristofaro *et al.* (1982) as one of the best alloys for power transformers, and has been commercialized under the trademark name Metglas 2605S2 by Allied Signal.

Co-based alloys exhibit remarkably high permeability and low coercivity with the addition of several percent of Fe, comparable to that of Supermalloy. (Supermalloy, an alloy of composition 79 wt.% Ni, 5 wt.% Mo, and the balance Fe, is the alloy having the highest known permeability, ~1 000 000.) This superior property originates from the zero-magnetostrictive nature, involving the least stress sensitivity.

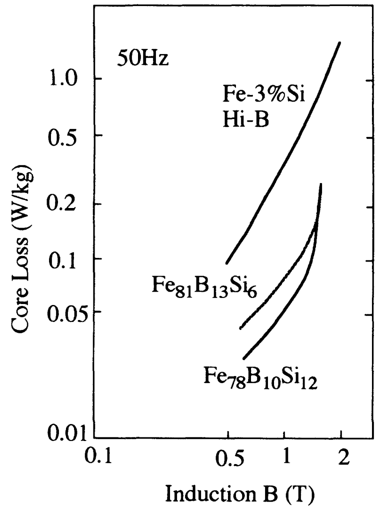

FIG. 31. Core losses as a function of magnetic induction for amorphous alloys and silicon-steel HiB.

One of the other characteristic features of amorphous alloys is that the magnetic anisotropy can be easily changed by annealing. Figure 32 shows that *B-H* loops vary greatly according to the presence or absence and the direction of a magnetic field during annealing. This indicates that one can enable the material to meet various application requirements by choosing the annealing condition.

Fe-based nanocrystalline alloys may also be regarded as a class of rapidly quenched magnetic materials. The first nanocrystalline magnetic alloy was developed by Yoshizawa *et al.*, (1988). They produced a nanocrystalline structure of an FeSiBNbCu alloy by annealing the original amorphous alloy at temperatures above the crystallization temperature. Their grain sizes of 10–20 nm are much smaller than the width of a magnetic domain wall (>100 nm). The grain boundaries therefore do not act as obstacles to domain-wall motion. Also, the nanocrystals have random orientation, and thus their apparent magnetic anisotropy is averaged out. The nanocrystalline FeSiBNbCu alloy exhibits very low coercivity and high permeability due to its very low magnetostriction. The values of permeability are comparable to those of Co-based amorphous alloys, and the saturation magnetic induction is much greater than that of Co-based amorphous alloys. The nanocrystalline FeSiBNbCu alloy is commercialized under the trademark name Finemet by Hitachi Metals.

The occurrence of low coercivity in nanocrystalline materials has been interpreted theoretically by Herzer (1990). Smaller grain

FIG. 32. Examples of hysteresis loops depending on the direction of a magnetic field applied during annealing.

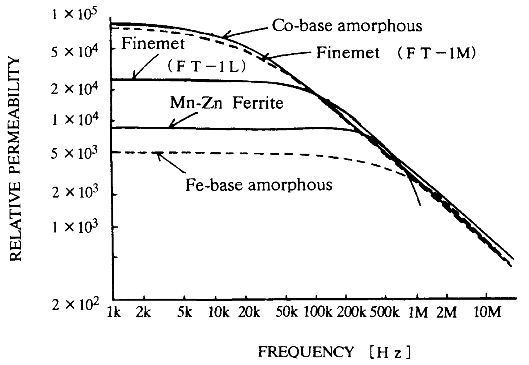

FIG. 33. Relative permeability of Finemet compared with those of Co-based and Fe-based amorphous alloys and Mn-Zn ferrite. FT-1L and FT-1M represent different anneal conditions.

sizes have so far been believed to give rise to large coercivity. The magnetic characteristics of nanocrystalline alloys are compared in Figs. 33 and 34 with those of Co-based amorphous alloys and other magnetic materials. Nanocrystalline alloys also behave in a manner similar to amorphous alloys with respect to magnetic field applied during annealing. By choice of anneal conditions, various *B-H* loops can be obtained as shown previously in Fig. 32. In addition, nanocrystalline materials have a characteristic feature superior to amorphous materials. This is a high thermal stability due to the crystalline nature, suggesting a longer service life of products made with nanocrystalline material.

3.2 Applications of Amorphous Metals

3.2.1 Distribution Transformers The use of amorphous metals in distribution transformers was first proposed by Luborsky (1978). He indicated that replacing traditional grain-oriented silicon steel by amorphous metal could save huge amounts of energy because of its low core losses. The project of realizing his idea was first carried out in the U.S.A., followed by Japan and some other countries. Test results showed a 70% reduction of core losses. Today, the largest market for amorphous metals being used in practice is for distribution transformers. The authors estimate that more than 300 000 amorphous-alloy–cored trans-

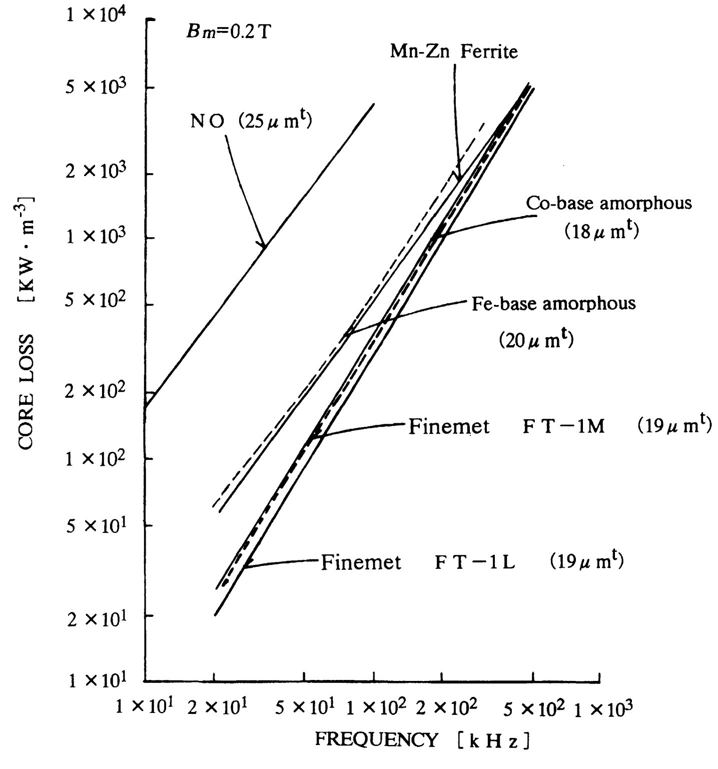

FIG. 34. Core losses of Finemet as a function of frequency compared with those of Co-based and Fe-based amorphous alloys and Mn–Zn ferrite.

formers had been built over the world by the end of 1994.

There have been two types of cores, wound cores and stacked cores, for power transformers. Wound cores, relatively small in size, are generally used for distribution transformers such as pole-mounted transformers.

Amorphous material is produced in ribbon form. Its thickness is about ten times thinner than that of silicon steel. Too thin materials are not beneficial in building stacked cores, and therefore wound cores are used in practice for amorphous-metal transformers. Wound cores are roughly classified into no-cut cores and cut cores. Figure 35 illustrates typical structures of the two types. No-cut cores are made up of continuous strips with no cut between each wrap, resulting in good magnetic performance. Hence, this type has been widely adopted for amorphous cores, which are sensitive to stress. In no-cut cores the coils are wound after fabrication, and thus a cruciform core cross section is more effective in increasing core space factor for the round coil window, but less advantageous in terms of cost because of the necessity of preparing core materials of various widths.

Cut cores have a joint for each turn, as is shown in Fig. 35(b). This makes it possible to insert core materials of identical widths into the rectangular window of the prefabricated coil, resulting in a larger coil-opening space factor and hence a smaller tank size. Almost all silicon-steel wound-core transformers are built of this type. However, there are considerable difficulties with thin and sometimes brittle materials such as amorphous metals. Cut cores are sometimes poorer in magnetic performance compared with no-cut cores for a given magnetic path length. But actual cores of rectangular shape have a shorter average length of core legs and thus result in core losses comparable to those of no-cut cores.

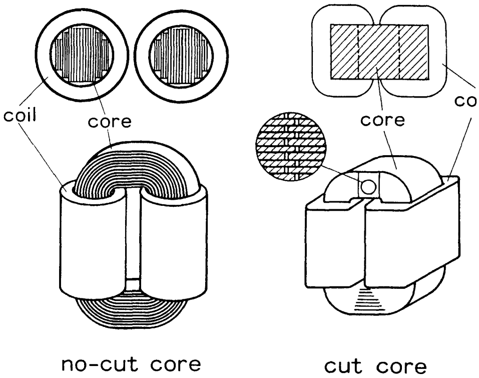

FIG. 35. Schematic illustrations of (a) no-cut core and (b) cut core.

In the first stage of commercialization, the no-cut type was adopted because of the ease of the core-winding process and good magnetic performance, but recently the proportion of cut cores is increasing. A number of evaluations of the magnetic performance have been conducted on commercial-size amorphous-metal distribution transformers. The results show that the core losses are 70% lower than for silicon-steel transformers, as expected, regardless of rated capacity. Also, the results of field tests indicate that amorphous-alloy transformers have a lifetime long enough for field service, as reported by Ng *et al.* (1991).

Attempts have also been made to apply amorphous materials to stacked-core transformers. The results showed as low core losses as for wound-core transformers. However, the thinness of amorphous material requires much more labor and time for cutting and stacking as compared with the use of silicon steel.

To improve core-processing efficiency, thick materials have been developed. One is a consolidated lamination of conventional ribbons, which has been patented by Kushnick *et al.* (1985). This material, commercialized under the trademark name Powercore, is 120–140 μm thick for 6–12 layers. Efforts have also been made to produce thick ribbon directly by rapid quenching. A new casting method proposed by Sato *et al.* (1989) uses a multiple-slotted nozzle as shown in Fig. 36. An increase in nozzle plurality enhances the

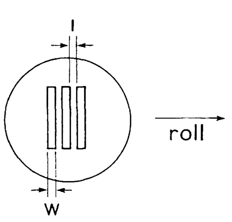

FIG. 36. Geometry of a multiple-slotted nozzle.

cooling ability substantially, and consequently ribbons thicker than 100 μm can be obtained in the amorphous state. Increasing the breadth of a slot in planar flow casting does not result in a significant increase in ribbon thickness, as reported by Fiedler *et al.* (1984).

Ribbons of 60 and 100 μm in thickness made using multislotted nozzles are as ductile as is needed to be wound without fracture around 2- and 10-mm-diam rods, respectively, as reported by Sato *et al.* (1989). The advantage of using thick ribbon is more prominent for stacked cores than for wound cores. The magnetic performance of wound cores tends to be degraded with increasing ribbon thickness, probably as a result of the incompleteness of stress relief by annealing. On the other hand, for stacked cores thick ribbon brings about good results. A 90° joint stacked core of 58-μm-thick ribbon exhibited core losses 30% less than one of 28 μm. Too thick ribbon, however, does not provide good performance, as reported by Sato *et al.* (1989). The core losses of a 92-μm ribbon core are approximately equal to those of a 28-μm ribbon core, and the exciting power of the former is considerably degraded. This is probably related to a difficulty in cutting ribbons due to the brittleness of thick ribbon. Uneven edges of cut thick ribbon would yield a large magnetic resistance at the corner joints.

3.2.2 High-Frequency Power Devices

3.2.2.1 Switching-Mode Power Supply. To miniaturize electronic devices and drive them efficiently, switched-mode power supplies are widely used today. Increasing switching frequency makes it possible to reduce the size of power supplies. In switched-mode power supplies, various kinds of magnetic components are mounted as shown in Fig. 37: common-mode chokes, normal-mode chokes, smoothing chokes, saturable reactors, and so on. These components can be further reduced in size with further increase in switching frequency. Thus the use of amorphous and nanocrystalline materials is particularly beneficial because of their excellent characteristics at high frequencies.

Most of the magnetic components used in switching power supplies can be replaced by components made with amorphous and nanocrystalline material. Co-based amorphous saturable reactors, used in magnetic-amplifier–type power supplies, contribute greatly to an increase in switching frequency because of their low core losses and the high squareness (ratio of remanence to saturation) of their *B-H* loops. Amorphous and nanocrystalline materials are commonly used today in power supplies operating at frequencies 200–500 kHz; the use of traditional Permalloy cores has been limited to below 50 kHz. Recently ribbons as thin as 5 μm have been produced by Yagi and Sawa (1990) using vacuum casting. Sawa *et al.* (1993) reported that a switching power supply using ultrathin material exhibited excellent performance for operation at 1.6 MHz.

Common-mode chokes are magnetic components to remove high-frequency noise from input current. Thus high initial permeability at high frequencies is needed for core material. Co-based amorphous and Fe-based nanocrystalline alloys are suitable for common-mode chokes because they exhibit the highest initial permeability. Common-mode chokes are often required to cut off impulse noise of high voltage. In this case, Fe-based amorphous alloys are used because of their relatively high saturation magnetization. The cores are annealed to round shape [cf. Fig. 32(b)] to obtain a low remanence. Furthermore, saturable reactors of Co-based amorphous alloys have been developed to absorb the surge voltages and spike-shaped current noise caused by recovery of diodes. The lead wire of a diode has only to be inserted into the window of a coil-free saturable core.

Amorphous alloys are also applied to

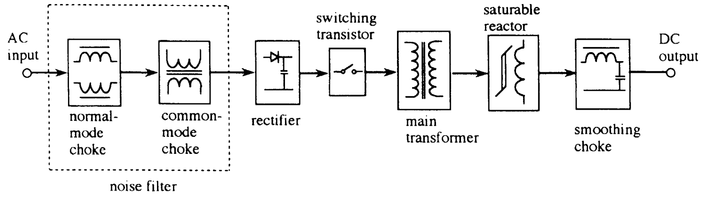

FIG. 37. Main components used in switched-mode power supply.

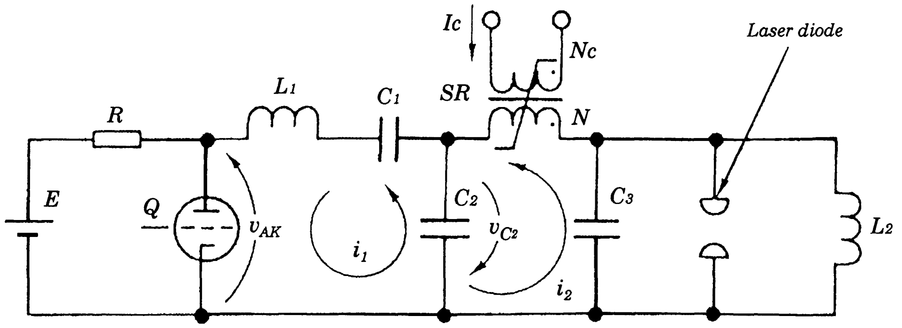

FIG. 38. Pulse generator using a magnetic pulse-compression circuit.

smoothing chokes to rectify ac current and remove ripples from dc current. To avoid the saturation of the cores due to biasing dc current, high saturation induction and a flat *B-H* loop are required for the cores. For this purpose, Fe-based amorphous-alloy cores are used in the form of cut cores, or they are annealed without the cutting process to a partially crystallized state.

3.2.2.2 High-Power Pulse Compressor. Pulsed high-power compressors are used as energy sources to drive pulsed lasers and linear accelerators. The characteristics of pulsed power required are short pulse length, large pulse peak height, high repetition frequency, and so on. For example, an excimer laser needs a pulse of several tens of kilovolts and of a repetition frequency of 500 Hz. In order to generate such sharp and high-power pulses, a pulse-compression circuit such as is shown in Fig. 38 is employed. In this circuit a saturable reactor plays a substantial role as a magnetic switch. After the main switch *Q* turns on, energy stored in the capacitor C_1 flows only into capacitor C_2 because the current flow to C_3 is blocked by the high permeability of a saturable core in unsaturated state. At the moment when the core is saturated, the current begins to flow out of C_2, and almost all of the stored energy is transferred to C_3 because the inductance L_1 is much higher than the inductance of the saturated core. The peak value of the current i_2 is enhanced to τ_1/τ_2 times the peak value of i_2, where τ_1 and τ_2 are the widths of pulse currents i_1 and i_2, respectively. A larger value of τ_1/τ_2 gives a higher pulse-compression ratio or gain, requiring a higher permeability of the saturable core in the unsaturated state. The wave forms of the current and voltage in a pulse-compression circuit are shown schematically in Fig. 39. The total

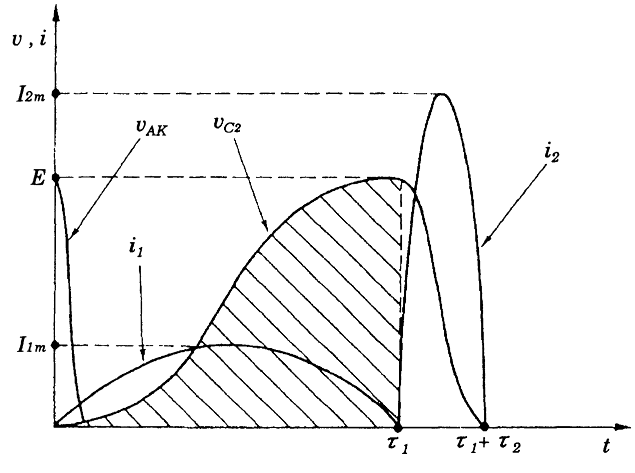

FIG. 39. Voltage and current wave forms in magnetic pulse-compression circuit.

compression ratio can be enhanced further by use of a series pulse-compression circuit.

The magnetic properties of materials required for the saturable core of a pulsed-power compressor are

1. large saturation induction,
2. low core losses,
3. large ratio of the permeability in the unsaturated state to that in the saturated state, and
4. large squareness of the *B-H* loop.

In view of these requirements, amorphous or nanocrystalline material can be favorably applied. The use of amorphous metals for magnetic pulse compression has been proposed by Birk *et al.* (1985). Nanocrystalline material is also a candidate. Nakajima *et al.* (1993) conducted a test for comparison between Fe-based and Co-based amorphous alloys and nanocrystalline material. The result showed a superior performance of nanocrystalline material (Finemet), which meets both requirements of downsizing and reducing core losses.

3.2.3 Sensors Amorphous metals have unique natures that are beneficial in sensor applications. For example, they have both high mechanical strength and soft magnetic properties. This nature is employed in magnetic heads requiring high wear resistance and high permeability. Amorphous metals also exhibit an extremely high electromechanical coupling factor. Thus transducers or sensors using amorphous material are expected to convert, effectively, mechanical quantities into electrical signals or vice versa. Actually, numerous sensor devices using amorphous metals have so far been proposed, and some of them have already been commercialized. Amorphous sensors can be classified into two categories according to the magnitude of the magnetostriction of the materials used. For low magnetostriction and high magnetostriction, Co-based and Fe-based alloys, respectively, are available. High magnetostriction generally causes a high electromechanical coupling factor; low magnetostriction yields a large inductive effect due to high permeability.

The magnetomechanical or magnetoelastic effect is a reflection of stress-sensitive magnetic properties arising from the large magnetostriction, which is favorably applied to mechanical stress or strain measurement.

Amorphous magnetic wires made by water quenching (Ohnaka *et al.,* 1982) have very unique properties as sensor materials, as has been reported by Mohri *et al.* (1992). This is attributed to their characteristic domain structure. Figure 40 illustrates a model proposed by Humphrey *et al.* (1987) for the domain structures of as-cast amorphous wires. Figure 40(a) shows the domain structure of a positive-magnetostriction wire such as Fe–Si–B alloys, and Fig. 40(b) that of a negative-magnetostriction wire such as Co–Si–B alloys. The outer shell of the positive-magnetostriction wire is composed of domains magnetized perpendicularly to the wire surface, while that of the negative-magnetostriction wire is magnetized in the circumferential direction. These domain structures are considered to result from peculiar quenched-in stresses that are compressive for the outer region and tensile for the inner region.

The inner-core domain structure is stable in the absence of domain walls. As soon as a reverse domain is nucleated at one end of a wire by application of a magnetic field in the direction opposite to that of the magnetization of the inner core, the domain wall propagates very fast in the direction of the field and is eliminated at the other end. The reason is that the state of the absence of a domain wall is the lowest in magnetostatic energy. This bistable flux reversal generates a sharp voltage pulse in a coil wound around

the wire, which is known as a large Barkhausen effect. The large Barkhausen effect is used to detect a magnetic field with high sensitivity.

On the other hand, a negative-magnetostriction wire generates a voltage between its longitudinal ends when a magnetic field is applied perpendicular to the wire length. This voltage is induced by a flux change due to circumferential domains. This effect, called the Matteucci effect, is also applied to sensing a magnetic field at high sensitivity.

Examples of amorphous sensors are listed in Table 6. The numbered items in the table are described below in more detail. They are already used in practice, or are on the way to practical use.

3.2.3.1 High-Permeability. A-1. Magnetic recording head: Magnetic heads for audio and video devices were the first application of the high permeability of zero-magnetostrictive amorphous alloys. Cores were made by an etching process. Nowadays, the amorphous material for heads is shifting from ribbon to thin film prepared by a sputtering process (see SPUTTERING).

A-2. Current sensor: A current sensor using amorphous metal wire has been reported by Kashiwagi *et al.* (1991), whose circuit is shown in Fig. 41. Two amorphous-wire cores in a multivibrator bridge detect a field around a conductor bar and measure several hundreds of ac amperes. The sensibility of detecting a field and its range can be controlled by changing the length of the amorphous-wire cores. The detectable range is within ±300 A at 0–2 kHz, which is applicable to vector control for invertor-excited induction motors (see MACHINES, ELECTRICAL).

A-3. Magnetic-field sensor: Figure 42(a)

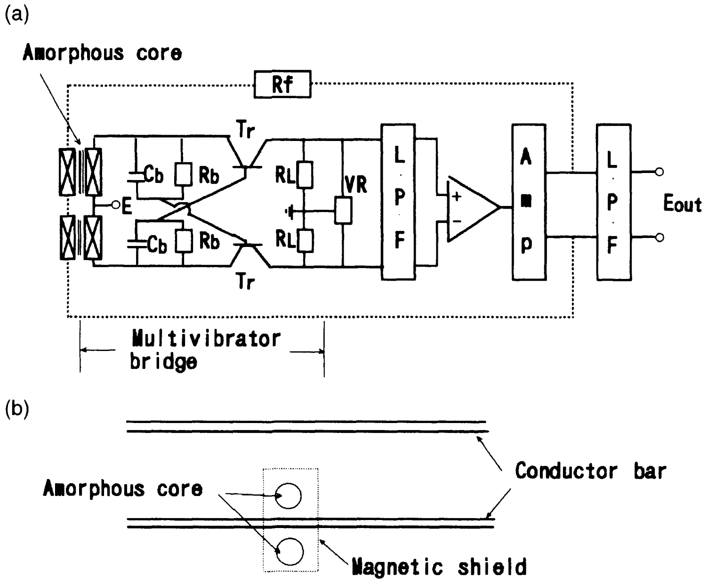

FIG. 41. (a) Current sensor composed of multivibrator bridge circuit and feedback circuit and (b) arrangement of amorphous core. RL, dummy resistance; LPF, low-pass filter; Tr, transistor; AMP, amplifier.

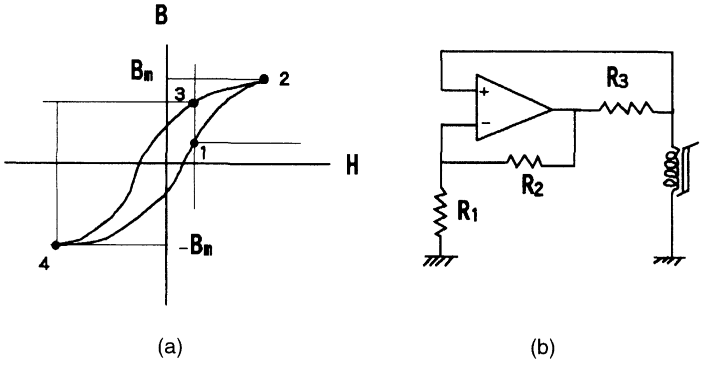

(a) (b)

FIG. 42. (a) Magnetization curve of an amorphous-ribbon core used for magnetic-field sensor, and (b) fundamental circuit for the field sensor.

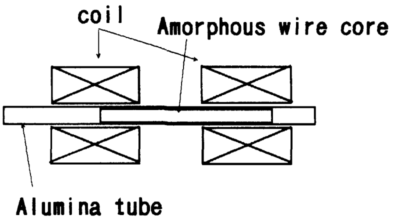

FIG. 43. Main portion of displacement-sensor head.

shows the magnetization curve of an amorphous-ribbon core. When an external field exists, the initial position for excitation corresponds to point 1 on the hysteresis loop. The difference ΔB_1 between $+B_2$ and B_1 is smaller than ΔB_2 between B_4 and B_3. A circuit to detect the field, shown in Fig. 42(b), checks the difference in exciting time between ΔB_1 and ΔB_2, obtained in practice by the integrated output voltage, and measures the strength and the direction of the field. This type of field sensor was presented by Takeuchi *et al.* (1990), providing the detection range (dc) of 0 to ±100 μT.

A-4. Displacement sensor: Mutual displacement of an amorphous core made from Co-based wire and two detection coils generates an inductance change depending on the position of the core, as shown in Fig. 43 (Yabe and Oono, 1988). The induction change of the two coils can detect the displacement. A multivibrator circuit for excitation at 0.5–30 kHz is used. The measuring range is ±(2–5) mm, and the accuracy is 0.5%.

3.2.3.2 Magnetomechanical Effect. B-1. Torque sensor: A torque sensor of high sensitivity and noncontact detection employing Fe-based amorphous ribbons has been developed by Hase and Wakamiya (1988). The sensor is used to measure the torque of a shaft in a screwdriver system. Fe-based amorphous strips are glued onto the surface of a shaft in a chevron pattern as shown in Fig. 44. The detectable torque ranges from +20 to −20 kgf-m with an accuracy of ±2.5% full scale.

When a torque is introduced on the shaft, tensile and compressive stresses of $\pm\sigma$ in the direction of ±45° relative to the axis are induced, where the stress σ is $16T/\pi d^3$ (T is torque; d is diameter), and the strain ϵ is σ(1

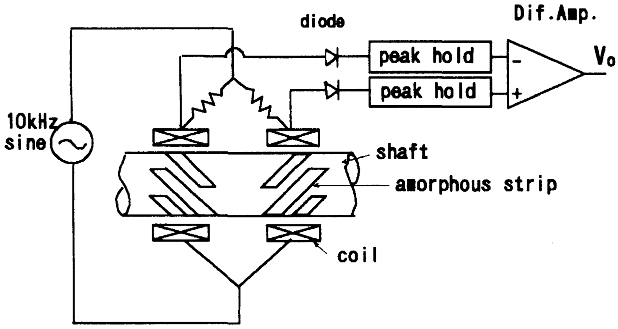

FIG. 44. Structure and electric circuit of torque sensor.

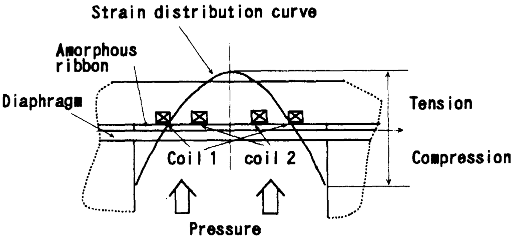

FIG. 45. Pressure sensor using amorphous ribbon fixed on a diaphragm, and schematic strain-distribution curve.

+ $\nu)/E$ (ν is Poisson's ratio; E is Young's modulus). Accordingly, the permeability of the strips changes in opposite senses and the value of an applied torque can be obtained by detecting the output voltage V_0, which corresponds to the difference in the end voltages of the elements.

To glue amorphous ribbons firmly on a shaft, glazing and laser treatment of Fe-based amorphous strips have been proposed by Hirose *et al.* (1994).

B-2. Pressure sensor: An oil-pressure sensor for automotive hydraulic control systems has been developed by Fukumaru *et al.* (1992). An amorphous strip is fixed on a diaphragm as shown in Fig. 45, where a curve of the strain distribution induced in the strip by oil pressure is also illustrated as tension and compression. The induced strain changes the permeability of the strip. In Fig. 45, coil 1 is set at the neutral position of the strain curve, and coil 2 is set at the position of tension. As shown in Fig. 46, a linear self-inductance change of coil 2 was obtained for pressures of 0 to 3 MPa. The voltage difference ΔV between coils 1 and 2 determines the magnitude of the strain, where the output of coil 1 is constant. The detectable pressure is 0–3 MPa, and the sensor output change is $\pm 3\%$ at 3 MPa at a temperature of -40 to $+120$ °C.

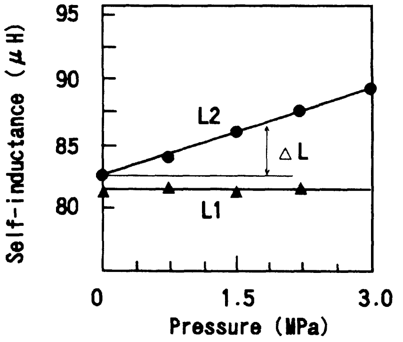

FIG. 46. Self-inductance changes of coils 1 and 2 placed at positions shown in Fig. 45 as a function of pressure.

A biomedical monitoring system as another application of a magnetostrictive sensor has been reported by Klinger *et al.* (1992).

B-3. Distance sensor: A distance sensor using an Fe-based amorphous-alloy ribbon as a magnetostrictive delay line was reported by Arai *et al.* (1976). The giant electromechanical coupling characteristics of Fe-based amorphous alloys are employed. An acoustic pulse generated by an exciting coil propagates along an amorphous ribbon as shown in Fig. 47. The magnetostrictive wave speed is 4–5 km/s, and a detection coil wound along the ribbon generates a pulse voltage in a position where a local field is applied by a magnet. The position is determined by the delay time measured from the time when the acoustic pulse is excited. The propagation speed of the pulse is too fast to control the sensitivity enough and to remove reflected waves. Instead, the use of domain-wall motion has been proposed by Uchiyama *et al.* (1989). The speed of domain-wall motion is an order of magnitude lower than that of the magnetostrictive wave, and also the reflection problem can be avoided.

3.2.3.3 Large Barkhausen Effect and Matteucci Effect. C-1. Revolution-counter sensor: A revolution-counter sensor using amorphous metals has been developed by Ogasawara (1987), who applied the large Barkhausen effect of Fe-based amorphous wires. An amorphous-wire core detects the field of a code disk with magnets embedded as shown in Fig. 48. The stable and sharp

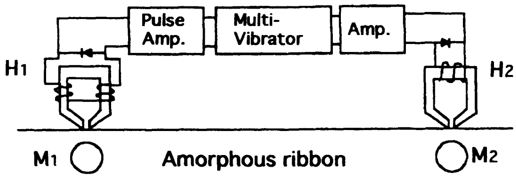

FIG. 47. Schematic setup of magnetostriction delay sensor. H_1, head for generating a supersonic wave; H_2, sensing head; M_1 and M_2, bias magnets.

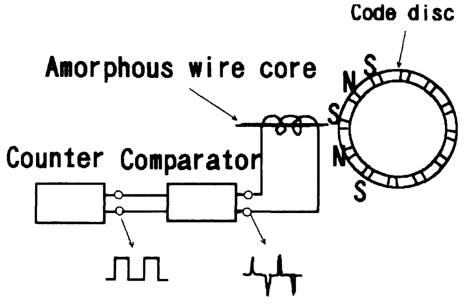

FIG. 48. Revolution-counter sensor using amorphous-wire core. Pulsed voltages are generated according to change in the sign of magnetic poles due to the revolution of code disk.

pulses induced by the field of the small magnet detect the angle of revolution. A rotary encoder with eight cores for an eight-channel code disk has been realized with a resolving power of 512 pulses (9 bits) per revolution, and maximum frequency of 10 kHz (900 rpm). The angle error is within ±1°.

C-2. Field sensor using magnetoinductive element: The magnetoinductive element (MI element) is an application of the Matteucci effect using amorphous wire. A circumferential flux change in an amorphous wire induces an ac voltage e_L between the two ends of the wire, when a high-frequency current I_w is applied to the wire with slightly negative magnetostriction, the magnetic domains of which are shown in Fig. 49 (Kawashima *et al.*, 1993). The voltage e_L is given by

$$e_L = \frac{d\phi}{dt} = \frac{1}{4\pi} l\mu_\theta(\omega,B_m)\frac{dI_w}{dt},$$

where l is the wire length and μ_θ is the permeability. If an external field H_{ex} is applied parallel to the longitudinal direction of the wire, the magnetization rotates to the axial direction and the amplitude $|e_L|$ of e_L is reduced by the reduction of the circumferential flux component as shown in Fig. 49. In Fig. 50, the normalized $|e_L|/e_L(H_{ex} = 0)$ is shown. Thus the MI element can detect a field.

The characteristics of the MI element are that

1. it is a simple device (no exciting coil),
2. it yields a large impedance change (50% for several gauss),
3. it has high sensitivity (10^{-5}–10^{-6} G with a 200-MHz multivibrator), and
4. it has high directivity.

Applications to data tablets and magnetic-head detecting fields are being developed.

C-3. Security sensor: When an amorphous wire is excited in an ac field of over 0.1 Oe, a high-harmonic voltage is generated by the Barkhausen effect. By use of this principle, goods with an amorphous wire attached can be detected when they pass through a gate installed with this sensing system. This system is put into practice in shopping centers and libraries.

3.2.4 Magnetic Shielding Amorphous ribbons that exhibit high permeability are suitable for magnetic shielding. Magnetic shields using amorphous alloys were first made by weaving narrow as-cast ribbons (Mendelsohn *et al.*, 1976). Shielding ratios obtained with these woven shields were comparable to those of Permalloy 80Ni–20Fe. The amorphous shielding has the additional advantages of being flexible and less sensitive to mechanical strain. Other applications of amorphous wires or ribbons that are woven into braids for a conductive shield are reported by Dismukes and Sellers (1978).

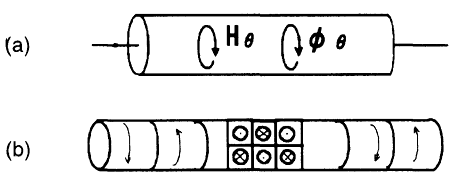

FIG. 49. (a) Circumferential magnetic field H_θ induced by the current flowing through the length of amorphous wire; (b) domain-structure model for tension-annealed amorphous wire.

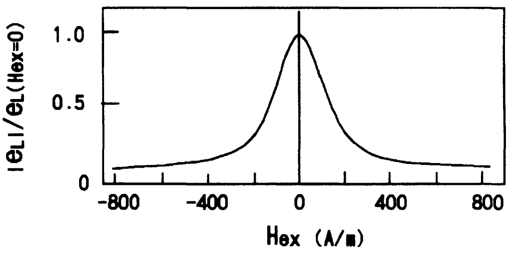

FIG. 50. Normalized inductive voltage due to circumferential flux change as a function of external field.

Shields using amorphous flakes produced by the cavitation method are reported by Ishii and Kaneko (1987). They randomly distributed and laminated as-cast amorphous fibers between two sheets of polyester films. But these two examples are inferior in performance because of the presence of numerous air gaps, which degrade the effective permeability and thus the shielding factor.

3.2.4.1 Cable and Gauge Shieldings. Co-based amorphous ribbon is wound helically around a cable to shield against magnetic-field leakage from the cable. A second layer wound in a counter sense is added to improve the shielding efficiency. It is reported by Hilzinger (1985) that a shielding factor $S = 100$ is obtained for fields up to 10 A/cm at 60 Hz.

Automobile gauge shielding using amorphous ribbon has been developed by Ichimura *et al.* (1991). As-cast Fe-based amorphous ribbon wound in a toroid is set inside the gauge case, instead of a drawn cup case made of Permalloy.

3.2.4.2 Composite Shielding Panel. A large-scale cylindrical magnetic-shielding case has been fabricated by Sasada and Oonaka (1994). This is a composite of amorphous alloy and Permalloy with a shaking system. Magnetic shaking refers to the application of an alternating magnetic field to a shielding material to keep the magnetic domain walls in vibrating motion (Bozorth, 1951). Co-based amorphous ribbons are spirally wound in 16 layers on the outer surface of a cylindrical Permalloy tube, as shown in Fig. 51. A toroidal coil wound around the amorphous layers and a meander coil arranged between the amorphous layers generate an ac magnetic-shaking field to enhance shielding effects. The typical effects of a biased shaking field are that the hysteresis curve narrows and its slope increases. Use of the system described provides an extremely low-field environment needed for SQUID (superconducting quantum interference device) measurements.

Another composite material, composed of amorphous metal and silicon steel, has been developed by Okazaki and Mogi (1994). Fe-based amorphous ribbons, annealed with no field, and silicon-steel sheets are stacked into a panel. If a shaking field is applied, this panel exhibits a remarkably large shielding factor of $S > 400$, as shown in Fig. 52. Okazaki and Ueno (1992) showed that such large shielding factors result from a combination of the circular magnetic domains of the amorphous ribbon used and ac magnetic shaking.

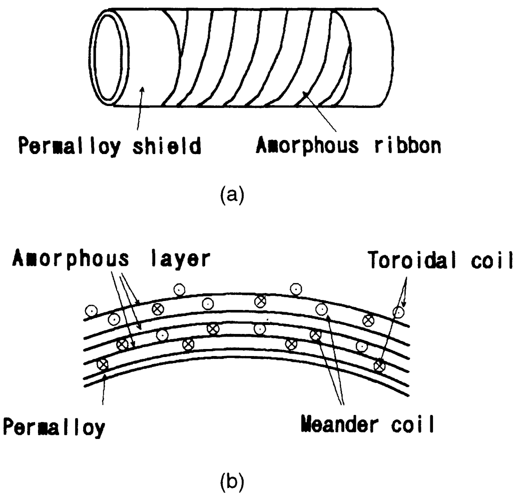

FIG. 51. (a) Schematic view of the cylindrical magnetic shield and (b) close-up view of the part of the cross section.

3.2.5 Magnetic Separation When a narrow soft-magnetic wire is placed in a magnetic field, a high magnetic-field gradient

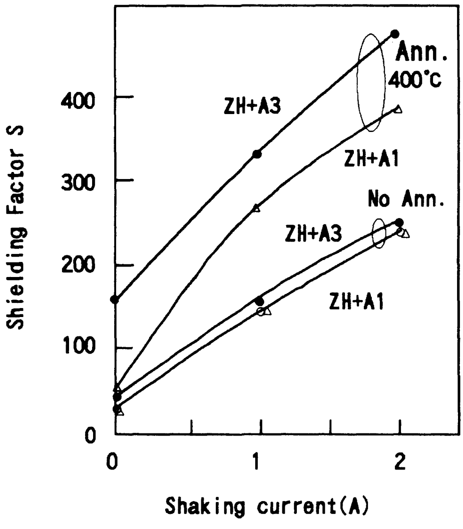

FIG. 52. Shaking effect on the shielding factor of silicon-steel sheets (ZH), with two Fe-based amorphous sheets (ZH + A1) and six amorphous sheets (ZH + A3). The effect of annealing also is shown.

is generated at the surface of the wire. Because a magnetic wire attracts magnetic particles strongly at the region of high gradient, this principle is applied to the filtration of magnetic contaminants from fluids. As a filter element, narrow amorphous-alloy ribbons are favorable for use. The reason is that amorphous ribbons have good corrosion-resistant and mechanical properties, together with soft-magnetic properties. The high corrosion resistance allows amorphous ribbons to be used in various kinds of fluids, and the high tensile strength and elasticity endure the pressure of the fluids. Additionally, a ribbon yields a much stronger attractive force at the edges than a round wire, as a result of the greater curvature and much smaller demagnetization coefficient across the fiber axis and parallel to the plane. It is reported by Kurahashi *et al.* (1990) that magnetic separation systems using amorphous-metal fibers have been put into practice to recycle hydraulic fluids and process fluids in the steel industry. They facilitate washing processing for removing magnetic particles by developing a rotary-type system. The use of amorphous magnetic filters greatly improves the efficiency of removing iron particles from skin-pass rolling oils, as shown in Fig. 53. Similar systems are also used as cleaners of pressing lubricants in the automobile industry.

3.2.6 Medical Uses

3.2.6.1 Intratissue Hyperthermia. For intratissue hyperthermia, which is expected to be one of the cancer therapies to heat tumors effectively (Dewey *et al.*, 1977), temperature-sensitive amorphous magnetic flakes coated with anticancer agents in capsules have been under development. Since the temperature rise of amorphous flakes is limited by the Curie temperature of the flakes, the maximum temperature can be controlled automatically when they are excited by an alternating magnetic field. Matsuki *et al.* (1994a) found that the maximum temperature also depends on the mean length of the flakes. Figure 54 shows their result that the maximum temperature for the $Fe_{66}P_{13}C_7Cr_{14}$ alloy with a saturation flux density of 0.44 T changes from 51 to 47.5 °C with an increase in the mean length of the flakes.

3.2.6.2 Energy-Transferring Coils for Totally Implantable Devices. A flexible transformer consisting of a pair of coils incorporating copper and amorphous magnetic fibers has been presented by Matsuki *et al.* (1994b) for such devices as an electrically driven artificial heart. Co-based amorphous fibers are wound radially on spiral copper coils as shown in Fig. 55. One of the coils is implanted in the body and receives energy at a position *g* apart from the other. Earlier work based on the same concept was reported by Smith *et al.* (1987).

3.3 Final Comments

The magnetic properties and applications of amorphous metals are outlined. Their unique natures resulting from the random

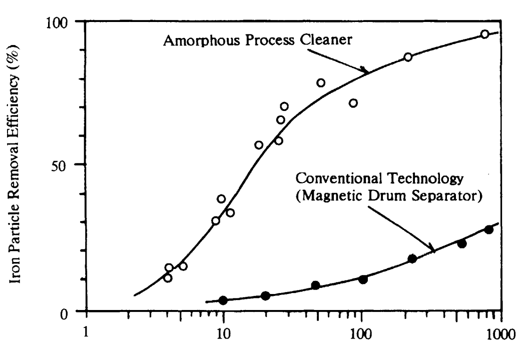

FIG. 53. The efficiency of removing iron particles from a fluid for the amorphous magnetic filter, compared with that of the conventional magnetic drum separator.

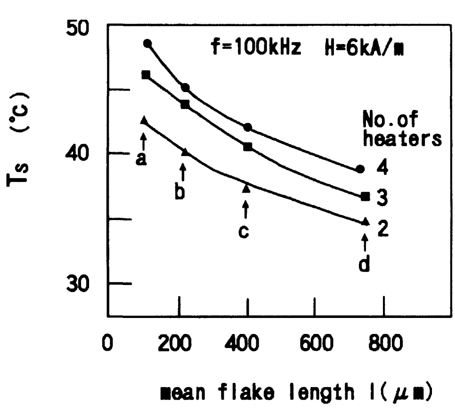

FIG. 54. Maximal temperature T_s as a function of mean flake length. T_c (°C): a = 51.0, b = 49.5, c = 48.0, d = 47.5. (Heaters filled with amorphous flakes were immersed in agar phantom.)

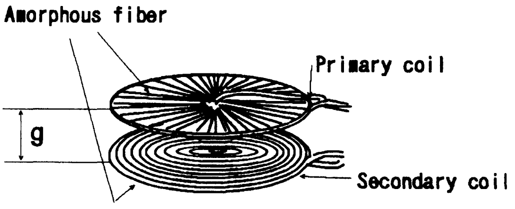

FIG. 55. A pair of transmitting coils with amorphous fibers.

atomic arrangement have been shown to be effectively used in various applications. Nevertheless, further improvements are needed for expanding the application fields drastically. One requirement is to produce thick sheets. Thick materials enable amorphous material to be applied to power transformers of stacked-core type and to motors. Though thick ribbons are made on a laboratory scale, they are not available commercially. Another requirement is to improve the workability of amorphous metals. The brittleness of amorphous metals, which increases with increase in ribbon thickness, may be the biggest problem to restrict the practice of amorphous metals. If heavy working such as deep drawing is possible at room temperature or a little higher, amorphous metals can also be used as structural materials with high corrosion resistance, bringing about a huge market. Readers who want to know about the mechanical and chemical properties of amorphous metals are referred to the book edited by Liebermann (1993) listed under Further Reading.

GLOSSARY

Amorphous Material: A material lacking the long-range order of a crystalline material. Includes noncrystalline, glassy, or disordered material.

Amorphous Si Solar Cell: Solar cell with *i*-type *a*-Si (and/or with Ge and C):H; the semiconductor provides optical absorption, electron–hole pair creation, and electron and hole separation layers.

Avalanche-Multiplication Effect: The phenomenon in which an electron or hole accelerated by an electric field creates an electron and/or hole by collision, which is accelerated and again creates an electron and/or hole, producing a cascade multiplication. The initial electron or hole can be produced by photon absorption, by injection from an electrode through a barrier, etc.

Boltzmann Distribution: A function giving the probability distribution of generalized position and momentum coordinates for a molecule of a gas in thermal equilibrium obeying classical mechanics.

Carrier Mobility: Carrier velocity under unit electric-field strength.

CCD: Charge-coupled device.

Chalcogen: Element from group VI of the periodic table (especially S, Se, Te).

Chalcogenide: Chemical compound containing an element, other than oxygen, from column VI of the periodic table (S, Se, Te).

CVD: Chemical vapor deposition.

Dangling Bond: The nonbonding state of a valence electron that usually forms a chemical bonding state in the covalently bonded crystalline material. Localized states induced by dangling bonds prevent the *p*- or *n*-type control of the material.

Dark Conductivity: Conductivity in the absence of incident light.

Electrochromic: Changeable in color when injected with positive or negative charges.

Electroluminescence: The emission of light resulting from application of an electric field to a material.

Faraday Rotation: Rotation of polarization of a beam of linearly polarized light when it passes through a transparent material in the direction of an applied magnetic field.

Gap States: States distributed in an energy gap. Gap states consist of localized states and tail states.

GRIN Lens: Graded refractive-index lens, consisting of a rod with a refractive index that has its maximum value on the axis, decreasing approximately as the square of the distance from the axis.

Halide: Compound material containing a halogen.

Halogen: Element from group VII of the periodic table (i.e., F, Cl, Br, I, At).

Harmonic: A sinusoidal component of a periodic wave, having a frequency that is an integral multiple of the fundamental frequency.

Hydrogenated Amorphous Silicon (*a*-Si:H): Amorphous silicon alloyed with hydrogen. Nominal hydrogen content ranges between 1 and 30 at.%. Typically, *a*-Si:H is prepared by glow-discharge decomposition of monosilane (SiH_4).

Image Pickup Tube: A vacuum tube in which a two-dimensional input image is converted into a one-dimensional electric signal over time by electron-beam scanning. An example is Vidicon-type operation.

IR Spectroscopy: Infrared spectroscopy. IR absorption and emission spectroscopy gives information on vibrational spectra of chemically bonded atoms and/or molecules.

ITO: Indium tin oxide.

Laser-Beam Printer: Carlson-process printer using a laser-beam–scanned image.

LCD: Liquid-crystal display.

Light-Induced Structural Change: Structural change in an amorphous material induced by light; this takes place more easily than in a crystal because of the nonequilibrium metastable nature of the amorphous material. In the case of *a*-Si:H, it is called the Staebler–Wronski effect.

Molecular Dynamics: A method for the simulation of the structure and/or motion of a collection of atoms by following the time evolution of the classical motion under a particular interaction potential.

Optical Bistability: The property of a substance or device that has two stable states of transmission, high and low, for a single input light intensity.

Organometallic Compound: A compound containing an alkyl or aryl radical bonded to a metal.

Passivation of a Dangling Bond: Termination of a dangling bond by an appropriate element or chemical fragment. Localized states induced by the dangling bond in the electronic gap are effectively eliminated.

Phase Separation: Separation of a two-component or multicomponent melt into two liquid phases differing markedly in composition from each other, resulting from immiscibility within certain ranges of composition and temperature.

Photochromism: Change in color when exposed to visible or near-visible light, and restoration in the dark.

Photoconductivity: Conductivity resulting from light irradiation. The light-irradiation condition should be specified.

Photoreceptor: A main part of the Carlson-process printer. The input image is converted into an electric-charge image on the photoreceptor surface, where it is held for a certain time (0.1–100 s).

Photovoltaic Effect: Photoinduced electromotive force in a heterogeneous structure involving a semiconductor, such as a *p-n* junction or a metal–semiconductor junction. An absorbed photon creates an electron–hole pair, and an internal electric field formed by the heterogeneous structure separates the electron and hole.

Quantum Efficiency: The ratio of the number of output quanta to the number of input quanta.

Random Network: The amorphous structure of atoms bonded into a network that shows no order beyond a few atomic dimensions.

SAXS: Small-angle x-ray scattering. Used mainly to characterize medium-range structures.

Tetrahedrally Coordinated Material: Covalently bonded material with sp^3 hybridized orbitals, such as Si, Ge, diamond, and gray tin.

Van Hove Singularity: Singular point in the energy–momentum dispersion curve. The phase velocity vanishes at the singular point.

Vitrification: Formation of a glassy or noncrystalline material.

INTRODUCTION

It is the goal of artificial limb replacement to restore as much of the function and appearance lost through amputation as possible. This having been said, it should be noted that the history of the development of this field was tied to developments in amputation surgery. In turn, the development of amputation surgery was to a large extent dominated by the ebb and flow of human warfare.

Artificial limb replacements in the form of peglegs date from antiquity. In the middle ages, armorers made artificial limbs to hide amputations incurred by their knight masters in battle. However, it was not until the late nineteenth century that the enterprise of artificial limb replacement flourished. During that period mortality from amputation was greatly reduced by the advent of aseptic surgical techniques and the use of anesthesia. This was particularly true during and following the American Civil War. In the United States, the *modern era* of prosthetics can be dated from 1945—the end of World War II—with the founding of the Committee on Artificial Limbs of the National Research Council.

The field of artificial limb replacements can be broadly divided into the areas of the upper limb and lower limb. The area of upper-limb prosthetics is dominated by considerations of prosthesis control and power, while the area of lower-limb prosthetics is dominated by considerations of passive mechanisms, material properties, and limb–prosthesis fit and alignment. For further reading on the history of artificial limb replacement or prosthetics the reader is referred to American Academy of Orthopaedic Surgeons (1960).

1. DESIRABLE ATTRIBUTES FOR PROSTHESIS CONTROL

The level of amputation is an important element in the restoration of functional control over a prosthesis. *The level of amputation is inversely proportional to the number of control sources available from the person, but the number of control sources needed is directly proportional to the level of amputation.* That is, the higher the level of amputation the fewer the available control sources but the greater the amount of function that must be replaced. A control source is the means used by the amputee to control a specific function or degree of freedom of the prosthesis—e.g., opening and closing of an artificial hand. Childress (1992) presented the following attributes of prosthesis control as desirable. While some of these attributes may be difficult, if not impossible, to achieve in practice, they are seen as desirable goals.

1. Low mental loading or subconscious control. This means that the prosthesis can be used without undue mental involvement. Successful control systems enable the users to use their artificial limbs almost subconsciously, the way we use our own limbs. In other words, the prosthesis should serve the user; the user should not be the servant of the prosthesis. This kind of control may require physiologically appropriate proprioceptive and sensory feedback in order to be achieved.
2. User friendly or simple to learn to use. This implies that the use of a prosthetic device should be intuitive and natural. The amputee should be able to learn to use the prosthesis quickly and easily.
3. Independence in multifunctional control. Control of any function, or degree of freedom, should be able to be executed without activating or interfering with the other control functions of a multifunctional prosthesis. For example, a person with prostheses on both arms should be able to use each arm independently. Operation of one prosthesis should not activate the prosthesis on the other side.
4. Simultaneous, coordinated control of multiple functions (parallel control). This is the ability to coordinate multiple functions simultaneously in effective and meaningful ways without violating the first and third attributes.
5. Direct access and instantaneous response (speed of response). All functions should, if possible, be directly accessible to the user and without time delay. Prosthetic systems should respond immediately to inputs.
6. No sacrifice of human functional ability. The control system should not encumber any natural movement that an amputee can apply to useful purposes. In general it is not wise to sacrifice a useful body action for the control of a prosthesis. The prosthesis should be used to supplement, not subtract from, available function.
7. Natural appearance. If possible, the control system should be operated in ways that are aesthetically attractive. Likewise, the mechanical response should be graceful. Control techniques that allow aesthetically pleasing action (e.g., smooth, flowing, graceful movement) are important to the dynamic appearance (dynamic cosmesis) of the prosthesis just as is static appearance (static cosmesis) in the form of shape and color. Movements that appear mechanical in nature attract unwanted attention in social situations and may not be pleasing to the eye.

2. UPPER-LIMB PROSTHESES

The task of replacing a lost hand or arm is a daunting one. There are 33 muscles acting on the hand. There are 18 intrinsic muscles and 15 extrinsic muscles controlling hand function. The human hand has 27 major bones, and over 20 joint articulations with 27 or more degrees of freedom. The arm contributes another seven degrees of freedom. Even if the hand is replaced with a simple single–degree-of-freedom gripper, as is usually the case, this still remains an extremely challenging control problem. Robotic hands that mimic the operation of the human hand have been built—for example, the M.I.T./Utah dexterous hand of Animate Systems Inc., Utah (Jacobsen *et al.*, 1982). However, the actuators and computer system required to control this hand occupy a space equal to that occupied by two small filing cabinets, and power is supplied externally from electrical mains. Thus, weight, size, and power considerations preclude the use of robotic devices, like the dexterous hand, in prosthetics applications.

The primary role of the human arm is to position the hand in space. The control of the arm is directed at controlling the position of the hand. Even though humans control their arms with what appears to be great simplicity, this is a highly complex and demanding task. Consider the example of the backhoe operator. The backhoe is essentially a mechanical arm that is under the control of the operator. When working this mechanical arm the operator uses both arms to pull levers, both feet to press pedals to operate the arm, and both eyes to monitor the task being performed by the digger. All this attention is needed, just to control a single mechanical arm! Now consider the plight of a person who has lost both of his or her arms at a high level (e.g., above the elbow) and one begins to have some appreciation of the task a limbless person faces in controlling an artificial (prosthetic) arm or arms. The problem of providing persons with artificial arms that are anywhere near as functional as the arms that were lost has been called one of the most challenging problems of medical engineering.

The famous physiologist Nikolai Bernstein (1967) observed that a blacksmith can precisely hit the same point on an anvil with a hammer time after time, but that the joint angles of his arm varied somewhat for each swing. This example highlights a problem that exists in deciphering how humans control motion. The position of the joints and their angles do not really matter as long as the hammer strikes its target. There is massive redundancy, in terms of degrees of freedom, in the human arm and torso. Small changes in posture are accommodated by changes in other joints such that the hand/tool still ends up on target. A robot doing the same task would travel in exactly the same, rigidly defined, trajectory each time. Robot arms generally have six degrees of freedom. This is the minimum required to specify both orientation and position of a point in space. The human arm and trunk, on the other hand, have in excess of thirty-four degrees of freedom to specify the same point.

The problem of the lack of specification of joint angles is known as Bernstein's redundancy problem and arises as a result of how the brain controls a motion. In Bernstein's opinion "... the structure of the central complex which governs the production of a given series of movements is much more closely related to spatial form than to muscle scheme ..."; or, to rephrase: The human control of movement appears concerned with spatial position rather than with control of a particular set of muscles.

In addition to this lack of specificity, the human arm is compliant (springlike); it has "give." When the hammer of the blacksmith strikes the surface of the anvil, the arm "gives" to absorb the shock and prevent damage to the joints. This "give" or compliance also stops the arm of the blacksmith from going into oscillation or instability upon contact (contact instability) with the anvil. The problem of contact instability is frequently encountered by robotic arms, unless the robot, the environment, and the nature of the interaction between the two (e.g., hammering the anvil) are precisely mathematically and mechanically defined. Contact instabilities can occur if this mathematical definition of the problem is even slightly off. The human arm does not have this problem because of its inherent compliance. This compliance is not a fixed quantity but can be varied depending on the task requirements: a stiff arm for bracing oneself against an expected blow, a relaxed arm for playing the piano. This change in arm compliance is achieved by the cocontraction of agonist/antagonist muscle pairs (simultaneous contraction of opposing muscle groups) that in turn varies joint impedance (stiffness). Considerable effort has gone into designing this type of compliance into robot arms and manipulators. In the field of prosthetics, Hogan (1982) developed impedance control for a prosthetic elbow. Human motor function, robot function, and prosthesis function would seem to have much in common; nevertheless, their different substrates and different constraints have so far limited the degree to which exchange of knowledge between these fields has been useful.

2.1 Design Constraints (Why Human, Prosthetic, and Robotic Arms Have So Little in Common)

Robotics concepts have had little impact on commercial prosthetics because of the severe physical constraints required for a prosthetic device to be successful. In any prosthetic device, size, weight, and power are all at a premium, far more so than in the related fields of robot or manipulator design. Limb replacements, it is thought, should be anthropomorphic (of human form) in general shape, size, and outline. Anthropomorphic does not necessarily imply that the artificial limb look exactly like its human counterpart, but it does mean that any replacement should have similar kinematics and kinetics, i.e., there should be a joint that operates (moves) like an elbow joint where one would expect to see an elbow joint, and the various limb segments should be of a size consistent with a normal human being. In remote manipulation a robot arm or manipulator is under the control of an operator who may be physically separated from the robot arm by a large distance, such as in space-based systems where a robot arm in space may be controlled by an operator located on earth. In such systems, a slave arm (the remote robot arm) is controlled by a master arm that is worn by the operator. This use of master–slave arms has led to the use of an anthropomorphic design for the general-purpose manipulator (see Fig. 1). The amount of mental effort that must be exerted (mental loading) is reduced if the slave arm is kinematically similar to the master arm. The master arm in turn is usually fitted to the operator's own arm to make the control more intuitive and subconscious.

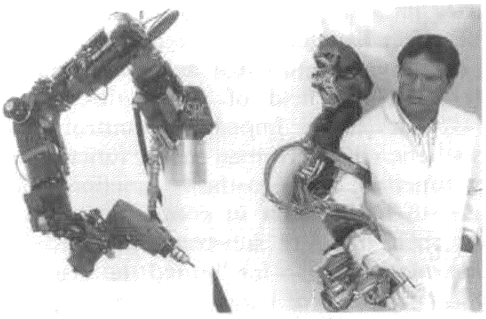

FIG. 1. Picture of an operator in the SARCOS dexterous, master–slave, force-reflecting teleoperator. The operator "wears" a master arm to control a remote slave arm. Consequently an anthropomorphic shape for both arms eases the mental control burden placed on the operator. Forces experienced by the slave are reflected back to the master and experienced by the operator. (Photograph courtesy of SARCOS Research Corporation, Utah, UT.)

It is important to realize that *people see what they expect to see,* so that if a person with an artificial limb replacement looks and moves in an expected manner the fact of the artificial limb will pass unnoticed to the casual observer. Often the terminal device, the hand replacement, will look only generally like a natural hand but because it is moved about in a natural-looking manner it will go undetected until closely scrutinized. This property is referred to as dynamic cosmesis. Static cosmesis is achieved when the device also looks like the limb it is replacing. Although a device might be statically "correct" in appearance it can look "wrong" or lifeless if it does not also have dynamic cosmesis.

The issue of weight is also very important to the success of any prosthetic limb. Contrary to what one might think, an artificial limb should usually be lighter than the limb it replaces. Arm replacements need to be as light as possible or else they may be rejected by the users. To be effective, artificial arms need to be worn by the user for periods in excess of 12 hours a day. The lack of an intimate connection between amputee and limb replacement means that the prosthesis will be perceived as an external load and therefore as something that must be carried.

Power must be conserved in prostheses. If the power source is the amputee, i.e., body power, then the prosthesis should not require excessive effort so as not to tire the user over the course of the day (frictional losses need to be minimized). If the artificial limb is externally powered (i.e., uses a power source other than the body, usually electric storage), the limb should be able to run all day from the same power source without needing to be recharged. In addition, it is desirable for the power source to be contained within the prosthesis. Electric batteries are the main source of energy for modern prosthetic arms, although pneumatic gas cylinders have been used. Both are heavy and occupy space but electric storage provides greater energy/weight and energy/volume ratios. The problem of portable prosthesis power is analogous to the power issues in the laptop computer industry where a major contributor to the weight of a portable computer is the battery.

Although some size, weight, and power constraints must be placed on robots and remote manipulators, these constraints are far less severe than in prosthetics. Robotic actuators can often be as large and as heavy as required to achieve a specific result. Power is usually not an issue since it can be obtained from the power mains. As a result of the radically different design constraints, robotics and prosthetics design have much less in common than one might expect.

2.1.1 Arm Replacement or Tool? The control of a joint's compliance or impedance (impedance control) is considered by some designers to be a physiologically correct form for prosthesis control. It would seem to follow that this kind of control is desirable and ought to be incorporated into prosthetic arm systems. This raises a philosophical question as to whether an artificial limb should be designed as a limb replacement or as a tool. A true limb replacement would be a fully functioning substitute limb that is intimately connected to and controlled by the amputee. The goal of such a limb replacement would be to match as closely as possible the properties and function of the original limb. Alternatively, the prosthesis as a tool can be regarded as an interchangeable device to be worn by the amputee, used as needed, and then ignored. The tool makes no pretense of trying to replace the lost limb physiologically but is there as an aid to help provide some of the functions that were lost. While the difference might seem to be subtle it will permeate the discussion throughout this section. The goal of some research in the prosthesis field is directed toward the prosthesis as a limb replacement, and this does seem desirable; however, in current practice we are mostly limited to the prosthesis as a tool. The major causes of this limitation are practical ones due to the severe design constraints previously mentioned and the difficulty in finding a sufficient number of appropriate control sources to control the requisite number of degrees of freedom.

Impedance control comes under the guise of the prosthesis as a limb replacement. As with the neuromuscular system, this type of control requires that a control signal be constantly applied/maintained to hold a particular position. This places a constant drain on the power source, which is technically undesirable. The presently available body-powered wrist, elbow, and shoulder joints can be considered to have a limited form of compliance control or two-state compliance control. Through the use of locking mechanisms these devices have more or less infinite impedance when a joint is locked or close to zero impedance when the joint is unlocked and free to be moved.

2.1.2 Function versus Appearance The relative importance of function vs appearance is another issue that faces the amputee, and assisting clinicians, when deciding on a particular type of prosthesis, if any. Static vs dynamic cosmesis has been previously discussed but very often there is a tradeoff to be made between function and appearance. Some amputees may be solely concerned with the visual presentation and reject a body-powered prosthesis because of the unsightly appearance of the control harness or of a hook-shaped terminal device. Others might find the function provided by these devices to outweigh poor appearance. Choice of prosthesis is ultimately based on many psychological and practical factors. Other factors affecting choice are age, sex, occupation, and degree of physical activity of the amputee, the amputee's attitude toward training, the type of amputation involved, and whether only one arm is affected (unilateral) or both arms are affected (bilateral).

While the physical constraints mentioned previously are severe, ultimately it is more the control constraints (shortage of independent control sources) and not the physical constraints that impede the development of today's prosthetic systems. It is for this reason that upper-limb prosthetics is often dominated by consideration of control. Presently available terminal devices have a single degree of freedom (opening and closing). Prosthetic arms requiring multi–degree-of-freedom control use sequential control with locking mechanisms to switch control from one component or degree of freedom to the next. Generally, since vision is the primary source of feedback, the greatest number of functions that are controlled in parallel is two. Otherwise the mental burden becomes excessive. In spite of these limitations, many amputees become skilled users of these devices and show surprising adaptability and inventiveness in overcoming functional challenges faced by them in everyday life.

2.2 Prehension or Grasp

The reduction of the hand to a single–degree-of-freedom terminal device in most artificial limbs was done to reduce the number of control sources required to control prehension. The function of the human hand may be divided into two subgroups: nonprehensile functions and prehensile functions. Nonprehensile functions of the hand are those functions where grasping is not required; for example, pushing an object, holding an object between the body and forearm, flicking, brushing, percussive motions such as playing the piano, etc. Prehensile hand functions are those cases where an object is grasped and held partly or wholly within the hand.

Numerous different classifications of hand prehension have been defined but it is the six patterns of Keller *et al.* (1947) that have endured the test of time and are the most widely accepted in the field of prosthetics (see Fig. 2). These patterns, as described in Klopsteg and Wilson (1954), are tip prehension, lateral prehension, palmar prehension, cylindrical prehension, spherical prehension, and hook prehension.

Tip prehension, lateral prehension, and palmar prehension are primarily the function of the thumb working in opposition with the index and middle fingers. Napier (1956) described these patterns as precision grips. Tip prehension, or fingernail pinch, is used mainly to grasp small objects. In lateral prehension the thumb holds an object against the side of the index finger as is the case when using a key. In palmar prehension (sometimes referred to as tri-digital pinch or three-jaw chuck) the thumb opposes either a single finger or two or more fingers. This is the grip most commonly used in daily activities. Cylindrical and spherical prehension are examples of power grasps as described by Napier. Power grasps use all the fingers of the hand to provide an encompassing grasp that firmly stabilizes the object being held. Hook prehension is achieved by flexing the fingers into a hook; the thumb is either alongside the index finger or used to lock the object held. Carrying a briefcase is a good illustration of this kind of prehension.

The grip of the hand is further improved by the ability of the hand to adapt passively to the shape of an object grasped. A grasped object depresses, or indents, the skin and underlying soft tissues of the hand, at first meeting little resistance. Consequently, the

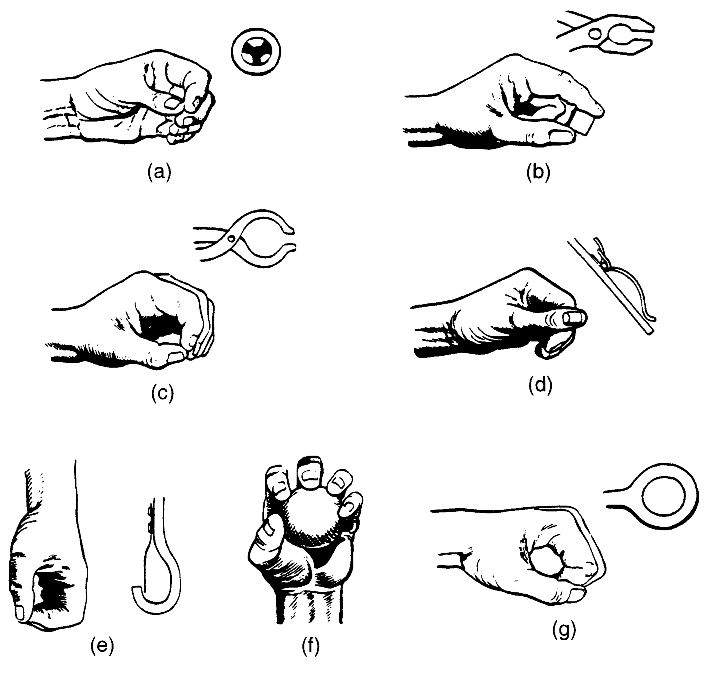

FIG. 2. Sketches of the prehension patterns defined by Keller *et al.* (1947). (a) Palmar prehension. Opposition of thumb with digits II and III in the near-closed position gives a three-jawed chuck prehension. (b) Palmar prehension. At openings of 1 to 3 in., opposition between thumb and digit II is in the manner of a pliers grip. (c) Tip prehension. Distal phalangeal segments of digits II and III and of thumb are strongly flexed to bring the finger and thumb tips into opposition. (d) Lateral prehension. Ball of thumb opposes lateral surface of digit II, usually at the second phalanx. (e) Hook prehension. Load supported by hooked terminal phalanges, thumb acting largely to prevent slipping volarly. (f) Spherical prehension. In addition to elements of grasp prehension, curving across the knuckle line permits conformity to spherical objects. (g) Cylindrical/grasp prehension. Digits curled about object, such as a handle; thumb curves and overlies finger tips to close the prehension "ring."

soft tissue adapts easily to the shape of the object grasped. However, the mechanical properties of the soft tissue are quite nonlinear and the conforming tissue becomes turgid as pressure is increased. This is demonstrated by blanching on the sides of the pads of the finger tips if sufficient force is applied. The rise in tissue stiffness after conformation to shape enables objects to be grasped with great security. This feature of the human hand would seem to be useful for robotic and prosthetic systems.

2.3 Prehension with Prostheses

The finding by Keller *et al.* (1947) that palmar prehension was the most frequently used pattern has meant that most prosthetic hands incorporate this pattern as the dominant pattern. The persistence of this configuration in prosthetic hand designs and its general acceptance over the years tend to support this finding. The passive adaptability afforded by the soft tissue of the hand is mimicked, to some extent, by lining the device with a soft plastic and covering it with a glove that has been molded to resemble the natural hand (a cosmetic glove).

Adequate reproduction of all six prehension patterns in an artificial handlike device requires three or four degrees of freedom. A four–degree-of-freedom device typically uses two for the thumb, one for the index finger, and one for the remaining three fingers. If flexion of the fingers is prevented, three degrees of freedom can be used: two for the thumb; and one to splay the fingers. Prosthetic hands with this number of degrees of freedom cannot at present be controlled in a meaningful way on account of the lack of suitable control sources. However, it is hoped that the use of surgical techniques to create additional control sites will remedy this problem. In the area of remote manipulation such hands have been developed for use with master–slave manipulators, the terminal device of the SARCOS system (Jacobsen *et al.*, 1990) shown in Fig. 1 being a case in point (see Fig. 3).

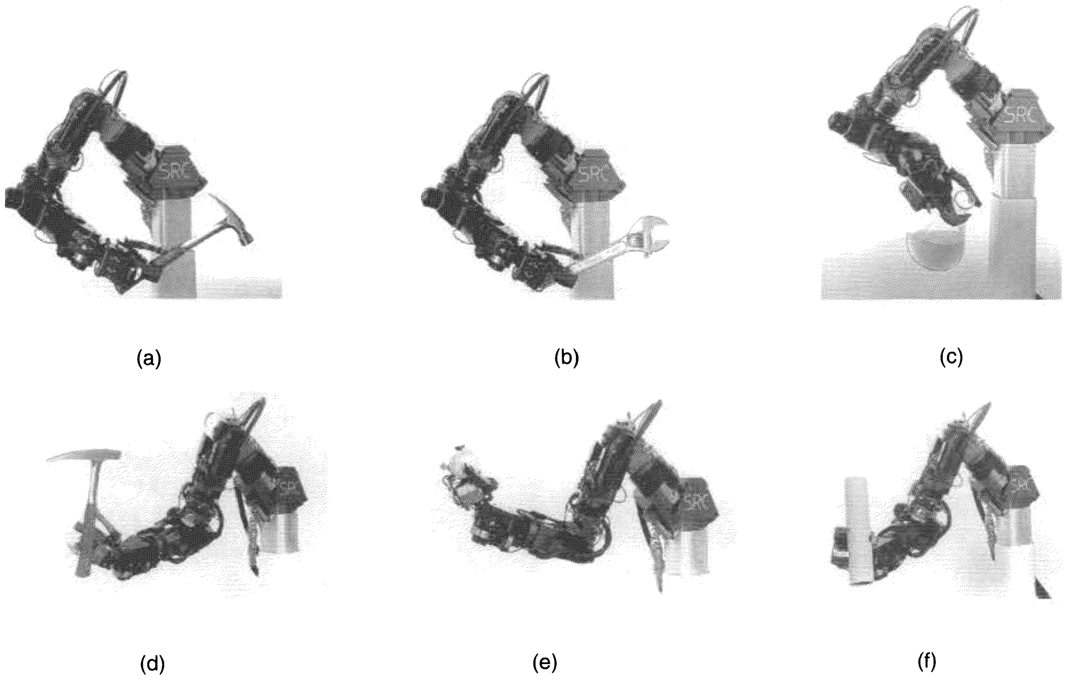

FIG. 3. Photographs showing various grasp patterns for the three–degree-of-freedom SARCOS dexterous manipulator terminal device. The index finger (digit II) is fixed. The thumb has two degrees of freedom to permit lateral and palmar prehension while digit III has the third degree of freedom to provide a stabilizing grip for spherical and cylindrical prehension patterns. (Photographs courtesy of SARCOS Research Corporation, Utah, UT.)

2.3.1 Handlike Prehensors Commercially available handlike prehensors are predominantly externally powered. The de facto standard handlike prosthesis is a mechanism manufactured by Otto Bock Orthopedic Inc. This mechanism is covered with a hand-shaped plastic liner over which is pulled a PVC or silicone rubber cosmetic glove (see Fig. 4). Hugh Steeper, Ltd. (Roehampton, England), and Centri (Sweden) also manufacture handlike devices for the adult. Child-size hands are also available, and there is a trend today to fit young children with birth or traumatic below-elbow deficiencies as early as possible. A number of child-size hands are manufactured by Variety Village Systems, Inc. (VASI), Otto Bock Orthopedic Inc., and Hugh Steeper, Ltd., among others (Michael, 1986; Heckathorne, 1992).

Palmar prehension in these handlike prehensors is achieved by using monocoque (single joint) fingers that are fixed in slight flexion at a position approximating the interphalangeal joints of the human hand. The resulting finger shape also creates a concave inner prehension surface that can be used to provide cylindrical prehension. Body-powered handlike prehensors are available but few are used effectively as active terminal devices. Frictional losses and poor mechanical advantage in the hand mechanism limit pinch force of body-powered hands. In addition, restriction of motion by the glove and/or plastic liner and the bulkiness of the hand's shape, which blocks vision, both serve to diminish the effectiveness of these devices (Fryer and Michael, 1992).

2.3.2 Body-Powered Non-Handlike Prehensors Non-handlike prehensors have the advantage of being able to incorporate many of the previously mentioned prehension patterns into a single–degree-of-freedom device. The split hook (Fig. 5) is an example of such a prehensor. It can perform tip, lateral, cylindrical, and hook prehension. This in large part accounts for the popularity of the split-hook prosthesis in spite of its less than appealing appearance. Supplied by Hosmer-Dorrance Corp., Otto Bock Orthopedic Inc., and other companies, split hooks come in many variations on the basic theme (Fryer and Michael, 1992).

2.3.3 Voluntary-Opening versus Voluntary-Closing Devices Body-powered terminal devices can be classified according to their mode of operation. They usually fall into one of two categories: voluntary-opening devices or voluntary-closing devices. Voluntary-opening components have an inherent closing force acting on the terminal device when the control cable is relaxed. Voluntary-opening components have an inherent opening force acting on the terminal device when the control cable is relaxed. The closing force of a voluntary-opening component

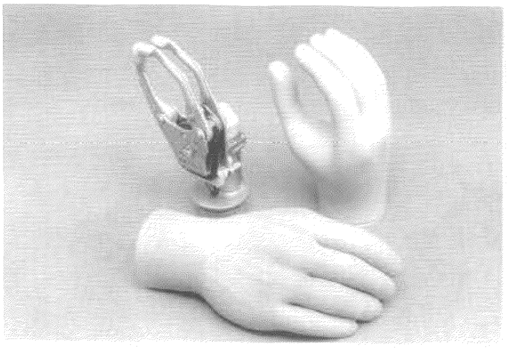

FIG. 4. Otto Bock Industries, Inc., externally powered handlike prosthesis. This device is the de facto standard for externally powered handlike prostheses. It consists of a drive mechanism (left) that is covered by a hand-shaped plastic liner (right). A cosmetic glove (bottom) is then worn over this liner. (Photograph courtesy of Northwestern University Prosthetics Research Laboratory, Chicago, IL.)

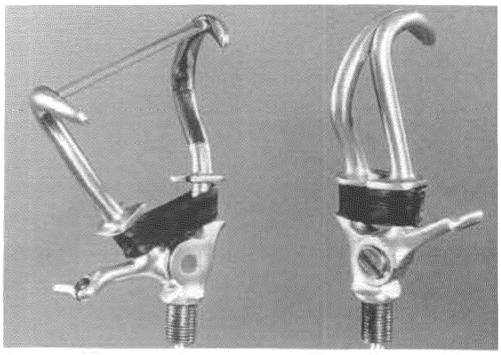

FIG. 5. The traditional voluntary-opening split-hook–type terminal device. This device exerts a closing force that must first be overcome before it can be opened. In the left-hand picture the hook is being held open by a spacer bar. (Photograph courtesy of Northwestern University Prosthetics and Orthotics Center, Chicago, IL.)

must be overcome before the terminal device will open. Prehension force with these devices is limited to the closing force (see Fig. 6, top). The opening force of a voluntary-closing component must be overcome before the terminal device will open. Prehension force in the terminal device is directly proportional to the force applied to the device (see Fig. 6, bottom).

The question of whether voluntary opening is superior to voluntary closing really depends on the design philosophy used. If a prosthesis is to be viewed primarily as a tool, to be used and ignored, then voluntary opening is appropriate. The terminal device acts simply as a vise that can be positioned anywhere in the amputee's work space. If, however, the prosthesis designer is striving for a limb replacement that is intimately joined to the amputee then the more physiologically correct control of voluntary closing (prehension force proportional to applied cable force) seems more appropriate. Nevertheless, the bulk of body-powered prostheses in use today employ voluntary-opening devices.

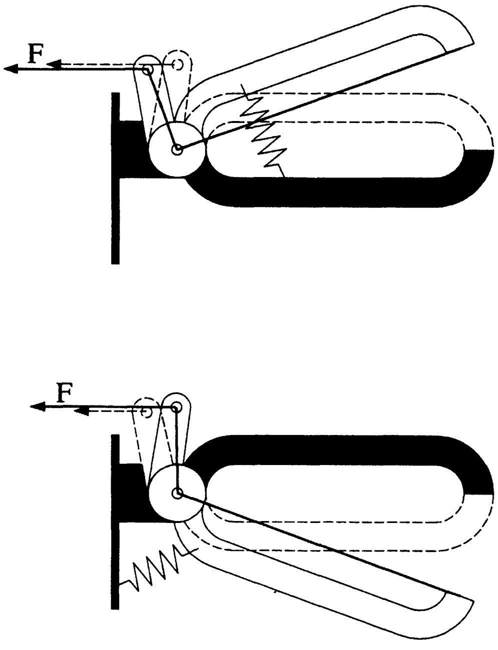

FIG. 6. Schematic showing the difference in operation between a voluntary-opening device (top schematic) and a voluntary-closing device (bottom schematic). A voluntary-opening device has a maximum grip force equal to the force that must be overcome before it will open. A voluntary-closing device has a maximum grip force equal to that applied by the user less the opening force that must be overcome.

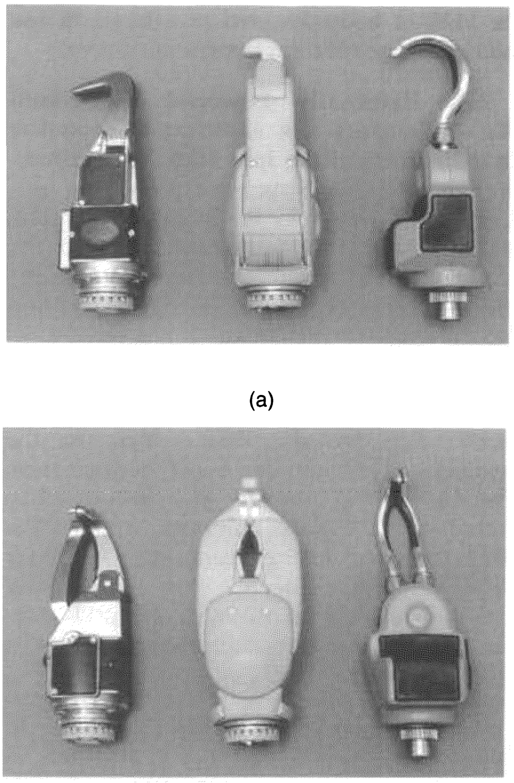
2.3.4 Externally Powered Non-Hand-like Prehensors In an effort to capitalize on the success of the split hook, the Hosmer-Dorrance NU-VA Synergetic prehensor uses a split hook in an externally powered configuration. The term synergetic refers to the fact that this prehensor uses two motors within the device, one to provide speed and the other to provide force (Childress, 1973). The Steeper Powered Gripper, available through Liberty Technology, and Otto Bock's latest line of child-size prosthetic hand mechanisms are also devices that use the principle of synergy to boost performance. The Otto Bock "Greifer" is a non-handlike prehensor that uses only one motor. The NU-VA Synergetic Prehensor, the Otto Bock Greifer, and the Steeper Powered Gripper can perform the equivalent of tip, lateral, and cylindrical prehension patterns (see Fig. 7) (Heckathorne, 1992).

2.3.5 Passive Prostheses Devices in this class, usually hands, are regarded as passive or passively functional prostheses. They have no moving parts and require no cables or batteries for operation. They are typically lightweight and reliable. Generic (standard) passive hand prostheses may consist of a cosmetic outer glove over a soft plastic hand with wire reinforcements in the fingers. Highly realistic hands, fingers, and finger parts can be custom sculpted and colored to match an individual's remaining hand.

Another class of passive prosthesis is the work or recreational prosthesis. A custom-designed system that serves only one function may aid the wearer more than one that is supposed to be multifunctional. In such cases the prosthetic device is worn on those occasions when it is needed. These devices range from tool adapters to sports mitts.

2.4 Artificial Arms

If the philosophy of the prosthesis as limb replacement is followed, arm prostheses ought to be designed as an integrated whole rather than a series of modular components. Most of the early artificial arms for the high-level amputee were designed in this manner.



(a)

(b)

FIG. 7. (a) Lateral and (b) "palmar" views of the Steeper Powered Gripper (left), Otto Bock System Electric Greifer (center), and Hosmer NU-VA Synergetic Prehensor (right) (photograph courtesy of Northwestern University Prosthetics Research Laboratory, Chicago, IL).

But as these systems failed to provide the expected function, there was a move away from designing complete arm prostheses to the design of specific or modular components, such as externally powered or body-powered elbow joints, powered or passive wrist rotators, passive humeral rotators, and whole ranges of different hooks, hands, and prehensors (Fryer and Michael, 1992; Heckathorne, 1992; Michael, 1986).

The current trend is to use a "mix and match" approach to make good use of the function available. This modular approach has the advantage of providing great flexibility and practicality for system design. However, it will probably never be able to attain the high functional goals that may be possible from a more integrated standpoint.

Prosthetic components for arm prostheses fall in one of two categories: body-powered or externally powered. Body-powered devices are functional prostheses that use some motion of the body to provide both the excursion and force necessary to power and control the prosthetic component. Externally powered devices, as their name suggests, receive their power from a source external to the body, usually electric.

2.4.1 Body-Powered Prostheses

Modern body-powered prostheses were greatly influenced by techniques used in aircraft flight-surface control. Of particular note was the adaptation by the Northrop Aircraft Co. of the Bowden cable for use in the prosthetics field. These cables, named for their inventor and the founder of the Raleigh bicycle company, have found extensive use in prosthetics applications. Their original use was as brake cables for bicycles. A Bowden cable consists of an inner core cable that is free to move within a sleeve cable that is fixed in place at either end.

The basic principles of the prosthetic design for body-powered devices are the same today as they were in the 1950s. These devices require a harness, to be worn about the shoulders, to which one or more Bowden cables are attached. The conventional below-elbow, body-powered prosthesis has a single control cable that runs from the harness to a terminal device. Terminal-device opening and closing are then controlled by shoulder shrug (biscapular abduction) and/or flexion of the residual upper arm (glenohumeral flexion) (see Fig. 8). For an above-elbow amputee an additional control cable is used to switch control of the harness from terminal-device opening to elbow flexion by unlocking the elbow. Figure 9 shows a typical above-elbow prosthetic fitting (the locking cable passes over the shoulder to the front of the elbow mechanism).

Body-powered prostheses of many kinds are available, and they are the most common kind of prosthesis used in the United States. The reason for their success is thought to be due to the intimate connection the control cable provides between the input and output. Just as a pilot "feels" connected to a plane's control surfaces, so the user of a body-powered limb feels closely connected to the operation of the prosthesis. These prostheses

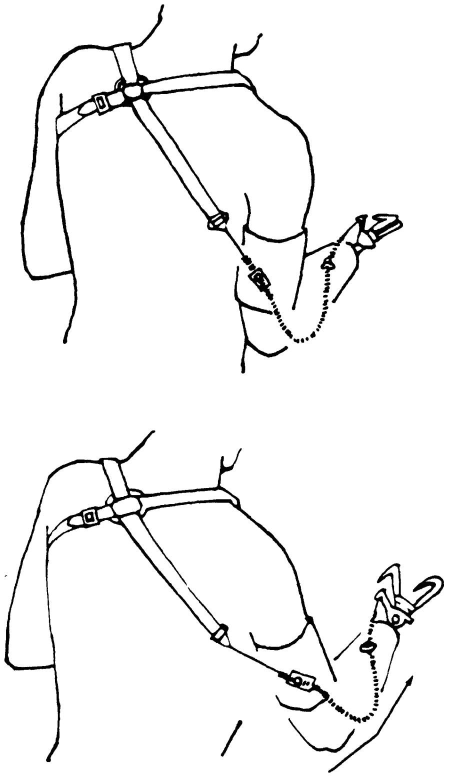


FIG. 8. Sketches of a body-powered control harness showing how glenohumeral flexion is used to control terminal-device opening (sketches courtesy of Northwestern University Prosthetics and Orthotics Center, Chicago, IL).

are also lightweight, durable, and of relatively low cost.

Although generally successful, body-powered prostheses have a number of shortcomings. The major issues are the uncomfortable harness mechanism; the somewhat ungainly control motions, particularly in the case of above-elbow prostheses; restricted range of motion; and limited load-lifting capacity (Fryer and Michael, 1992; Fryer, 1992).

2.4.2 Externally Powered Systems Externally powered prostheses are a relatively new (last 15 to 20 years) addition to the armamentarium of prosthetic devices. The electrically powered prosthesis under the control of myoelectric signals from residual muscles did not become commercially available until the late 1960s and did not gain widespread clinical acceptance until the early 1980s. A myoelectric signal is an electric signal that is generated as a by-product of a contracting muscle. Electrodes on the surface of the skin, placed near the contracting muscle, can pick up this signal and use it for the control of a prosthesis. Electrically powered hands for the below-elbow amputee are the most widely used externally powered prosthetic systems (see Fig. 10).

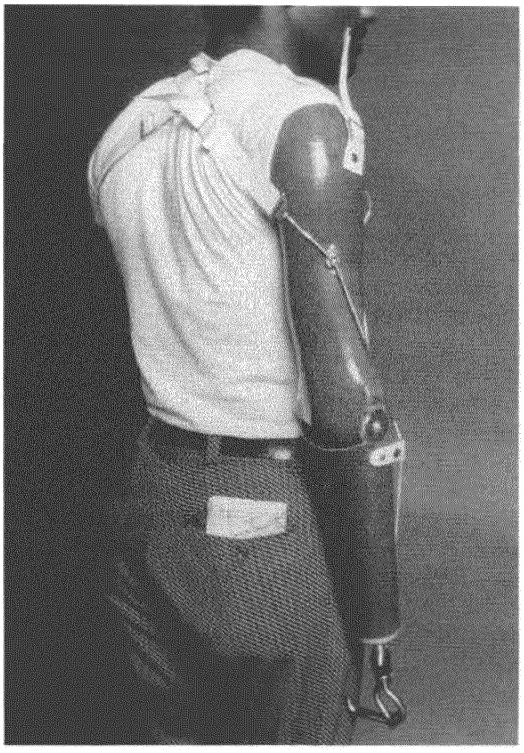

FIG. 9. Above-elbow body-powered prosthetic fitting. The same configuration of control harness as the below-elbow harness is used with the addition of a second "elbow-locking" cable. This cable switches the control from elbow flexion to terminal-device opening by locking and unlocking the elbow in place. (Photograph courtesy of Northwestern University Prosthetics and Orthotics Center, Chicago, IL.)

Currently available externally powered arms consist of an externally powered elbow and terminal device with the possible addition of a powered wrist rotator. The three most common externally powered elbows are the Liberty Technology Boston Elbow II, the Motion Control Utah Elbow, and the Hosmer-Dorrance NY Elbow. All these elbows can be used in conjunction with the previously described powered terminal devices (Heckathorne, 1992; Atkins and Meier, 1989).

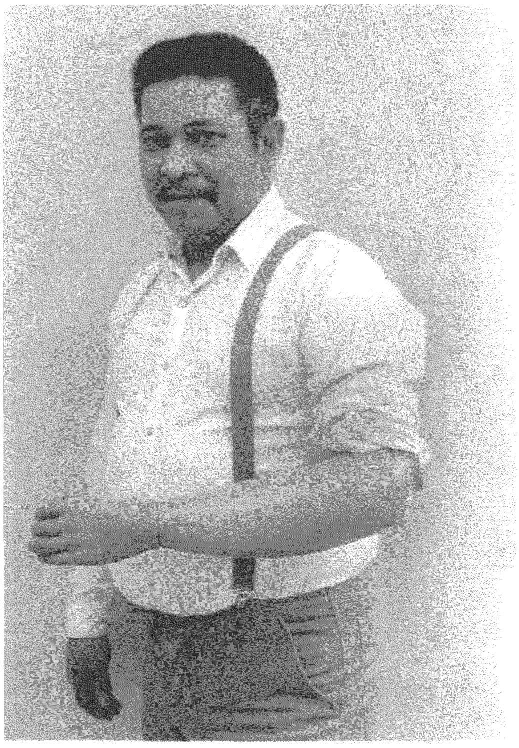

FIG. 10. A definitive below-elbow, externally powered, myoelectrically controlled, prosthetic fitting (photograph courtesy of Northwestern University Prosthetics Research Laboratory, Chicago, IL).

During the 1960s and 1970s much effort was invested in the development of externally powered, multifunctional, complete arm systems. While many of the ideas tried during this period failed to make it from the laboratory into everyday prosthetic practice, a number of multifunctional hands ended up making the transfer to the robotics field. The Belgrade hand (Razic, 1973) and Sven hand (Herberts *et al.*, 1973), while not commercial products, remain in use in robotics research applications. For example, the Belgrade hand has influenced the robotics field in the form of the Belgrade/USC robotic hand (Beattie *et al.*, 1994).

2.4.3 Hybrid Systems When body-powered and externally powered systems are linked together they are called hybrid systems. Hybrid systems are used most frequently with persons who have amputations above the elbow or who have bilateral arm amputations. Such systems can provide the user with the high gripping and/or high lifting capacities of powered systems and the fine control of body power. An example of hybrid control is illustrated in prosthetic limbs for persons with loss of both arms at the shoulder level. By providing the amputee with a body-powered limb on one side and an electric-powered limb on the other side, they enable the wearer to use the limb that is most appropriate for a specific task. This method also enables the limbs to be operated independently of each other, i.e., the body motions required to operate the body-powered side do not influence the state of the powered limb, and vice versa; they are decoupled. A hybrid system of the kind described is shown in Fig. 11.

The amputee in the photograph has a body-powered, single-cable, four-function system fitted on the right side. Chin levers

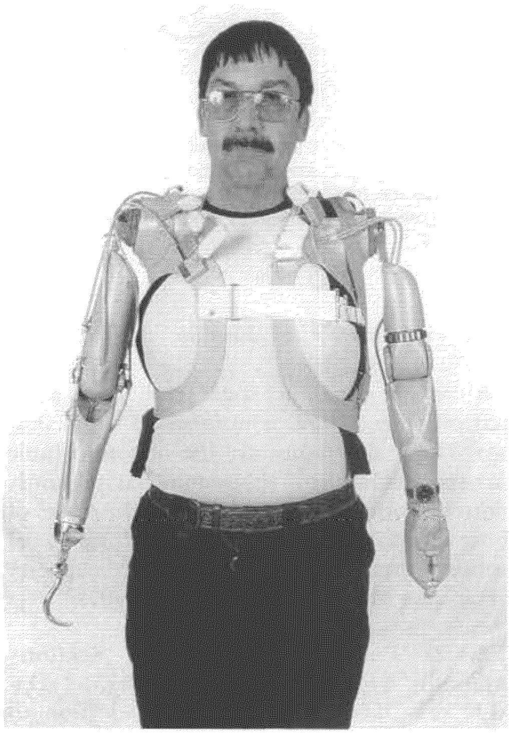

FIG. 11. Hybrid fitting of a bilateral shoulder disarticulation amputee. The body-powered prosthesis (right side in picture) is used as the dominant arm, with the electric limb (left side) assisting as the nondominant arm. See text for description of operation. (Photograph courtesy of Northwestern University Prosthetics Research Laboratory, Chicago, IL.)

are used to lock and unlock both shoulders (MICA locking shoulder joints), the elbow, and the wrist rotator. A lever on the wrist unlocks and locks the wrist flexion unit. Biscapular abduction (shoulder shrug) is then used to actuate unlocked components. The wrist rotator and wrist flexion unit are spring loaded to return these devices to their initial position when unlocked. Gravity is used to return the elbow to its initial position. The shoulder joints are positioned using gravity and bending of the trunk. By locking of all the joints the arm becomes a rigid extension of the user and the principle of extended physiological proprioception applies (see Sec. 2.7.1).

The left side is fitted with a powered elbow (Liberty Technology Boston Elbow) controlled by shoulder elevation pulling against a two-position pull switch. The powered prehensor (Otto Bock Greifer) and an Otto Bock powered wrist rotator are controlled by chin movement against rocker switches actuated by the chin.

The photograph of Fig. 11 illustrates a number of points made previously:

1. Because one side is mechanically powered, while the other is electrically powered, each side can be controlled independently of the other.
2. This fitting shows how components are modularly linked together to create a total arm prosthesis.
3. It shows how high-level amputees are fitted with body-powered and externally powered prostheses.
4. It illustrates how the limbs can be made rigid (high impedance) or free for movement (low impedance).
5. It highlights the difficulty in obtaining sufficient control sources to control a multi–degree-of-freedom arm. Many different methods must be used to control each degree of freedom.

2.5 Control

Numerous methods of control for upper-limb devices have been explored. Chief among these were harness and Bowden cable and/or mechanical switches for body-powered devices and electromechanical switches and myoelectric control for externally powered devices. The available control options can be broken into biomechanical and bioelectric/acoustic. A partial list of current and potential control options follows.

- I. Biomechanical
  - A. Movement/force from a body joint or multiple joints (position, force/pressure)
    - 1. Chin and head force/movement
    - 2. Glenohumeral flexion/extension abduction/adduction
    - 3. Biscapular and scapular abduction (shoulder shrug)
    - 4. Shoulder elevation and depression
    - 5. Chest expansion
    - 6. Elbow or wrist movement
  - B. Direct force/motion from muscle(s)
    - 1. Force/motion from a muscle tunnel cineplasty
    - 2. Force/motion from skin that is adherent to underlying muscle
    - 3. Krukenberg surgical procedure (long transradial amputation)
- II. Bioelectric/bioacoustic
  - A. Myoelectric potentials (muscle electricity)
  - B. Myoacoustic (muscle sounds)
  - C. Neuroelectric potentials (neuron and nerve signals)

Biomechanical inputs have been extensively used in the control of body-powered prosthetic components and have been mentioned in passing throughout the text (see Fig. 11). These same motions can be used to control externally powered components through the use of the appropriate electromechanical switch or force transducer (see Fig. 11). In general, either on/off or proportional velocity control is used with externally powered devices.

Proportional control is a form of control where the amount/intensity of the controlled output variable is directly related (proportional) to the amount/intensity of the input signal. For example, the output speed of a variable-speed power drill may be proportional to the amount the trigger is pressed. This is an illustration of velocity (speed) control; that is, output speed is proportional to the amount of input signal (in this case how far the drill trigger is pressed in). Proportional control is used where a graded response to a graded input is sought.

Position control of upper-extremity function relates prosthesis position directly to the input control signal. The amputee's ability to perceive and control prosthesis position is directly determined by his ability to perceive and control the input signal. With position control, unlike velocity control, the user must maintain the input signal to hold an output level other than zero. As the goal of the arm is to position the hand in space, the use of position control for positioning of the terminal device in space is considered to be most appropriate. Velocity control may be better suited for the control of prehension (Childress, 1992).

2.5.1 Myoelectric Control While most of the currently available externally powered upper-limb prosthetic systems use some form of velocity control, the merits of velocity control are being reevaluated, particularly in the context of position control, which in some cases appears preferable. Myoelectric control has received considerable attention since it first appeared in the 1940s. It was advanced as a natural approach for the control of prostheses since it made it possible for amputees to use similar mental processes to control prosthesis function as had previously been used in controlling their physiological limb. Myoelectric control uses the remaining neuromuscular systems in the amputation stump.

Myoelectric control derives its name from the electromyogram (EMG) signal, which it uses as a control input. When a muscle contracts it produces electric potentials (recorded as the electromyogram or EMG), as a by-product of that contraction. The intensity of the EMG signal produced increases as muscle tension increases. Surface electrodes placed on the skin near a muscle can detect this signal. The signal can then be electronically amplified and processed and used to control a prosthesis (see Fig. 12). See Parker and Scott (1985) for further reading.

2.5.2 Myoacoustic and Neuroelectric Control Myoacoustic signals are auditory sounds created as a by-product of muscle contraction. A myoacoustic control system is very similar in structure to a myoelectric control system but the elimination of unwanted acoustic noise may be a bigger problem than the elimination of unwanted electrical noise in myoelectric systems (Barry and Cole, 1990). It has not gained widespread use.

Neuroelectric control or the control of a prosthetic device by way of nerve impulses would appear to be a natural control approach. Although there is, and has been, research concerning prosthesis connections with nerves and neurons (Edell, 1986; Kovacs *et al.*, 1989) the practicality of human–machine interconnections of this kind is still problematic. Nervous tissue is sensitive to mechanical stresses and this form of control requires the use of implanted systems.

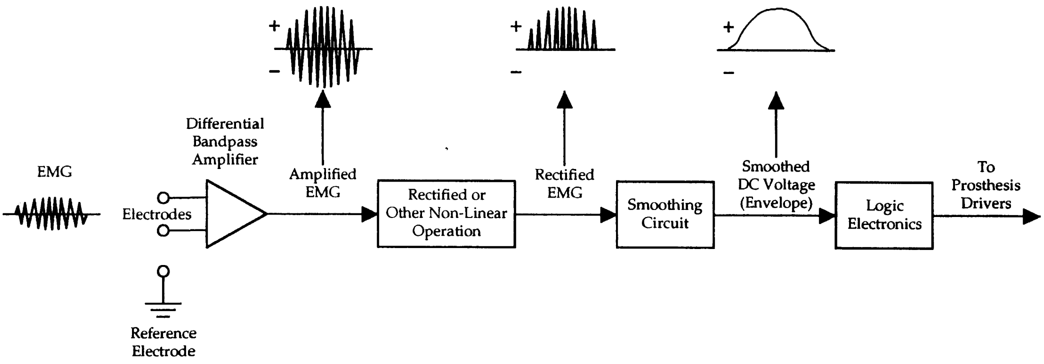

FIG. 12. Drawing showing myoelectric signal (EMG) processing in a typical myoelectric control system. Three "dry" metal electrodes are always associated with each muscle site. The small ac potential from the muscle is amplified and changed into a dc potential, often by rectification or by squaring. In a typical circuit this dc potential is commonly smoothed with a low-pass filter. The smoothed dc voltage E_s can be compared in a logic circuit with a threshold voltage E_{th}. If E_s is greater then E_{th}, then power is supplied to the prosthesis motor. If E_s is less than E_{th}, no power is supplied, and the motor is off.

2.6 The Issue of Feedback

Myoelectrically controlled systems are usually open-loop feed-forward in nature. That is, a control signal is sent from the user to the device but nothing in the way of feedback is returned except visual information. This lack of proprioceptive and sensory feedback is considered significant with either myoelectric or switch-controlled externally powered systems. Without proprioceptive feedback, subconscious multifunctional control of a prosthesis is probably not possible.

Constant visual monitoring is required for effective operation of velocity-control systems. For the control of multiple degrees of freedom this places an excessive mental burden on the user, greatly diminishing any benefits a prosthesis of complexity might offer. Visual and auditory feedback are slower, less automated, and less programmed than normal proprioceptive feedback and therefore place a greater mental burden on the operator (Soede, 1982).

Upper-limb prostheses are currently controlled primarily through *visual feedback* with some assistance from feedback that is incidental rather than by design (see Fig. 13). Examples of *incidental feedback* are motor whine, prosthesis vibration, socket forces, etc. Deliberate attempts have been made to provide feedback by means of mechanical vibration of the skin and by electrical stimulation of the skin. These forms of feedback are called *supplementary sensory feedback (s.s.f),* because they supplement the normal sensory feedback paths of the body. *Artificial reflexes,* which bypass the human operator altogether, are another method employed to reduce mental loading and improve performance. Artificial reflexes seek to remove the operator from the control loop and automatically respond to some external sensor input. They are essentially closed loops within the mechanism/prosthesis itself. A slip detector, for example, detects slippage of an object grasped by a prehensor and automatically increases prehension force until it detects that the slippage has stopped.

Feedback information can be received through the control interface, as in power steering for an automobile. *Control interface feedback* can provide feedback to the operator concerning the state of the prosthesis through the same channel through which the prosthesis is controlled. Information concerning prosthetic joint position, velocity, and the forces acting on it can be available to the operator through the proprioceptors of the controlling human joint. Feedback through the control interface can be in forms that are easily interpreted by the user and can be interpreted at a subconscious level. Consider the example of power steering for a car. When parking, the driver learns subconsciously to equate wheel position with steering-wheel position. Central to the implementation of feedback through the control interface is the design of the controller. The majority of prosthesis controllers, however, do not provide control-interface feedback, and it is for this reason, it could be argued, that externally powered limb replacements have not gained the widespread acceptance expected of them (Childress, 1992).

2.7 Parallel Development of Robots, Manipulators, and Prostheses

If one looks at the parallel development of aircraft, manipulator, and automobile control systems, the progression starts out with

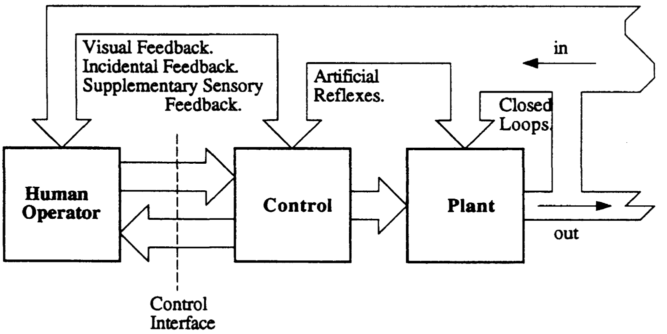

FIG. 13. Block diagram of the various feedback paths used in upper-limb prosthetics. See text for explanation.

the flight surfaces, the steering wheels, the remote manipulator, or the prosthetic joint controlled directly by mechanical linkages between the operator and the device. In early aircraft the tail flaps and rudder were physically connected to the joystick by way of control cables. In early automobiles the front wheels were physically connected to the steering wheel by a rack-and-pinion mechanism. The early master–slave manipulators were physically interconnected by cables. The early prostheses used a cable attached from the artificial joint to the shoulder harness. In all these cases the power to perform the control task was supplied by the human and feedback was available to the operator via the control interface. The pilot could "feel" what was happening to the aircraft flight surfaces through the joystick. The amputee had a sense of prosthesis state through the control cable.

As aircraft got larger and faster hydraulic power assist was added to the cable controls. As the automobile got heavier power steering was developed. The control input (the operator at a joystick or steering wheel) remained the same but instead of the operator powering the system, power was now provided by hydraulic systems that augmented the cable systems of aircraft and the steering of cars. But the same type of feedback, control-interface feedback, was maintained. Position, velocity, and force information were still fed back within these "boosted" systems. A similar pattern of development occurred with remote manipulators (i.e., human-powered cable systems were followed by electric-motor–boosted cable systems).

Unfortunately, it is at this stage that prosthetics development diverges from that of aircraft, automobiles, and remote manipulators. When prosthetic arm technology moved to externally powered systems, the control modalities shifted away from cable inputs that provided sensory and proprioceptive feedback to the operator and with one or two exceptions used open-loop velocity-control techniques (such as myoelectric and switch control) that provide little feedback to the operator beyond visual feedback.

This divergence from the path taken by aircraft, automobile, and remote manipulators can be attributed to the demanding physical design constraints of volume, weight, and power that must be met if a prosthesis is to be successful. The constraint problem resulted in essentially open-loop, velocity-controlled, externally powered devices. The major reason for this approach was simplicity. The actuator of choice, the electric dc motor, is inherently a rate-controlled device (i.e., its output speed is directly proportional to the input voltage). In addition a velocity-controlled system does not need to draw power to maintain a particular position.

While upper-limb prosthetics control development seems to have been retarded, the development of controls for the aircraft and manipulator industries has moved into the next stage and beyond. Aircraft controls, building on work from the field of teleoperation or remote manipulation, have done away with the direct physical interconnection of the pilot and flight surfaces and now use fly-by-wire systems. In these systems the pilot is connected to the output through electrical wire connections. Force feedback or force reflection is used to provide the pilot with the appropriate feedback or "feel."

For advanced fighter planes the stage beyond fly-by-wire has been reached. These planes are inherently unstable, i.e., the speed of response and accuracy required to ensure stable operation are beyond human capability. Thus, a human operator is incapable of controlling them alone, and so now "boosted control" has been added to "boosted power." A similar stage of development has been reached in the area of force-reflecting remote manipulators. Here the kinematic and dynamic properties of a microslave manipulator are scaled, using a technique called bilateral impedance shaping (Colgate, 1993) to match those of the controlling master arm so that the contact forces experienced by this manipulator "feel right" to the operator. Bilateral impedance shaping is a means of constructively altering the impedance of a task. This is particularly valuable if the task impedance or feel is very different from those normally experienced by the human limb, such as in the case of the human arm controlling a micromanipulator. See Thring (1983) for further reading.

2.7.1 Extended Physiological Proprioception The work of Simpson (1974) was an exception to the trend taken by upper-limb prosthetics into open-loop velocity control. Simpson advocated essentially the same developmental process as that taken by the aircraft and auto industries, that of augmented cable control. He demonstrated that this was a viable approach for the subconscious control of multifunctional prosthetic arms [the Edinburgh arm (Simpson, 1969)] and coined the phrase "extended physiological proprioception" (e.p.p.) to indicate that the body's own natural physiological sensors are used to relate to the operator the state of the prosthetic arm. That is, the operator extends his own proprioception into the prosthesis; the prosthesis becomes an extension of the amputee's self. Simpson's work was largely ignored at the time and is only now beginning to receive serious attention in the clinical setting. The success of the conventional, body-powered, Bowden-cable–operated prostheses, it could be argued, can be attributed to this idea of e.p.p.

The use of tools such as pencils, pens, knives, hammers, and the like illustrates the simplest form of e.p.p. We naturally use these extensions of our bodies without thinking about their control, because we extend our proprioception through these tools. Similarly, blind persons uses long canes to extend their range of feel of the outside world. A golfer or tennis player does not watch the head of the club or racket during a swing. Both are able to judge the angle and position of the head of the club or racket in space based on how it feels in the hand. In both cases the proprioceptive capabilities of the wrist and other joints have been extended to include the club or racket. The club or racket becomes a natural extension of the player's hand/arm.

The success of the below-elbow myoelectric hand prosthesis can be attributed to e.p.p. in its simplest form. The below-elbow prosthesis socket can be viewed as an extension of the elbow joint with the hand itself behaving in a mode similar to a pair of pliers. A prosthesis for the lower-limb, below-knee amputee is another example of simple e.p.p. The below-knee prosthesis becomes an extension of the shank from the knee.

Control of *another joint* by a physiological joint through e.p.p. is more complex than the e.p.p. control of a simple rigid extension. The artificial joint may be powered by the physiological joint as in body-powered prostheses, or it can be externally powered, receiving only the control input from the physiological joint. A prerequisite for the e.p.p. control of another joint is that the two joints, the physiological joint and the artificial joint, be *mechanically interconnected.* In this way, motions and forces experienced by one joint result in equivalent motions and forces being experienced by the other, and vice versa (see Fig. 14). This type of system is known as an unbeatable position servomechanism. A hand-operated bicycle brake is a rudimentary example of an e.p.p. system. These systems are cable-operated manual-control systems similar to the cable-control mechanisms of early biplanes and body-powered prostheses. The cyclist is able to achieve fine braking control because it is possible to sense how hard the brakes are being actuated through the cable connecting the brake to the brake handle.

As previously mentioned, the success of conventional body-powered devices has been attributed to the e.p.p. that is inherent in their mode of operation, particularly those devices for below-elbow amputees. The use of Bowden cables means that external forces experienced by the artificial joint/terminal device are transmitted, via the cable, to the shoulder harness and felt across the shoulders.

Control of an externally powered prosthetic component by e.p.p. is similar in concept to power steering for a car. The driver feels, through the handling of the steering wheel, the action of the car's front wheels. Furthermore, the driver cannot "beat" the response of the front wheels because the steer-

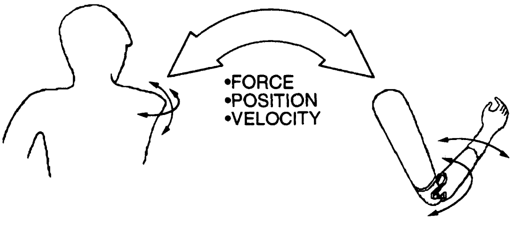

FIG. 14. Diagrammatic representation of a two–degree-of-freedom e.p.p.-controlled electric prosthesis. Shoulder elevation/depression would be linked to elbow flexion/extension. Shoulder protraction/retraction would be linked to wrist pronation/supination. Feedback is through the control interface that actuates the prosthesis so that the operator gives and receives information in a way that is similar to the interaction found in extension tools used in the human hand (e.g., hammer).

ing wheel and the front wheels move together in a one-to-one correspondence.

E.p.p.-like control can be implemented using two motors instead of using Bowden cables for the linkage between the natural and artificial joints. In such a system, one motor is used to drive the prosthesis and the second motor is used to implement the restraining linkage that the cables previously provided. The second motor provides the proprioceptive feedback. This combination of two motors is referred to as a master–slave system. One motor is slaved to the other. This use of a dual-motor master–slave servo system has been applied in the area of human amplification and remote manipulation, where reduction of weight, space, and power consumption are not primary concerns (see Thring, 1983).

2.8 Surgery for Improved Control

The role of surgery is vital to the success of a prosthetic fitting. History has shown that the greatest success in prosthetic fitting is achieved when the surgeon, amputee, prosthetist, physical therapist, physician, and engineer work together as a team. Muscle-tunnel cineplasty is a good example of where this interdisciplinary approach was needed to ensure success. In muscle-tunnel cineplasty surgical intervention is used to provide direct mechanical connection between muscle and prosthesis. The procedure involves the construction of a skin-lined tunnel, by way of skin grafts, through a muscle belly (see Fig. 15). Developed in its original form by the German surgeon Ferdinand Sauerbruch (1916), the procedure owes much of its success to the team approach used at Sauerbruch's facility. Sauerbruch's technique was modified by Lebsche in Munich, and the modified approach was used in the United States after World War II.

The use of surgical techniques to create pectoral or other tunnel cineplasties offers a means of creating badly needed control sources for persons with high levels of amputation. The use of tunnel cineplasties as control inputs to externally powered prosthetic components provides a means of physically linking a skeletal muscle to an externally powered device. If the controller embodies the concept of extended physiological proprioception (e.p.p.) then feedback information about prosthesis state can be given to the amputee through the cineplastized muscles' own proprioceptive and sensory apparatus. It is possible to envision a below-elbow amputee with independent multidigit control through the use of multiple miniature forearm cineplasties providing control inputs to multiple e.p.p. controllers, one cineplasty per controller per digit to be controlled (see Fig. 16). Alternatively it might be possible to create multiple miniature pectoral cineplasties, for high-level above-elbow amputees, to control a multi–degree-of-freedom arm prosthesis in a more subconscious manner than is now possible.

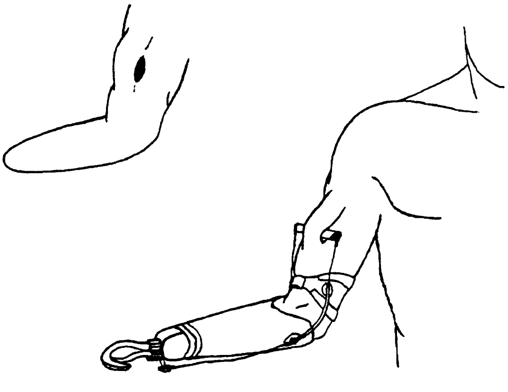

FIG. 15. Sketch of a Sauerbruch/Lebsche biceps muscle-tunnel cineplasty and prosthesis. A skin-lined tunnel is surgically constructed through a skeletal muscle that has been freed from its point of insertion (the biceps in this case). A pin is then placed in the tunnel and mechanically attached by way of cables to a prosthetic terminal device. Traditionally a voluntary-closing split hook was used in the United States. Voluntary contraction of the cineplastized muscle causes the pin to move, resulting in terminal-device closure.

A variation on the surgical procedure for muscle-tunnel cineplasty is the tendon-exteriorization cineplasty procedure (Beasley, 1966). The procedure uses tendon transfers combined with skin flaps to bring a tendon loop outside the body. This procedure might be used to create exteriorized tendons for the control of a four–degree-of-freedom prosthetic hand (see Fig. 17).

In Sweden, pioneering work in the area of direct skeletal attachment of prostheses to humans has been carried out by Dr. Per-Ingvar Brånemark and his team. These surgeons and orthopedic engineers have created

FIG. 16. Schematic of multiple miniature tunnel cineplasties, used in conjunction with e.p.p. controllers, controlling a multifunctional hand prosthesis. It is envisaged that each prosthetic digit would be under the control of an individual muscle with a miniature tunnel cineplasty via an e.p.p. controller. This presents the intriguing possibility of someday achieving subconscious coordinated multidigit control for externally powered hand prostheses.

infection-free interfaces for direct skeletal attachment systems for upper- and lower-limb amputations. This work evolved from work with titanium implants in the jawbone for holding artificial teeth and progressed to the placement of titanium sockets in the skull to retain maxillofacial prostheses and for the attachment of highly efficient bone-conduction hearing aids (Brånemark, 1985). Brånemark seems to have overcome the infection problems that have curtailed previous direct skeletal attachment efforts (Hall *et al.*, 1967; Hall and Rostoker, 1980) with innovative surgical techniques and post-operative procedures. Should direct skeletal attachment prove itself viable, it could revolutionize the prosthetic fitting of amputees (upper and lower).

2.9 Medical Manipulators or Rehabilitation Robots

Medical manipulators form a special class of artificial arm replacement. These devices are mechanical arms that attempt to provide arm function for persons who have lost control of their arms, such as in high-level quadriplegia. These devices fall into one of three categories:

1. powered orthoses,
2. industrial or custom-designed manipulators for use with a dedicated work station in highly structured environments, or
3. custom-designed manipulators for use in unstructured environments.

The initial work in the field of rehabilitation

FIG. 17. Subject with tendon-exteriorization cineplasties wearing a prototype full e.p.p.-controlled, externally powered hand prosthesis. Top photograph shows the connection to the flexor compartment tendon loop. Bottom photograph shows the connection to the extensor compartment tendon loop. The e.p.p. controller and mechanical linkage are arranged to provide full motion of a modified Otto Bock hand mechanism. This was a proof-of-concept fitting done to examine powered prosthesis control using direct muscle attachment. This was the first step toward the goal of controlling a four–degree-of-freedom hand using direct muscle attachment. (Photographs courtesy of Northwestern University Prosthetics Research Laboratory, Chicago, IL.)

manipulators used the idea of anthropomorphic systems and developed powered orthoses that were essentially externally powered exoskeletons that moved a paralyzed person's arm to perform a desired manipulation. These systems later evolved into mechanical arms that were mounted on a wheelchair or in a dedicated work space. The paralyzed limb is not transported in later systems. See American Academy of Orthopaedic Surgeons (1981) for further reading.

Persons with high-level quadriplegia do not have the use of their arms; consequently the anthropomorphic master–slave approach of conventional manipulator design is not necessarily the most practical design approach. Yet many medical manipulators evolved from or use upper-limb prosthetic components. The APL/JHU manipulator (Seamone and Schmeisser, 1972) (Fig. 18), developed at the Applied Physics Laboratory of Johns Hopkins University, evolved from a shoulder-level arm prosthesis, while the Stanford Robotic Aid (Leifer *et al.*, 1978) (Fig. 19), which is built around a commercially available industrial robot, the Unimation PUMA-260 arm, uses an Otto Bock "Greifer" prosthetic prehensor as its end effector. Both these systems are remote from the user and operate in dedicated work spaces. See Leifer (1981) and Preising *et al.* (1991) for review.

As with myoelectrically controlled prostheses, the control of these devices is essentially open-loop feed-forward in nature. The burden of feedback and monitoring of manipulator position is placed totally on the visual system. Subconscious control is lost, with concomitant increase in mental loading to the user.

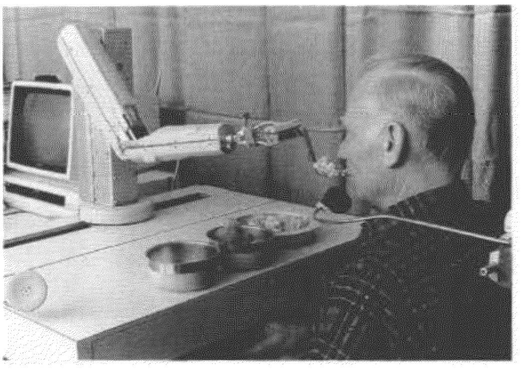

FIG. 18. The APL/JHU rehabilitation manipulator. This device evolved from an externally powered shoulder-level prosthesis system. The end effector is a modified voluntary-opening split hook. This system is used in a highly structured environment. (Photograph courtesy of Machiel Van der Loos, Department of Veterans Affairs Medical Center, Palo Alto, CA.)

The Handy 1 Rehabilitation Robot from Rehab Robotics Ltd., Staffordshire, England (Fig. 20), has achieved the greatest field success so far in the area of personal robotic assistants. It is the first commercially available robotic aid capable of assisting the severely disabled with everyday tasks such as eating, drinking, shaving, etc. Developed at Keele University (Topping, 1995) this device has found success through the simple nature of the interface between the user and the device and through the mobility of the unit (it can be easily moved from room to room). A single switch is the sole mode of control and is the only part of the system that may be different for each individual person. Because of this feature the Handy 1 can be operated by almost any part of the body. Originally designed for persons with cerebral palsy, stroke accident, multiple sclerosis, and muscular dystrophy, the Handy 1, in the eating mode, presents the user with food. The user then uses gross trunk movements to take the food from the robot. The device can be used in a similar fashion to assist with grooming and personal hygiene. It is this limited idea of presenting objects (e.g., comb, washcloth,

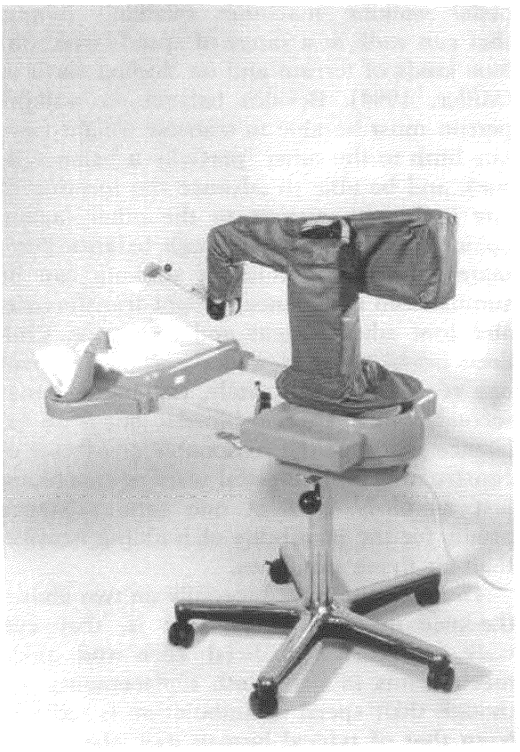

FIG. 20. The Handy 1 Rehabilitation Robot. This device owes its success to the simplicity of its user interface and to its ability to be moved easily from place to place. An object (food, toiletries, etc.) is "presented" to the user who then employs gross trunk movements to eat or to use the presented object. (Photograph courtesy of Rehab Robotics, Keele, England.)

etc.) rather than trying to be a mechanical arm replacement that is at the heart of this device's success.

3. LOWER-LIMB PROSTHESES AND WALKING ROBOTS

Humans can ambulate reasonably well on artificial legs, particularly if the amputations are below the knee. Persons with one limb missing below the knee can walk almost normally if they are reasonably healthy, if they have good gait training, and if they have a well-fitted functional prosthesis. Walking on two artificial below-knee prostheses is something akin to walking on stilts and many people can also walk quite naturally with two limbs missing below the knee. Today's below-knee prostheses use modern materials to achieve combinations of shape and compliance that are appropriate for walking and running. Figures 21 and 22 illustrate prostheses of this nature. The runner in Fig. 21 has run 100 meters in 11.65 s. These prostheses, products of Flex-Foot Inc., are made of composite carbon fiber material. The foot is shaped in the form of a flexible cantilever beam that bends during walking. In addition, the pylon to which the cantilever is attached, in Fig. 22, is pistonlike and will shorten under load through the readily visible side leaf spring. Control of the limbs comes through intimate fitting sockets that provide extended physiological proprioception (e.p.p.) from the knee. Foot function is achieved through shape and through bending (compliance),

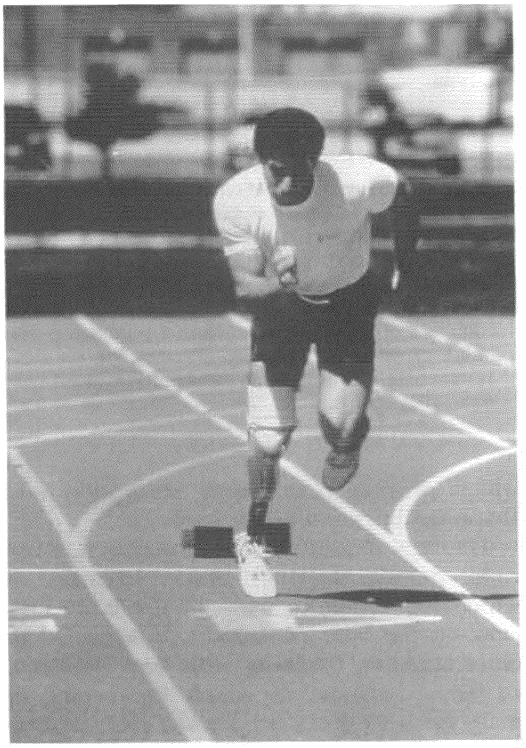

FIG. 21. Dennis Oehler, one of the fastest leg amputees in the world, running on a Flex Foot®. He has run the 100 meters in 11.65 s. The Flex Foot® has a flexible keel that stores energy during the stance phase of walking or running and releases this stored energy at toe off to provide an added boost to the user. Feet of this type have been termed dynamic response feet. (Photograph courtesy of Flex Foot® Inc., San Diego, CA.)

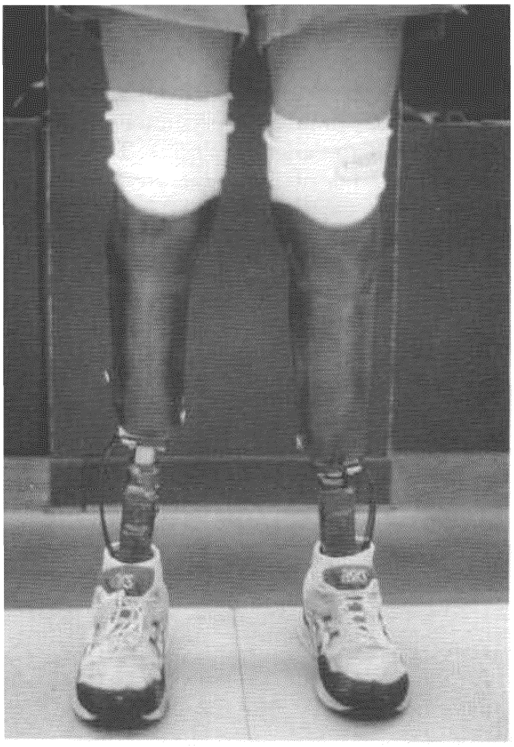

FIG. 22. The latest incarnation of the Flex Foot®, the Reflex Foot®, still has the carbon-fiber keel of the original Flex Foot® but now also includes a vertical leaf spring and piston on the shaft of the leg. These springs can be seen in the above photograph. These springs act essentially like shock absorbers, limiting the amount of shock transmitted to the amputee during stair climbing and walking. (Photograph courtesy of Northwestern University Prosthetics Research Laboratory, Chicago, IL.)

which provide both shock absorption and shape modification under load.

Humans require good balance to stay upright during walking. Static balance, in which the center of mass of the body projects on the base of support, is achieved in quiet standing (walking with zero velocity). Dynamic balance, in which the center of mass often projects outside the base of support, is required for bipedal walking. Walking is often regarded as a process of falling and catching oneself. Perry and associates (1981) have described walking as a continuous event of falling from one foot to the other to move the body forward. Balance is the key to bipedal walking, and the lack of good artificial balancing ability is one of the primary reasons it is difficult to build bipedal walking machines (walking robots) that can walk at a range of speeds over various kinds of terrain and on sloping surfaces (Miller, 1994). Besides balance, a walking person must be able to transfer weight from one limb to the other (partially a balance issue), and be able to advance the location of one limb with respect to the other (again, balance is involved). Although balance dominates, the main issues of walking can be summarized as balance, weight transference, and foot advancement and clearance. Children begin to learn walking skills at about one year of age. Ultimately, walking becomes second nature. Human bipedal gait is an existence proof for the reasonable possibility of constructing agile bipedal walking machines, just as birds were at one time existence proofs for the possibility of building heavier-than-air flying machines.

Humans can walk bipedally on two above-the-knee artificial limbs; that is, they can walk on passive artificial knee and ankle mechanisms in both limb replacements. Although their speed of ambulation is reduced from that of typical human gait, the ambulation ability they achieve is a tribute to their excellent balance system and to their control of muscles around the hip joint and pelvis (see Fig. 23). A person amputated at the hip level on one side can also walk reasonably well on a hip disarticulation prosthesis. Walking ability of this nature testifies also to the capacity of a remaining limb to compensate for one that is missing.

Legged locomotion is an interesting area of robotics, prosthetics, and animal studies. Raibert (1984, 1990) points out that legged locomotion has potential practical applications for vehicular mobility over rough terrain. He also points out that technical development of walking machines may assist with the understanding of animal movement, including human bipedal ambulation. Likewise, he notes that animal studies may assist with the design of walking machines. It might be added that study of walking on prostheses may help us understand normal human walking and/or robotic walking and that knowledge about robotic walking and human walking may influence artificial limb designs. This kind of interplay between disciplines occurs often in science and engineering. It is worth noting, for example, that the photographic studies of animal locomo-

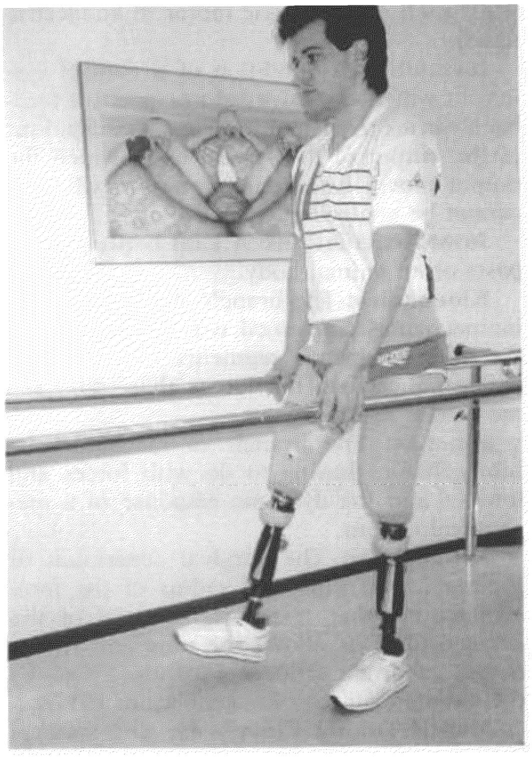

FIG. 23. A bilateral above-knee amputee walking bipedally on two above-the-knee artificial limbs. In the photograph he is shown walking between parallel bars during his early gait training. He now walks with the aid of a cane, which is primarily an aid to balance. (Photograph courtesy of Northwestern University Prosthetics Research Laboratory, Chicago, IL.)

tion (originally studies of horses) by Edward Muybridge in the United States and by E. J. Marey in France played important roles in the development of cinematography.

Comprehensive introductions to locomotion and walking machines may be gained through Todd (1985) and Raibert (1986), and through two special issues on legged locomotion published by the *International Journal of Robotics Research* (see Raibert, 1990, 1984). Suggested introductions to human walking are Perry (1992) and Rose and Gamble (1994). Perry's book examines human pathological ambulation as well as normal walking. The Rose and Gamble book contains a chapter by C. W. Radcliffe concerned with walking on prostheses. McMahon (1984) provides readers with a general overview of human and animal locomotion issues.

4. CONCLUSION

Presently, the field of limb prosthetics finds itself in a stage of development similar to that of the aircraft industry back in the 1930s, when the DC-3 airplane was introduced. In the aircraft industry this plane represented a watershed between seat-of-the-pants empirical design and scientific design using theoretical constructs of aerodynamics. The field of prosthetics seems to be at a similar point in its development. Significant advances have been made, to a great extent by empirical means. Now, near the end of the twentieth century, it is anticipated that further gains will be made through the enhancement of empiricism by theoretical and computational science.

GLOSSARY

Abduction (Adduction): The lateral movement of the limbs away from (toward) the median plane of the body.

Above-Elbow: Refers to the those amputations that occur above the elbow and below the shoulder (transhumeral).

Agonist/Antagonist: Muscles acting in groups or pairs. For any given movement some muscles in the group or one muscle in the pair must be either relaxing or contracting. The agonist muscle is the muscle that is directly engaged in contraction as distinguished from muscles that have to relax at the same time; thus in bending of the elbow, the biceps brachii is the agonist and the triceps the antagonist.

Anthropomorphic: Human shaped. Attribution of human qualities to nonhuman organisms or objects.

Artificial Reflex: A reflex that bypasses the human operator altogether for the purpose of reducing the mental loading placed on the operator and to perform an operation automatically without requiring intervention from the operator. Artificial reflexes seek to remove the operator from the control loop and automatically respond to some external sensor input. For example, a slip detector detects the slippage of an object and automatically increases prehension force until the slippage stops.

Below-Elbow: Refers to those amputations that occur below the elbow (transradial).

Bilateral: Both sides.

Bilateral Impedance Shaping: Used in the area of remote manipulation, bilateral impedance shaping is a means of constructively altering the impedance or "feel" of a task. This is particularly valuable if the task impedance or feel is very different from those normally experienced by the human limb.

Body-Powered: Driven by power provided by the amputee through some body motion.

Cocontraction: The simultaneous contraction of both muscles in an agonist/antagonist muscle pair.

Contact Instability: The instability that can occur when a robot manipulator comes into contact with a surface.

Control-Interface Feedback: Sensory feedback information that is received through the control interface—e.g., as in power steering for an automobile. Control-interface feedback provides feedback to the operator concerning the state of the prosthesis through the same channel through which the prosthesis is controlled.

Degrees of Freedom: The number of axes of rotation or joints that need to be controlled.

Dynamic Cosmesis: The appearance of a prosthesis or device when it is in motion. Good static cosmesis does not necessarily ensure good dynamic cosmesis.

Extended Physiological Proprioception (e.p.p.): A concept used to explain how a person is able to extend the body's proprioceptive capabilities into objects held in the hand or controlled by physically linking the object to a physiological joint.

Externally Powered: Driven by power from a source external to the body—e.g., batteries to drive an electric motor.

Feed Forward: Process control in which changes are detected at the process input and an anticipating correction signal is applied before process output is affected.

Flexion/Extension: The act of bending/unbending or condition of being bent/extended; decrease/increase of the angle between the bones forming a joint (e.g., in bringing the hand to the mouth the elbow of the arm flexes).

Incidental Feedback: Those forms of sensory information that are available to the amputee by default rather than by design (e.g., pitch of an electric motor in an electric hand).

Instability: A condition of a control system in which excessive gain or positive feedback causes persistent, unwanted oscillations in the output of the system or in which the output moves to a constraint from which it cannot be controlled.

Joint Articulations: A joint between rigid parts of an animal body.

Kinematics: The branch of mechanics or biomechanics concerned with description of the movements of segments of the body without regard to the forces that cause the movement to occur.

Kinetics: The branch of mechanics or biomechanics having to do with forces and torques and the dynamic response of a mechanical system.

Krukenberg: The surgical separation of the remaining ulna and radius of the forearm stump after traumatic removal of the lower arm. This allows the ulna and radius to act as crude pincers. First described by the German surgeon Krukenberg in 1917.

Muscle-Tunnel Cineplasty: The surgical alteration of the muscles in a stump after amputation so that it is possible for them to impart motion and direction to an artificial limb. Developed in its modern form by the German surgeon Sauerbruch in 1916.

Myoacoustic: The acoustic sounds created as a by-product of muscle contraction.

Myoelectric: The electric signal created as a by-product of muscle contraction.

Neuroelectric: The electric signal created by the firing of a nerve.

Open-Loop: A system is open-loop when the system outputs are controlled by system inputs only, and no account is taken of *actual* system output.

Oscillation: Any effect that varies periodically back and forth between two values.

Passive Prosthesis: A prosthesis that is neither body-powered or externally powered.

Prehensor: A gripping device that may or may not look like a hand.

Remote Manipulation: The control of a manipulator that is physically remote from the operator.

Static Cosmesis: The appearance of a prosthesis when it is stationary. Good static cosmesis implies an aesthetically pleasing device.

Supplementary Sensory Feedback (s.s.f.): The deliberate attempt to provide additional sensory feedback, usually by mechanical means (e.g., mechanical vibration of the skin). These forms of feedback supplement the normal sensory feedback paths of the body.

Terminal Device: The gripping mechanism used by a prosthesis, robot, or manipulator.

Unbeatable-Position Servomechanism: The core of an extended physiological proprioceptive system. The input and output joints are physically linked to each other so that one cannot lag or lead the other.

Work Space: The volume surrounding an amputee that can be reached with the aid of prostheses.

INTRODUCTION

Prosthetic materials represent a subclass of biomaterials: those materials used in the fabrication and manufacture of medical and surgical devices and implants. A very wide range of materials has been used experimentally in such applications but few have been successful: Degradation of materials by harsh biological environments and adverse biological response both to materials and to their degradation products have limited successes to a remarkably small number of biomaterials. Applications for prosthetic materials vary from surgical instruments, superficial dressings, and fluid-administration equipment to indwelling but not implanted devices such as contraceptive barriers and dental restorations and to temporary and chronic implants, such as breast-augmentation devices, heart valves, and total hip and knee replacements (Fig. 1). Implantation is normally assumed to require professional (medical/surgical) intervention, to result in breaching of one or more epithelial layers, and to leave in place materials and/or components after the initial procedure. The overall performance requirements are similar in each application, modified by device design and functional requirements, tissue type contacted, device size relative to the patient, and duration of exposure. However, this review focuses primarily on those materials used for chronic (>30 days) implant (and some dental restorative) applications. The majority of these biomaterials have previously proven themselves in other demanding environments, such as in marine and aerospace applications, and have been selected and adapted for use as biomaterials.

Despite the limited materials choices available to designers, large numbers of implants are now being used in orthopedic, cardiovascular, and other applications, providing significant improvements in life quality and duration for perhaps as many as 18 million patients in the United States alone by 1994 (Moss, 1991). Serious problems, involving both materials deterioration and adverse biological response, have arisen in plastic and reconstructive applications, revealing the

need both for better understanding of biomaterials–biological systems interactions and for the development of improved biomaterials. Increasing success in implant applications is demanding qualification of biomaterials for service lives exceeding ten years and development of new materials to meet newer applications. More recently, biomaterials are beginning to be designed and fabricated *de novo,* and composite structures with organic-derived materials or living cells are in early stages of evaluation.

1. BIOMATERIALS

1.1 Historical Perspective

The dream of replacement of diseased or lost portions of the human body is probably older than the practice of medicine itself. With the advent of the organized study of medicine and of surgery, early attempts were made using tissues and body parts from other humans and from animals. These led almost universally to failure due to infection and what is now recognized as adverse immune responses, leading to rejection.

With the development of aseptic surgical techniques by Lister in the 1860s, the search for nonreactive biomaterials began. Early applications were limited to relatively noncorrodable pure metals, such as gold, platinum, and silver. The last material was successful as a result not so much of its inertness but of the relative tissue tolerance for its corrosion products, which have also proved to be bactericidal. Catgut and other natural materials were used as sutures; here tissue reaction plays a useful part in strengthening the wound scar by promoting modest inflammation and collagen elaboration. Real progress in the successful clinical use of biomaterials began to be made in the 1940s, with the development of sulfonamide and penicillin to treat local and systemic infections and the adaptation of more corrosion-resistant alloys, especially cobalt-based superalloys, as biomaterials. World War II experience in the internal stabilization of fractures with adjunctive use of blood transfusions provided dramatic reduction in both limb loss and mortality, proving the worth of surgical implants.

The postwar era saw a dramatic expansion in the availability of commercial synthetic polymers, many of which have subsequently proven useful as biomaterials. Perhaps the real watershed events, heralding the widespread modern use of chronic implants, occurred in the late 1950s when Furman and Robinson demonstrated the first successful direct electrical "pacing" of the heart and Charnley evolved the modern polymethylmethacrylate-cemented metal-on-polymer total hip joint replacement.

1.2 Definitions and Fundamental Concepts (Williams, 1987)

A *biomaterial* is most generally a nonviable material used in a medical device, intended to interact with biological systems. This interaction may be characterized by examination of the *host response,* the reaction of a living system to a biomaterial, and of the *material response,* the reaction of a biomaterial to a living system. While biomaterials may have a pharmacological effect or contain an active agent as a component, the term "biomaterial" is reserved to those substances that remain, at least for a period after implantation, in their original form and obtain their *primary* or intended effect through physical rather than pharmacological action. In the past, it was the practice to refer to successful biomaterials as being "biocompatible," suggesting that they generally displayed low or absent host or material responses, but more recently a *biocompatible material* is defined relative to a *specific* application as having acceptable host and material response in that setting. Chemical composition, materials form, processing, cleaning, sterilization, size relative to the host, site of implantation, host disease state, and expected service life as well as nature and amount of degradation products all affect biocompatibility. Thus, a biomaterial that is highly successful in one application may well fail in a different, although related, situation. Since biocompatibility is now viewed as a relative rather than an absolute attribute of candidate biomaterials, great emphasis must be placed upon application-specific materials qualification through the use of well-defined or standard test procedures, both *in vitro* and *in vivo*, and evaluation in relation to both positive and negative control materials, when they are available. Furthermore, since biological performance is so application dependent, regulatory practice tends to focus on the resulting devices and their human clinical performance rather than upon the biomaterials from which they are fabricated.

Biomaterials may be divided into four performance classes by host response; the search for materials in these classes also mirrors the historical development of the field of biomaterials:

1. *inert* materials, which elicit little or no host response;
2. *interactive* materials, which are designed to elicit or promote a specific host response, such as hard-tissue adhesion;
3. *viable* materials, possibly incorporating host tissue and/or live cells, which are capable of being actively remodeled and/or resorbed;
4. *replant* materials, consisting of live native cells or tissue, cultured *in vitro* from cells obtained previously from specific patients or donors.

Both viable and replant materials are perhaps more properly termed *tissues* but are expanding the definition of biomaterials because of their fabrication, before clinical use, through *in vitro* (bio)engineering intervention, termed *tissue engineering*. Thus some authors distinguish between manufactured or man-made biomaterials on one hand, and natural or native biomaterials, including live cells and tissues, on the other hand.

1.3 The Biological Environment

As is the case for all materials in engineering applications, the selection and development of implantable materials are strongly affected by the intended service environment. Conditions within the human body present a high-demand, largely invariant environment. This environment is remarkable aggressive, combining high chemical activity, similar to that encountered in tropical marine applications, but enhanced by the presence of free radicals and active, energy-using enzyme systems, with a highly variable spectrum of multidirectional mechanical stresses. However, *homeostasis*, the maintenance of conditions necessary for mammalian life, results in a specific local environment of any implant that is extraordinarily constant in both physical conditions and composition. Complex, multiple control systems exist to maintain this constancy for the sake of the health of the local cells and organs; thus, deviations from established conditions caused by the presence of foreign materials, such as implants, may be expected to incite restoring responses. It is these restoring responses and their adverse effects on both the materials and the host itself that frequently limit the usability of a material as a biomaterial. For this reason, it is common to speak of prosthetic applications as being *materials limited:* That is, the ability to design and contrive implants exceeds the biological performance of materials available for their construction.

Although it is usual to speak of a single biological environment, there are regional, age, and disease-state variations in conditions experienced by implanted biomaterials. Furthermore, specific cell types are capable of altering pH and $p\text{O}_2$ significantly in their immediate or *pericellular* environment. Finally, different patients may impose different requirements upon the same implant as a result of differences in individual expectations, activity level, and life setting, and evidence is emerging for patient-specific differences in host response to biomaterials. Investigation of the utility of a biomaterial for a specific implant application requires determination of the lifetime performance requirements for that implant, termed the *implant life history.* Stainless steel has been used in temporary sutures, in fracture stabilization, and in structural elements of heart-valve replacements. Brief consideration of these three applications suggests large qualitative and quantitative differences in expected implant life history, leading to an understanding of the more generally satisfactory performance of stainless steels in the first two applications as compared with the last one.

2. HOST RESPONSE TO IMPLANTED MATERIALS

2.1 Inflammatory Response

The response to implanted biomaterials is the normal wound-healing response, specific to the tissues involved in the implant site, modulated by the degree of trauma involved but complicated by the long-term presence of a foreign body, the implant. These responses take various forms, the most general of which, always present in formed (solid) tissues, is termed the *inflammatory* response. This is a cell-mediated response directed toward stabilizing the injured area, restoring physiological status *quo ante,* removing dead or damaged tissue elements and foreign material, and correcting the structural and functional loss due to the initial insult.

The four classical signs of inflammation are redness (*rubor*), swelling (*tumor*), pain (*dolor*), and heat (*calor*). The initial biological event is a rapid dilation of local capillaries and an increased "stickiness" of their endothelial cell linings. This attracts and permits invasion of a succession of cell types, some from adjacent tissues but most from circulating blood. First to arrive are *neutrophils,* small end-state cells that are capable of engulfing (*phagocytozing*) particles of up to 5–7 μm in maximum dimension, with maximum stimulation apparently occurring for particles in the 0.1–1.0-μm range. The primary role of neutrophils is to ingest tissue fragments, foreign particles, and bacteria, which they degrade and digest by release of stored enzymes. Neutrophils are a part of the leukocyte lineage of blood cells, and they are accompanied and succeeded by *eosinophils,* another end-state phagocytic cell type, and by *monocytes,* a larger, more versatile phagocyte. Monocytes circulate in blood and are also resident in tissue, in the form of *histiocytes.* When attracted to injury sites, monocytes undergo morphological changes associated with cellular activation and are termed *macrophages.* They have metabolic capabilities and, more importantly, as a consequence of interaction with both native and foreign materials, can synthesize and release a wide range of cellular mediators, collectively termed *cytokines,* which serve as chemical messengers to a wide range of cells involved in both nonspecific and specific host responses.

If the local insult persists for prolonged periods, such as is the case in the presence of a solid, somewhat reactive implant, monocytes can fuse to form multinucleated *foreign-body giant cells,* of up to 80–100 μm in size, which are capable of engulfing much larger particles and greater volumes of foreign material than smaller mononuclear phagocytes.

Finally, in the case of healing in the absence of a solid foreign body, the injured area, cleared of dead tissue elements and foreign debris, undergoes remodeling or *resolution.* This is mediated primarily by biosynthetic cells, termed *fibroblasts,* and the results are tissue specific: Skin and muscle injuries lead to collageneous union or scarring, cartilage injuries to formation of a provisional or fibrocartilage, while cortical and cancellous bone may partly or completely regenerate. Specific tissues, such as cartilage and bone, may be reconstructed by specialized cells, in this case *chondroblasts* and *osteoblasts,* respectively, leading to regeneration rather than collageneous scarring.

The presence of an implant generally interferes with this succession of processes. Chemical reactivity of the implant may prolong the latter stages and prevent the final, or resolution, stage, producing chronic inflammation. However, if this does not occur, and in the absence of an adverse host response, such as a specific immune response, infection, or neoplastic transformation (*carcinogenesis*), resolution of an implant site will proceed to one of four end points:

1. *Extrusion:* Implants in contact with epi-

thelial tissue (skin and the lining of natural internal body cavities) will be surrounded by a downgrowing extension of such tissue, directed toward extruding the implant from the body. This is termed *marsupialization,* because of the resemblance of the tissue to a kangaroo's pouch.

2. *Resorption:* If the implant is degradable and resorbable, the tissue site may condense to a collapsed scar or, in the case of bone, completely remodel to normal (regenerated) tissue.
3. *Integration:* For a very limited number of materials, such as "bioactive" glasses of selected compositions and some metals, such as pure titanium, direct "bonding" or apparent adhesion to normal tissue may take place.
4. *Incapsulization:* In the most general case, the implant is surrounded and walled off from normal tissue by a collageneous, relatively acellular tissue termed *capsule,* which much resembles scar tissue. The thickness of this tissue, and its cellular content, predominantly histiocytes, reflect the chemical reactivity of the implant, its ability to move relative to the surrounding tissue, and features of its surface geometry. In a bony location, the capsule may be mineralized and is called a *sequestrum.*

If the implant site becomes infected, either because of previous infection, by bacteria carried in during surgery, or by bacteria seeded through the vascular system from a distant postoperative infection site, the presence of an implant interferes adversely with host defense mechanisms. The geometry of the implant–tissue interface plays a role, as may local suppression of macrophage function by corrosion and dissolution products. Implant-site infection frequently is accompanied by a local acidosis, which can increase the corrosion rate of some metallic implants. Finally, many bacteria are capable of forming a protective enveloping film (*glycocalyx*) on the surface of implants, and, as a result, implant-site infection usually requires surgical removal of the implant as an element of treatment.

Particulate debris, introduced during surgery or released by corrosion or wear processes, also has potentially adverse local and remote effects. If the particles are such that cellular degradation is limited or impossible, such as for many implanted materials, then cytokines released by phagocytes during attempted digestion produce potent stimulation of many other types of cells. This may induce local excessive fibrosis (scar/capsule elaboration) and may provoke destruction of normal tissue, such as seen in cellularly mediated bone loss (*osteolysis* or *small-particle disease*) secondary to wear-debris production by total joint replacement prostheses.

2.2 Coagulation and Hemolysis

When foreign materials contact blood, coagulation occurs. In the intact system, this process, leading to the formation of a fibrin clot, termed *thrombosis,* and subsequent tissue repair, acts to minimize blood-fluid and cellular-element loss. It is relatively nonspecific and is triggered by a wide range of physical disturbances to blood and the walls of the vascular system. Coagulation progresses through two biological cascades, with a final common pathway.

The first, or intrinsic, pathway is triggered by activation of a protein, *factor XII,* also called the *Hageman* factor, by contact with a foreign surface (other than the healthy, intact, endothelial-cell lining of vascular processes). Simple physicochemical arguments suggest that any implanted biomaterial rapidly becomes coated with proteins and other biological molecules present in tissue fluids and blood. Such films are not stable but, like adsorbed layers on surfaces in gaseous milieus, experience a progression of molecular species and concentrations. This succession, termed the *Vroman effect,* after its discoverer, in the case of coagulation involves a succession of molecules including *kininogen, prekallikrein, fibrinogen,* and *albumin.* Many of these molecules, such as prekallikrein and factor XII, on surface contact, are altered in structure and molecular weight by the forces involved in surface adsorption and thus become new or activated species.

The other, or extrinsic, pathway is triggered by release from damaged cells of *factor III,* also called *tissue thromboplastin,* and its activation by surface contact. Both pathways lead to activation of *factor V,* release of *prothrombin* (and its activation) from *platelets,* small circulating blood elements, and to the eventual activation of *factor XIII* leading to the formation of a fibrin clot.

Clots incorporate living and dead cells in a fibrous fibrin network. They may be adherent, in which case they cause local disruption of blood flow, or nonadherent, in which case they are shed and trapped in downstream capillary beds, producing damage in remote organs such as lung, kidney, and brain. There have been many approaches to minimizing thrombosis by implant materials, but most focus on presenting smooth, "slippery" surfaces with surface energies, as measured by *critical surface tension* (γ_c), near 25 dyn cm, to circulating blood. Prevention of thrombosis, particularly in blood vessels smaller than 6 mm in internal diameter, remains one of the key problems in biomaterials.

Hemolysis is the release of hemoglobin, the primary oxygen-carrying complex, from red blood cells (*erythrocytes*) primarily as a result of mechanical damage to their cell walls. It is desirable to avoid hemolysis both because of the intrinsic toxicity of hemoglobin and because of the loss of oxygen-carrying capacity due to cell loss. Both the roughness and the surface energy of biomaterial surfaces play small but significant roles in producing hemolysis. However, the dominant mechanism is mechanical, either by adverse hemodynamics produced by blood flow through implants or external blood-processing systems such as blood oxygenators, since shear stress above 1500–3000 dyne/cm^2 can cause direct noncontact cell lysis, or through physical impact, such as in heart-valve closure.

2.3 Adaptation

Mammalian tissue grows and remodels by cellular replication (*mitosis*), increase in individual cell size (*hypertrophy*), and cellular differentiation and maturation from stem-cell populations (*regeneration*). These processes, which direct normal development and restoration of the effects of physical damage and disease, are affected by the presence of implants. The abilities of tissues to adapt themselves to local requirements, including reaction to the chemical, physical, or electrical properties of implants, are collectively termed *adaptation.*

A naturally occurring example of adaptation is the progression of tissue types seen in the healing of bone fractures. This involves four stages of development. An initial *hematoma* stage rapidly progresses to the *soft callus* stage, in which a mass of mineralized collageneous tissue (*callus*) bridges the fracture plane and restores bone stiffness. This soft callus adaptively remodels to a more organized *hard callus* and then to restoration, by *remodeling,* of the original form of the bone before fracture. These last two stages are apparently driven by physical signals resulting from mechanical stress applied to the bone and associated tissues and are an expression of Wolff's law, usually understood as "The form being given, tissue adapts to best fulfill its mechanical function" (Wolff, 1892).

If a fractured bone is stabilized by implants, the adaptive response includes reduction in the volume and stiffness of the hard callus as well as, in the long term, decreased density of bone, as a consequence of load sharing between the implant and the hard tissue. This latter effect is termed *stress shielding* and also occurs in association with medullary (central) fixation elements of partial and total joint replacement devices. In the case of replacement of the femoral head with a metallic component with a intramedullary fixation element, rarefication (*osteoporosis*) and resorption occur in the proximal cortical bone, especially on the medial side, where mathematical analyses predict the greatest reduction in peak stress (from the stresses encountered in the intact bone) while overgrowth (*hypertrophy*) occurs at the distal end of the device, where elevated stress concentrations are expected. Reduction in the relative stiffness of the implant element coupled to bone, by replacing the metal alloy used by one with a lower elastic modulus or by reducing the average areal section moment, reduces the magnitude of these effects in experimental animal models.

Hard tissue also shows other adaptive responses. Healing bony tissue will grow onto implant-surface features of almost any size and into interconnected pores of at least 100 μm in diameter. Nonloaded implants or ones located in regions in which bony tissue is not normally found, such as medullary spaces, display later resorption of such ingrown tissue.

Soft tissue also shows adaptive effects, primarily related to use or disuse. Although there are general claims made for a soft-tissue adaptive law similar to Wolff's law, the evidence is much less clear than in the case of hard tissues. While excitable soft tissue (muscle) clearly adapts to use, there has been no widespread success in mediating soft-tissue response to implants. Perhaps the most pressing problem has been the desire to direct the formation of a new endothelial-cell layer on the inner wall of blood-conducting devices, such as arterial grafts. Despite many claims to the contrary, the primary response still seen is a firm fibrin clot, with occasional islands of endothelial cells (a *pseudointima*), rather than the desired mature, continuous endothelial-cell lining or *neointima*. Similarly, attempts to regenerate tendons and ligaments by providing a disintegrating or resorbable scaffold most generally still lead to elaboration of scar tissue, with some functional reorganization, rather than to formation of an appropriate vascularized, enervated tissue replacement.

Finally, there is a growing recognition that electrical signals may play various roles in the natural organization and maintenance of both hard and nonexcitable soft tissues. Research and clinical application have shown that faradic, capacitive, and more complex electromagnetic signals at field strengths that produce tissue potential gradients of 0.1–1 mV/cm are able to produce a range of stimulatory effects, although the biological mechanisms are as yet unclear. The former effect, of stimulation of growth by a negatively charged (cathodic) electrode, represents a special case of an implanted biomaterial. The primary clinical application has been in the treatment of recalcitrant *nonunions,* i.e., fractures of bone that will not unite without further treatment.

2.4 Immune Response

In addition to the nonspecific responses to foreign materials described in Secs. 2.1 and 2.2, specific composition- and/or structure-mediated responses, termed collectively the *immune* reaction, are produced by a system of agents and cells that reside in all mammalian tissues. This system is based upon the production of specific molecules (*antibodies*), which recognize and combine with foreign materials, or *antigens.* With the exception of introduced proteins, as in the case of implants fabricated from insufficiently processed human or animal tissues, the local biological reaction to biomaterials is actually mediated by reaction to adsorbed native proteins whose structure and/or composition may be altered by chemical or physical reaction.

The common recognized form of immune response is a *type IV delayed hypersensitivity.* This is produced by *antigen* reaction between antibodies bound to the surface of a leukocyte subpopulation, the *T lymphocytes,* and has local clinical hallmarks of chronic inflammation, except that both *lymphocytes* and *neutrophils* may persist in the implant site for very long periods of time.

Systemically, remote-site *dermatitis* (skin irritation), secondary to release of free antibody, is a recognized complication of biomaterial implantation. A large but controversial clinical and experimental literature exists that suggests the possibility of exacerbation or possibly primary causation of a number of immune-system disorders, including *asthma, scleroderma, myositis,* and *lupus erythematosis.*

Metals, particularly chromium, cobalt, and nickel, can produce such immune responses, with the antigen probably being a *hapten* or complex formed between corrosion products and soluble proteins. Immune sensitivity to metals, primarily due to workplace exposure, is a well-recognized clinical phenomenon with perhaps 10% of adult populations in developed countries sensitive to at least one of these three metals. Activation of a prior sensitivity and acquisition of new sensitivities have been demonstrated as consequences of chronic implantation of metallic biomaterials. Despite the existence of a number of convincing case reports, the quantitative contribution of specific immune response to the causality of more widely recognized adverse clinical symptoms, such as pain, local swelling, and loosening of devices anchored to bone, has not been clearly established. A long-term concern is the ability of these haptens to suppress the chemotactic abilities of neutrophils in sensitive individuals, thus possibly interfering with resistance to bacterial infection in implant sites.

Some monomers, especially methacrylate

monomer, released from polymers, have been shown experimentally to cause human immune sensitivity, especially after repeated contact, as experienced by dental laboratory technicians, but demonstration of clinical symptoms related to implantation of such materials is still unclear. There is current significant clinical concern about immune response to poly(dimethyl)siloxane (silicone elastomer), especially in the form of gel released from breast-augmentation implants. Although immune-system disorders are reported by some patients and several investigators have apparently detected specific antibodies to finely divided silica (silicon oxide) and to silicone elastomer, the causal relationship between the presence of such antibodies and clinical symptoms is unproven, as is the general case for all such responses.

Human immune responses to either permanent or resorbable implanted ceramics have not been reported.

2.5 Carcinogenesis

Cancer (*neoplasia*) in mammals is recognized as uncontrolled multiplication and spread within the individual of abnormal forms of host cells. The key features of such growth are seemingly uncontrolled cellular replication, autonomy of growth, and intrusion into other tissues and organs. Such neoplastic growth is the direct consequence of inheritable changes in cellular genetic code.

Cancer is a multiphase process that can be initiated and/or promoted by a variety of conditions and agents. The two primary mechanisms of concern related to the use of implanted biomaterials are *chemical carcinogenesis* and *foreign-body carcinogenesis.*

There is a widespread societal concern about chemical carcinogenesis. Alarm concerning dioxin contamination, due to industrial accidents as in Serveso, Italy, or deliberate dispersion, as in Times Beach, Missouri, in the U.S., and concerning Alar™ pesticide residues on fruit has tended to obscure some of the realities of our 20th-century experience with cancer.

Despite the common perception that cancer is increasing, overall age-adjusted cancer death rates, with the exception of death due to lung cancer and, perhaps, brain cancers, have remained constant or, in the case of cancers of the liver, the stomach, and, in women, the uterus, have declined steadily over the past 50 years. However, increasing life expectancy, especially in the older, more cancer-prone segments of the population, and reductions in age-adjusted death rates due to heart attack and stroke have increased the relative incidence of death due to cancer. This combined with the continuing increase in deaths of men due to lung cancer, believed largely related to increases in tobacco smoking since WWI, and a parallel incidence increase for women since the 1960s have further heightened the impression of overall increase.

Similarly, repeated "scares," such as previously noted, have conveyed the impression that "everything" causes cancer. Insofar as chemical agents are concerned, the opposite is the case: While there are probably more than 1 500 000 identified chemical compounds, only a few thousand of these are suspected carcinogens, based upon observations in animals, and fewer than three dozen can be classified as known—that is, presumptive—carcinogens in humans.

However, despite this relatively rosy outlook, there are continuing concerns about possible chemical carcinogenesis related to the use of chronic implants. Nickel, cobalt, and hexavalent chromium are presumptive human carcinogens, and other agents, including vanadium and some polymeric degradation products, especially those released by polyvinyl halides and some polyurethanes, are suspected human carcinogens.

Despite the long history of the use of many biomaterials, the evidence for implant-mediated chemical carcinogenesis is sparse. Chemical carcinogenesis typically requires a long latent time between exposure and tumor expression: At low doses in humans, this period can easily exceed twenty years, as is the case for asbestos-induced *mesothelioma* (a tumor of the lining of the chest cavity). Many implants, such as orthopedic or cardiovascular devices, are placed in tissues that show low intrinsic rates of neoplastic transformation. However, there are now several apparently reliable reports of implant-site tumors occurring ten years or more after total hip replacement with components fabricated of stainless steel and/or cobalt-based alloys.

Epidemiology of implant patients is sufficiently weak that there is great difficulty in relating release of corrosion or degradation products from one site with possible changes in incidence and/or progression of tumors in other sites. Several studies of total hip joint replacement patients suggest the possibility of an elevated incidence of tumors of the circulatory system, especially lymphomas, which is consistent with the concern for such possible systemic or remote-site causation. Interest in this clinical area remains active and is encouraged by an apparent trend to implant permanent orthopedic devices in younger patients.

Foreign-body carcinogenesis is well recognized in rodents. In many strains of mice and rats, subcutaneous implantation of chemically inert solid materials, of a wide range of compositions, results in neoplastic transformation of the adjacent soft tissues. This phenomenon was first observed in the 1940s and has come to be called the *Oppenheimer effect,* after its discoverers. Concern about the possibility of such an effect in human clinical populations has been widely expressed, especially in relation to implants used in plastic and reconstructive surgery, which are often placed in analogous tissue sites. Extensive retrospective clinical follow-up studies have failed to demonstrate elevated tumor incidence (vs operated but unimplanted soft-tissue sites) for periods of up to fifteen years. While these negative findings are encouraging, they should be viewed with caution, as latency times may be extremely long for such chemically passive implants, and implant-site inflammation, due to chemical or mechanical irritation, tends to suppress such tumor formation in animal models. Furthermore, the histological appearance of the tissue capsule surrounding chronic implants closely resembles the *benign fibrous histiocytoma* associated with tissue volumes in which local blood circulation has failed, such as *infarcts* in bone. Such conditions in nonimplant sites display a low but significant rate of transformation to *malignant* fibrous histiocytoma, a tumor type that is the most frequent of the tumors reported in implant sites. However, it may prove to be the case that the human immune system, which is much more sophisticated than that of rodents, may be able to provide long-term protection from foreign-body carcinogenesis.

2.6 Metabolic Effects

Mammals have a well-developed circulatory system that supplies oxygen and nutrients to cells in all tissues while conveying metabolic and catabolic end products to excretory organs. This system is characterized by relatively high flux rates in the presence of local maintenance of chemical composition and concentrations.

There are two major consequences of this situation that are of importance in the consideration of the effects of implants on metabolic processes. First, tissues are extremely clean or pure, with the elements oxygen, carbon, hydrogen, and nitrogen, in declining order of abundance, making up 96.9 wt % of all tissues. Second, other elements (apart from the so-called *physiological elements:* calcium, phosphorus, potassium, sulfur, sodium, chlorine, and iron), although present typically at only parts per billion to parts per million concentrations, have closely controlled concentrations and play "catalytic" or amplified roles in metabolic processes. For example, chromium, with a total body burden (in a 70-kg individual) of <6.6 mg and a daily dietary intake of ~0.2 mg, is an essential constituent or cofactor in all sugar metabolism, Cobalt, although a key ingredient in the essential vitamin B_{12}, is sufficiently toxic that it is absorbed only in trace amounts as a bacterial preformed compound (*cobalamine*) and thus is the rarest quantified element in the mammalian body, with a typical human body burden of <1.5 mg.

Dietary materials enter the human body through the gastrointestinal (GI) tract, primarily by way of active (energy requiring) absorption processes. Passing through this first control interface, the GI intima, they are taken up and distributed through the circulating plasma pool, involving both arterial blood supply and venous blood and lymphatic fluid return. In a 70-kg individual, this volume contains ~3.2 L of water and is coupled to the GI tract through fairly rapid diffusion and exchange coefficients, which are dependent upon molecular weight, molecular composition, and deviation from normal (control) concentrations of solutes. The plasma pool communicates directly with an interstitial pool (~15.7 L) that consists of all extracellular fluid within the tissues outside of the circulating blood and lymphatic pathways. This interstitial pool is subdivided kinetically into a "fast" compartment (~8.4 L), probably representing ions and molecules in solution, and a "slow" compartment (~7.3 L), probably representing precursor combination and physisorption to cell walls and membranes. The fast compartment, in turn, communicates with cellular function through both active transport and passive diffusion across cell walls. The intracellular space, containing genetic material and in which metabolic and catabolic processes occur, has an effective volume of ~23 L, representing 55% of body water content and 33% of body weight.

Soluble degradation products from implants, whether released by dissolution, leaching, or corrosion, effectively pass initially into the fast interstitial compartment. Thus the act of surgically implanting a biomaterial bypasses at least one and probably more regulatory barriers. Released materials may then enter local cells directly or pass into the plasma pool where transport and remote-site storage compete with excretion through renal excretion and bile synthesis pathways. Clinical studies of patients and analyses of cadavers with metallic implants have shown small but significant serum concentration elevations of metal content (50%–300%) that can be related to 10–100-fold elevations in tissues both surrounding the implant and in remote-storage tissues, especially in the liver, even in the presence of satisfactory clinical performance.

All metallic ions released are rapidly complexed with organic molecules, binding either nonspecifically to albumin or specifically to high–molecular-weight carrier proteins from the immune globulin family. These binding processes usually represent relative amplification of normal physiochemical processes, related to transport, utilization, storage, and excretion. However, differing metallic ionic radii with multiple valence states may result in adverse biological consequences because of ionic species competition. Thus, chromium[III] may compete with iron[III] for binding to *transferrin,* the normal iron carrier molecule, reducing tissue iron availability and inducing relative *anemia,* as shown in animal studies. Similarly, the higher binding avidity of aluminum[III] than of magnesium[II] to many organic ligands may play a role in aluminum's ability to induce osteoporosis and possibly promote Alzheimer's disease.

The issue of release of organic agents from implants is more complex. The presence of lipids and other nonpolar species in body tissues and fluids results in an ability to solubilize, transport, and store a wide range of both polar and nonpolar organic molecules. It is possible for released molecular species to resemble normal enzyme substrates sufficiently that they can enter normal metabolic pathways. In some cases this leads to simple catabolic degradation; however, metabolic intermediates, such as aromatic amines produced by metabolism of some low–molecular-weight polyurethanes, may have unexpected toxicity. There is a poor understanding of the metabolic/catabolic pathways for all but the most simple synthetic organic molecules, leading to a common practice of performing metabolic fate studies, utilizing radiotracer-marked materials in a small-animal model, as part of the biocompatibility testing and qualification of new biomaterials.

Finally, cell-mediated and passive transport of wear and other small debris from implant sites is often observed. Surgical exploration reveals accumulation of macrophage-borne debris in regional lymph nodes near the implant site, while animal and human cadaver studies demonstrate transport of debris to remote organs, including the lungs, liver, and spleen. Asymmetric particles, such as wire fragments, can move passively through tissues to great distances, as a result of muscular contraction and relaxation forces. The biological significance of such findings is still in dispute, as is the general issue of bioavailability of biomaterial degradation products in general: That is, the mere finding of a foreign material within a tissue may not be easily related to the effect that its constituents can have upon intracellular processes.

3. MATERIAL RESPONSE TO IMPLANTATION

3.1 Swelling and Leaching

Implanted materials are placed in an aqueous phase with both polar and nonpolar components. Thus, there is the possibility for exchange of solutes between the implant and the surrounding fluids and tissue elements. This is a consideration in the use of polymers as biomaterials.

Polymers, as fabricated for a variety of industrial applications, usually contain a wide range of additives, including plasticizers, fillers, colorants, and mold-release agents as well as residual catalysts, monomer, and, in the case of chemosets, reaction products. When these polymers are adapted for biomaterial use, there is a general policy to eliminate or at the least minimize such low–molecular-weight products that can be removed by leaching. Unfortunately, in many cases, a residual level of plasticizers and low–molecular-weight polymers is required to produce fabricatability and maintain desirable mechanical properties. Leaching of these materials may cause local inflammation, generally related in magnitude to the interfacial concentration of such species. Loss of low–molecular-weight species from polymers may result in increased tensile modulus, thus stiffening the implants, but also may reduce yield strength.

The ability of polymers to release low–molecular-weight species by diffusion is used in the fabrication of reservoir systems for release of antibiotics and other treatment agents. A common example is the use of antibiotic-impregnated PMMA during total joint replacement after removal of a device from an infected site. The combination of a high–diffusion-rate reservoir with a low–diffusion-rate "metering" membrane can provide relatively constant rates of release over periods of months. This design approach is used in the design of implantable fertility-control systems.

Polymers can also absorb water and, in some cases, lipids and other nonpolar solutes. In addition to generally decreasing tensile modulus and raising yield stress, absorption may reflect a lack of osmotic equilibrium with the local biological environment. Under this condition, absorption may generate sufficient internal pressure to cause static tensile failure, seen as cracking and crazing.

3.2 Corrosion and Dissolution

All metallic materials will release elemental metals as a consequence of implantation. Alloys intended to serve as biomaterials are selected both for their low intrinsic or uniform corrosion rate and for the biological acceptability of the released corrosion products. Thus, the principal alloy systems in use are ones that are either electrochemically noble (gold or platinum based) or are able to be rendered highly passivated by preimplantation chemical formation of surface oxides/hydroxides. The primary alloy systems used are thus low-carbon stainless steels and cobalt-based superalloys (both rendered passive by chromium–oxygen reaction layers) and titanium-based alloys, rendered passive by formation of TiO_2–Ti_2O_5 surface layers.

Two points are important to take note of with regard to uniform corrosion:

1. The traditional engineering definition of absence of corrosion (total dissolved metal concentration at equilibrium $\leq 10^{-6} M$) is an inadequate selector, since this threshold concentration corresponds to 50–60 ppb for metallic elements, such as cobalt and chromium, that have confirmed biological activities at two orders of magnitude lower concentration.
2. Protective nonconductive coatings, such as paint, or layers of sacrificial elements, such as zinc galvanize, generally cannot be incorporated into biomaterials because of the generally adverse host response to such materials and to their degradation products.

Initial *in vivo* uniform corrosion rates are generally predictable by suitable *in vitro* measurements, if performed in physiologic (0.85%) saline solution at values of pH and pO_2 appropriate to the intended application. Most useful biomaterial alloys, when evaluated at near neutral pH, after adequate cleaning and passivation, display uniform corrosion rates $\approx 10^{-8}$–10^{-7} g/cm^2 day (Steinemann, 1980), with titanium-based and noble alloys somewhat more corrosion resistant than passivated chromium-containing alloys. However, the presence of monatomic free oxygen radicals, hydrogen peroxide intermediates, and active specific and nonspecific protein ligands renders such determinations only approximate. Furthermore, in the absence of surface damage or relative movement between implant and adjacent tissue, the maturation of adsorbed protein layers and continued growth of passivating layers may reduce uniform corrosion rates with increasing time of implantation.

Unfortunately, the fabrication of biomaterials into functional implants produces a number of other corrosion effects that may produce adverse material or host response, including the following.

The high ionic conductivity of interstitial and other body fluids permits the possibility of galvanic corrosion when two metallic components of an implant have different electrochemical potentials as a result of differences in composition or processing. It is generally held that cobalt-based superalloys, titanium-based alloys, and bulk carbon (either pyrolitic or vitreous) can be coupled in this fashion without risk, but none of these materials are safely coupled to stainless steels.

Crevice corrosion is also a problem encountered when multipart devices admit body fluids into narrow, deep interpart spaces, such as the screwhead–plate interface in fracture fixation devices. Pitting, intergranular, and leaching corrosion may also take place but are usually related to inappropriate processing. Relative motion between passivated parts may lead to fretting corrosion as an apparently accelerated form of wear. In this respect, there is significant evidence that *in vitro* studies, in the absence of serum proteins, tend to overestimate the fretting rate for any particular configuration of components.

Detailed mechanistic study of *in vivo* corrosion is still at an early stage. However, evidence has been found in model systems that organic ligands can bind and remove metal without charge separation, that surface protein layers on metals turn over, producing continuing fresh binding, and that adsorption and diffusion of amino acids can alter corrosion rates, apparently secondarily to changes in the electrical conductivity of passivation layers. Finally, there is some evidence for direct biological corrosion, reflecting attempts by phagocytic cells, especially monocytes, to dissolve implants or, as previously stated, a strong acidic shift in *p*H in the presence of infection.

Both soluble (absorbable) polymers and ceramics, especially in the calcium phosphate systems, undergo passive dissolution, primarily controlled by local *p*H and concentration of dissolved species. At least two modes of *in vivo* dissolution are recognized: surface recession and internal dissolution. The latter, more common for hydrophilic materials, presents a possible hazard of fine particulate release, which may produce local adverse cellular response (see Sec. 2.1).

3.3 Bulk Mechanical Behavior

Mechanical function of biomaterials in implant applications is dominated by three fundamental intrinsic materials properties: elastic modulus, yield strength, and fracture (or ultimate) strength. These properties, when expressed in the design of an implant, affect respectively the ability to deform reversibly, the maximum load without irreversible deformation, and the minimum load to produce fragmentation. In specific applications, other mechanical properties such as hardness, toughness, ductility, creep rate, and fatigue strength may become important.

The elastic modulus, whether in tension/compression or in shear, is primarily determined by the nature of atomic bonding within materials and thus is little affected by exposure to the biological environment. The elastic moduli of metals, ceramics, and composites are very little affected by implantation. However, polymers may be affected by leaching and absorption (see Sec. 3.1) and by chemical processes that alter the pattern of covalent bonds within their bulk. In general, chain scission processes, which lower average molecular weight, tend to reduce elastic moduli while cross-linking tends to raise elastic moduli, particularly for polymers with large side groups. Implantation may also result in oxidation and a concomitant increase in moduli.

As is the case for elastic moduli, only polymers undergo real changes in yield strength upon implantation. The most usual reaction is an increase in yield strength, with a concomitant reduction in ductility and toughness. Thus many polymers become brittle after prolonged implantation.

Ultimate strength is dependent upon both bulk structure and surface properties. Metallic, polymeric, and ceramic materials, as fabricated into biomaterials, are all polycrystalline to a degree, thus possessing grain or domain boundaries. Corrosion, dissolution, and absorption phenomena all selectively affect these boundaries, reducing the strength of the material. Furthermore, most fracture processes depend upon propagation of defects to produce a fracture plane. Therefore, local surface or grain-boundary attack increases the number and size of such defects, reducing strength of the material.

Finally, corrosion processes, by promoting dissolution of passivation layers, generally act to reduce fatigue strength in low-stress, high-cycle applications. This phenomenon is especially seen in stainless steels but may also occur in cobalt-based alloy systems. Titanium-based alloy systems with their higher oxide stabilities generally do not show this effect, although high local chloride or sulfide concentrations may have a deleterious effect.

The effects of implantation on composites depend upon two factors: the effects on the phases of the composite and on the phase interfaces. If composite properties depend upon maintenance of particular interfacial property values, then *in vivo* degradation becomes extremely difficult to predict.

It is worth noting here that *in vitro* simulation of *in vivo* degradation of bulk properties is generally unsuccessful. While *in vitro* conditions designed to reproduce specific biological environments appear to produce lower average degradation than later encountered in *in vivo* exposure, the effects of specific biological processes, associated with enzymatic attack, molecular complexing, and surface calcification, are difficult to predict. Thus, long-term animal implantation studies are a prerequisite to clinical introduction of new material formulations.

3.4 Friction, Wear, and Lubrication

Tribological properties (friction, wear, and lubrication) (see TRIBOLOGY) become of extreme importance in applications in orthopedics and maxillofacial surgery that involve partial or total replacement of joints. Natural joints are highly developed structures in which the porous resilient articular (*hyaline*) cartilage on each side of the interface provides very low coefficients of friction combined with low wear rates and considerable ability to absorb energy in high-velocity impacts. Synovial tissues within the surrounding soft-tissue capsule of each joint secrete both low–molecular-weight phospholipids, which act as surface lubricants, and high–molecular-weight hyalauronates, which assemble to carrier proteins to produce bottle-brush-shaped, extremely hydrophilic complexes, rendering the resulting joint fluid viscous and maintaining joint surface separation. A final lubricating feature of cartilage is its high water content (<70%), a portion of which is expressed reversibly under load, providing a high-pressure fluid film that aids in reducing both friction coefficients and wear rates.

Joint replacement materials are nonporous and rigid in comparison with cartilage. The most common wear pair in use today is cobalt-based superalloy (either cast or forged) articulating against ultrahigh–molecular-weight polyethylene (UHMWPE). This and other combinations work best when the UHMWPE component is either concave or flat; convex components show a 3–5-fold higher wear rate. Synovial tissues left in the site after surgery reproduce a nearly normal synovial fluid as a lubricant. This combination demonstrates *in vivo* an adequate dynamic coefficient of friction of 0.05–0.10 (~15–20-fold higher than the natural joint) with a linear wear rate (in the hip) of about 0.1 mm/yr.

The wear observed in this material combination is primarily of the UHMWPE, and 70%–90% of the resulting particles are <1 μm in maximum size. Wear rates in knee replacement applications are similar, but fewer, somewhat larger particles are typically produced. The principal wear mechanism appears to be a combination of abrasion, adhesion, and fatigue. *In vitro* simulations in the absence of proteins or hyalauronates produce polymeric transfer films that are periodically shed, resulting in cigar-shaped particles as long as 300 μm; however, these are very rarely seen in recovered human tissues. UHMWPE, because of its softness, is quite prone to plowing damage by the roughness of the counterface. Thus scratching of the metallic head or inclusion of "third bodies" (metal fragments, bone chips, etc.) into the interface can produce dramatically accelerated polymeric wear. As a result, titanium and titanium alloys have proven less successful as articulating counterfaces for UHMWPE. No other polymers have been found so far that routinely display lower *in vivo* wear rates than UHMWPE.

Harder, smoother surfaces, such as alumina and zirconia, appear to produce lower polymeric wear rates when articulated against UHMWPE. So-called "hard-on-hard" articulating pairs, especially metal–metal (cobalt-based) and alumina–alumina, while having somewhat higher coefficients of friction, have wear rates reportedly as low as 2.5–5 μm/yr. However, design problems and concern about biological hazards associated with cobalt-alloy use and about brittle fracture of ceramics have limited the use of these European systems in the U.S. so far primarily to clinical trials.

4. BIOMATERIAL APPLICATIONS: PROSTHESES AND ARTIFICIAL ORGANS

4.1 Orthopedic

Orthopedic implants may be divided into two main categories: those used for treatment of trauma and those used in musculoskeletal reconstruction.

The use of implants in treatment of musculoskeletal trauma is of ancient origin but, as previously noted, gained real momentum during WWII, due to the availability of improved, more corrosion-resistant alloys, sulfonamides and antibiotics to fight infection, and blood transfusions. These advances made it possible both to preserve life of the multiply injured soldier and to perform extensive reconstructive surgery in areas, such as the skull, neck, shoulder, spine, and hip, where extensive blood loss would be expected because of the anatomic inability to apply pressure bandages or tourniquets. German surgeons, especially Küntschner, pointed the way; their advances were eagerly imitated by French, British, and U.S. surgeons with much of the postwar development then occurring in Switzerland, within a surgical-industrial alliance called the AO-Group. The result is that today there is an extensive armamentarium of hardware for treatment of almost any fracture, from massive disassociation fractures of the pelvis to isolated fractures of the small bones in the wrist, hand, and foot. The material of choice for most of this hardware is one or another variant of a low-carbon version of 316 stainless steel, alloys containing typically ~18% chromium, ~14% nickel, and typically less than 0.08% carbon. These alloys combine good corrosion resistance and low relative cost with moderate tensile and fatigue strength yet are sufficiently ductile so as to permit intraoperative adjustment of implant shape. Although modern alloys in this family are quite stable for long periods of implantation, such hardware is still viewed as a temporary implant and it is recommended that it be removed by two years after implantation, if the patient's medical condition and life expectancy warrant a second procedure, because of concerns for stress shielding, secondary hematogeneous infection, and release of corrosion products. Recently, polylactic–polyglycolic copolymers have been used as isolated resorbable pins, screws, and connectors to obviate the need for later removal, but lack of strength and concerns about premature dissolution have limited this development.

The great breakthrough in orthopedic procedures involving biomaterials has been the increasingly successful total replacement of the knee and hip joints. These joints may be damaged by trauma, be attacked by infectious or autoimmune diseases, or simply wear out through overuse or old age. Previous to the 1950s, surgical correction depended upon anatomical realignment (*osteotomy*), various procedures involving interposition of natural or artificial materials, or fusion. The general result was continued disability and reduction of life expectancy, due to loss of cardiovascular capability.

John Charnley, working at Wrightington, U.K., developed a total hip joint replacement (THR) combining the following elements: a polymeric acetabular cup, bedded in the pelvis with cure-in-place chemosetting methyl methacrylate (PMMA) "bone cement," and a metallic femoral component with a small-diameter (originally 22 mm) head, also secured with bone cement (Fig. 2). The combination of the metal–polymer [originally stainless steel–polytetrafluoroethylene (later quickly replaced by UHMWPE, molecular weight ~3–6 million)] articulating interface with the nonadhesive PMMA cure-*in-situ* grouting material to distribute stresses to the underlying bone has proven so successful that such systems now can be expected to show survival [= absence of surgical revision (re-

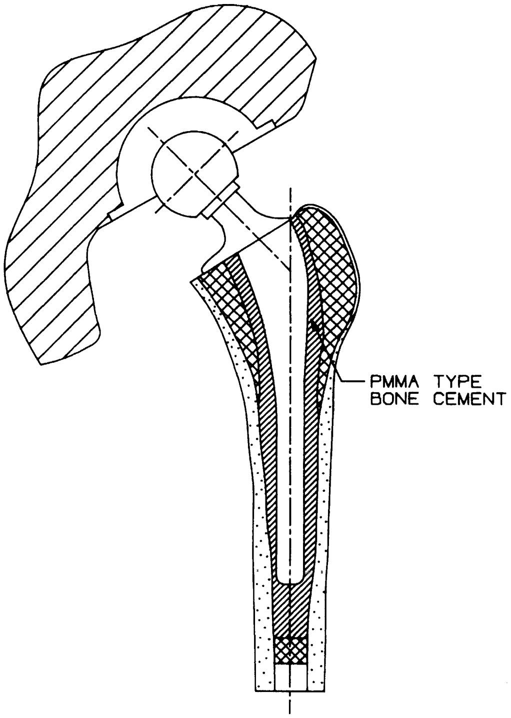

FIG. 2. Generic PMMA-cemented total hip replacement utilizing the design elements introduced by Sir John Charnley. Modern surgical technique involves meticulous preparation of the bony beds, sizing components to provide thin (2–3 mm) uniform cement mantles, and pressurization of cement after insertion. (Courtesy Howmedica Orthopaedic Div., Rutherford, NJ.)

placement) for pain related to loosening] of >95% at ten years after insertion. This has resulted in an estimated U.S. clinical population of perhaps 1.5 million THR patients, with an annual operative rate probably exceeding 120 000.

Modern developments include the substitution of high-strength cobalt-based alloys (typically 27–30 wt % chromium, 5–7 wt % molybdenum, various minor alloying agents, balance cobalt) for stainless steel in the femoral component, the use of modular or multipart components permitting better fitting of the device to the underlying bone, and use of ceramic femoral heads for lower polymer wear, and introduction of alternative fixation systems, frequently applied to lower-modulus titanium-based alloys (such as 6 wt % aluminum, 4 wt % vanadium, balance titanium), utilizing porous metallic or "bioactive" calcium hydroxyapatite surface coatings. Concerns remain for the long-term failure of these devices, used both with and without PMMA cement, secondary to osteolysis mediated by submicron UHMWPE wear debris.

The same technology has also yielded great success in replacement of the knee, with such procedures possibly now exceeding total hip replacement in frequency, and with somewhat less success in replacement of the shoulder, elbow, ankle, and small joints in the hand and wrist. The latter applications are dominated by relatively non-load-bearing alignment or spacing devices, fabricated primarily from silicone elastomer with various fabric reinforcing elements. Polymeric materials are also used for replacement of ligaments but with quite poor long-term clinical success.

Ceramics are little used in orthopedic applications because of their inherent susceptibility to brittle fracture under tensile or shear loading. Alumina and, more recently, zirconia have been used as femoral heads in THR, particularly in Europe and Japan. Various resorbable or nonresorbable ceramic materials, primarily calcium phosphates such as calcium hydroxyapatite and tricalcium phosphate, have been used to augment or replace bone grafts.

4.2 Cardiovascular

The use of implanted biomaterials in treatment of cardiovascular disease has centered on three applications: repair of the valves and body of the heart, partial or total replacement of the heart, and replacement of portions of central and peripheral arteries and veins. All three applications have been hindered by a continuing inability to provide truly thromboresistant (nonclotting) artificial surfaces to circulating blood.

There have been various attempts to replace lost valve function in the heart. Modern designs provide either a passive movable occluder, such as a ball, or flapper elements, which are constrained by a ring and/or cage enclosure. Figure 3 illustrates a typical modern design in which a single free pyrolitic carbon disk is retained by a series of struts in a titanium-alloy ring covered with a woven polyester or polyethylene terephthalate

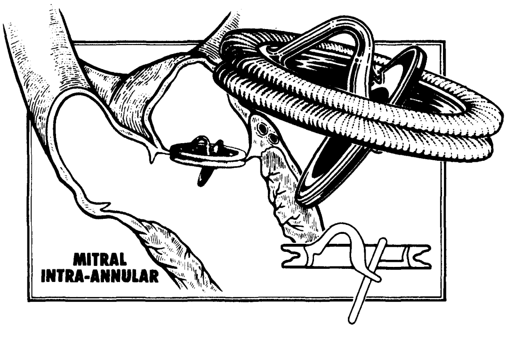

FIG. 3. Modern mitral valve replacement of the Hall type. This valve is passive, requiring blood backflow during diastole to close the orifice during a portion of each heartbeat cycle. (Courtesy Medtronic, Inc., Minneapolis, MN.)

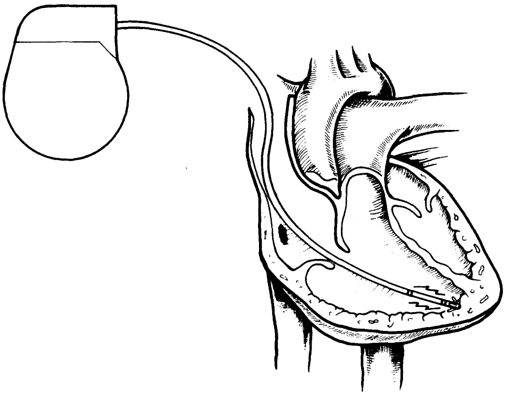

FIG. 4. Single-chamber pacemaker system. The different environments and performance requirements require different materials and combinations for each component (left to right): pacer, lead (with insulation), and dipole stimulating electrode. (Courtesy Medtronic, Inc., Minneapolis, MN.)

sewing ring for attachment to the opening left after excision of the diseased natural mitral valve. Continuing problems exist associated with wear of the occluder and fragmentation of the sewing ring. The latter component presents a significant problem if implant-site infection occurs. Such infections also promote thrombosis and are sufficiently life threatening that surgical replacement is frequently necessary.

Valves are also fabricated from porcine heart valves, with various chemical processes used to increase tissue strength and reduce antigenicity. Note that such devices are not meant to be resorbable but permanent and are limited in their utility by a tendency for the tissue leaflets to calcify with time *in vivo,* in a manner similar to naturally occurring atherosclerosis. Perhaps 30 000 heart valves of all types are implanted annually in the U.S. with probably ten times that number in use (Moss, 1988).

The implantation of electronic devices to regulate heart activity and, more recently, to permit closed-chest resynchronization (*defibrillation*) of erratic heart activity represents another major advance in biomedicine. Early devices were bulky, had battery lives as short as 1–2 y, and frequently experienced mechanical lead failure. Figure 4 illustrates a typical modern design. The electronic components, with a lithium battery that may last 5–7 y, are enclosed in an electron-beam–welded titanium-alloy case that is implanted in the chest cavity. The pacing lead is typically fabricated of a high–spring-constant cobalt- or platinum-based alloy in a polyurethane or polysiloxane insulating sheath. The electrode assembly is made of similar materials and is designed to be self-retaining after insertion. This device illustrates the point that there is no "ideal" biomaterial: Biomaterials, with appropriate biological performance of the application, must be selected for the particular processing and performance requirements of each component of the particular design.

Nearly half a million (Moss, 1988) U.S. patients have heart pacers today, with the incidence expected to rise rapidly as the population ages and materials and device technology continues to advance.

Vascular prostheses, as well as patches for heart-wall defect repair, are typically knitted or woven from polyester fiber, although some are fabricated from nonwoven polyester and/or polytetrafluoroethylene materials. The success of these devices depends upon achieving an appropriate porosity, generally measured as water permeability. Higher permeabilities favor tissue growth through the wall of the implant, leading to a more viable neointimal layer. However, higher permeabilities also permit greater blood loss intraoperatively and in the early healing period. All of these prostheses tend to shed small thrombi and to encourage excessive tissue overgrowth (*hyperplasia*) where they are connected to natural vessels, particularly at the "downstream" end.

Although vascular prostheses below 5-6 mm internal diameter are used, they tend to become blocked by thrombosis within weeks to months after implantation and require surgical clearance or replacement. Such periodic replacement is preferred to limb amputation, but it is clear that the problem of the small-bore vascular prosthesis remains unsolved.

While extracorporeal blood pumps and oxygenators are in routine use in surgical procedures, attempts to produce long-term implantable artificial hearts and, more recently, left ventricular assist devices have been largely unsuccessful. The primary clinical limitation is the combination of hemolysis and small-thrombi shedding, which may result in regional lung and brain infarction, produced by the biomaterials lining the blood conduit. More successful has been repetitive renal dialysis, in the presence of kidney malfunction or failure. Many patients are able to tolerate the required 2–3 times weekly 4–6-h contact with biomaterials in the blood conduit; however, kidney transplantation, from either donors or cadavers, is still a more definitive and long-term solution. Although chronic arterial–venous shunts, of various materials, are implanted to ease this procedure, no implantable dialysis system is in use clinically.

4.3 Dental and Maxillofacial

Dental and maxillofacial implant applications include filling defects in teeth produced by infection (*dental caries*), replacing portions or all of adult teeth lost through trauma or disease, providing bony anchorage for artificial teeth or groups of teeth (*dental bridges*), and augmenting bone for preservation of teeth or for retention of removable dental devices (*dentures*). Because of the proximity of the mouth to the GI tract, concern for biological performance of dental implant materials is usually extended to a wide variety of materials used in preparing dental implants, including cleaning agents, adhesives and cements, and impression and casting materials.

The success of modern dentistry is based upon the widespread use of silver–mercury amalgams for replacing diseased tooth tissue (*enamel* and *dentine*). Typically these consist of a solid phase, 40–70 wt % silver, 22–30 wt % tin, 2–30 wt % copper, which is mixed just before insertion 1:1 with metallic mercury. The formation of various mercury-containing intermetallic compounds produces a relatively stiff, strong, self-retaining body, which can be used within an hour and matures in 5–7 days. More recent concern about the possibility of mercury release and its conversion to biologically active compounds, such as methyl mercury, has resulted in various ceramic-particle–filled polymer-based chemoset composites being used in this application.

Tooth replacements were traditionally made of gold alloys, with strengthening alloying agents added, covered by ceramic enamels for prosthetic considerations. Recently, other precious-metal alloys, as well as nonprecious-metal alloys, such as cobalt- and nickel-based superalloys, have begun to be widely used for crown and bridge prostheses, driven by cost considerations. Cobalt-based alloys are widely used for fully implanted components, such as alveolar ridge augmentations designed to support artificial teeth. In fact, the initial use of such alloys for biomedical applications was in the related field of orthodonture where they won favor as being "tasteless," in contradistinction to the stainless steel alloys that they have displaced.

Pergingival devices, such as tooth posts, that permanently penetrate soft tissue became widely successful over the past decade after the observation of Bränemark that bone would bond directly (*osseointegrate*) to the surface of chemically pure titanium. Retention rates exceeding 95% for periods of up to ten years have been reported. More recently, more complex structures, involving surface textures and internal pores to permit bone ongrowth or ingrowth, have supplemented earlier smooth designs, and calcium hydroxyapatite coatings, believed to promote earlier bone apposition, have been added as adjuncts.

A wide variety of materials has been used to replace bone lost around teeth through periodontal disease and to reinforce and reconstruct bony support in individuals who have lost some or all of their teeth. The most widely used such material is microporous, granular calcium hydroxyapatite (100–300 μm), but other materials, including resorbable glasses and processed natural materials, such as processed bovine cancellous bone and coral, have seen some success.

The nature of dental practice, with most procedures performed in office rather than hospital settings, makes the annual volume of procedures difficult to estimate although one recent study (Langer and Vicanti, 1993) suggests an annual total of 10 000 000, with many patients receiving multiple implants.

4.4 Plastic and Reconstructive

Plastic and reconstructive applications focus on three problems: repair of birth defects, reconstruction of the residual effects of trauma or cancer surgery, and perceived need for esthetic enhancements. The first two applications represent some of the highest achievements of the surgical art. Soft materials, such as polyurethanes, polysiloxanes, and low- and mid-molecular-weight polyethylenes, are used in conjunction with soft- and hard-tissue materials, both harvested from other sites within the patient's body and obtained through an extensive tissue and organ bank system within the U.S. The use of vascularized flaps and bone segments and extensive stretching techniques to ensure skin coverage further enhances the functional and esthetic aspects of the results of such procedures. In some cases, when extensive reconstruction is not possible, as in the loss of portions of the nose or ears, fully synthetic external orthoses may be used, anchored to osseointegrated titanium percutaneous posts. Such devices have proven very successful for periods exceeding ten years. However, load-bearing applications, such as permanent anchorage of partial limb-replacement orthoses with percutaneous devices, still are not successful, because of continuing breakdown of the so-called *three-phase junction,* the point where tissue, implant, and air meet, leading to pain, infection, and marsupialization and requiring eventual removal of the device.

It is unfortunate that these truly miraculous advances have been to a considerable degree obscured by the profligate use of implants to enhance sexual function and attractiveness. The former goal, primarily in men, involves procedures to place solid or inflatable implants within the penis, for correction of impotence related to circulatory disease or as a consequence of pelvic surgery. Such devices, as well as prosthetic replacements for the testis, have proven of uneven clinical success.

Far more common, in the U.S. at least, has been the use of implants to increase breast size in women and, in some cases, to reconstruct breast volume and appearance after cancer surgery. Breast implants have been fabricated from polyurethane and polysiloxane elastomers and filled with silicone gel or saline solution. Implants with early grades of polyurethanes are no longer used, because of concerns about possible chemical carcinogenesis by aromatic amine degradation products. Implants with silicone gel fillers are no longer used because of problems of leakage, rupture, and implant-site calcification and scar contraction. Before such procedures were discontinued, hearsay estimates (in the absence of sound data) suggested that between 500 000 and 1 000 000 U.S. women had received breast implants. There is ongoing litigation in the U.S. concerning possible systemic and remote-site effects, believed due primarily to release and distribution of silicone gel. This litigation has resulted in a tentative class action damage settlement of $\$4.2 \times 10^9$, which has had a distinct chilling effect both on the supply of currently used polymeric biomaterials and on efforts to develop better replacement materials.

4.5 Miscellaneous Applications

One of the earliest successful modern implant applications in the U.S. was the development of the polysiloxane indwelling shunt for draining fluid from the cranial cavity into the spinal canal, thus preventing progressive brain damage in children born with the condition of *hydrocephalus.* The most common implant, the Holter shunt, is named for its inventor, John Holter, an aerospace engineer who pursued this problem because of the birth of a son with this defect. Related neurosurgical applications include closure of the skull after trauma or surgical procedure, frequently with tantalum plates or mesh, and attempts to encourage nerve regrowth by provision of sheaths fabricated from various metallic and polymeric materials.

Small–material-volume but high–procedure-rate devices play vital roles in modern medical management. These include polymeric vent tubes to drain the middle ear during infection (~300 000/yr) and polymethylmethacrylate intraocular lenses as a treatment for cataracts and other degenerative conditions of the eye in the elderly (~800 000/yr) (Moss, 1991).

Biomaterials play an extensive role in fertility control, especially outside the U.S. The use of intrauterine devices (IUDs) promotes an adverse local host response preventing implantation of the fertilized ovum in the uterus. The most common material used is pure copper, an ordinarily "incompatible" material, on a polymeric support. Polymers are also used as implantable reservoirs for long-term release of hormones for female fertility control. Male fertility may be controlled reversibly by injection of *in situ* curing polysiloxane into the vas deferens, preventing admission of fertile spermatozoa into the ejaculate.

4.6 Hybrid Devices

A number of hybrid devices, utilizing cells from patient or donor sources cultured *in vitro* and combined with resorbable or metabolizable supports and matrices, are in various stages of animal and preclinical evaluation. As of now, none have entered routine clinical use. There is general concern over regulatory issues related to the potential for inadvertently causing infection, especially by human immune viruses and other difficult to detect, very long-expression-time biological agents, such as Creutzfeldt-Jakob and Epstein-Barr viruses. These concerns are also present in the increasing use of "live" (unprocessed) tissue transplants. Recently, in the U.S., the FDA has indicated that it intends to regulate the quality and safety of transplanted tissues and organs. This will occur initially through oversight of the conduct and practices of tissue banks, and will certainly lead to active regulation of the safety and effectiveness of hybrid biomaterials.

5. CONCLUSIONS

5.1 Clinical Status

Biomaterials are in broad use today in the U.S. and the developed countries. Their use in the developing countries of the third world is still limited by lack of manufacturing facilities, lower surgical standards, poor hygiene, and, in some cases, cultural opposition. In the U.S., various estimates made in the early 1990s suggest that as many as twenty million permanent (>30 days duration) surgical implants may now be in use, with orthopedic and cardiovascular applications attracting the most attention. Recent poor experience with silicone-gel–filled silicone breast implants and polytetrafluoroethylene-containing interposition spaces for the temporomandibular joint (TMJ) have led to a current re-evaluation of the commercial, legal, and ethical risks associated with the use of chronic implants. One immediate effect is the present and pending withdrawal from the U.S. market by many manufacturers of materials used in implants. Since most current biomaterials are modified or selected grades of commodity materials used in vastly greater volumes for other applications, such withdrawal in the face of rising product-liability litigation is understandable but is raising questions about the future availability of biomaterials.

Implant performance is strongly device and application oriented; thus, it is not possible to provide a list of generally recognized and accepted (thus, safe and effective) implantable biomaterials. However, the list given below is of inert and interactive biomaterials currently in human clinical use in the U.S. in at least one application.

Polymers:
- Polyacetal
- Polyamide (Nylon™ 6,6)
- Polycarbonate
- Polyethylene (ultrahigh molecular weight)
- Polyethylene terephthalate (Dacron™)
- Poly(tetrafluoroethylene) (Teflon™, Gore-Tex™)
- Polylactic/polyglycolic acid copolymers (resorbable)
- Poly(methyl methacrylate)
- Polyurethanes
- Polypropylene
- Poly(dimethylsiloxane) (silicone elastomer) (Silastic™)
- Polysulfone
- Polyvinyl chloride

Metals and Alloys:
- Cobalt–chromium–molybdenum based al-

  - loys (collectively but incorrectly termed Vitallium™)
  - Gold and gold-based alloys (dental only—usually not implanted)
  - Copper–mercury–tin–silver amalgam (dental only—not implanted)
  - Platinum- and palladium-based alloys
  - Stainless steels (primarily type 316 low carbon; type 304 used in very restrictive applications)
  - Tantalum
  - Titanium
  - Titanium–aluminum–vanadium (α–β type) alloy
  - Titanium-based β-type alloys
- Ceramics:
  - Aluminum oxide (alumina) (bulk, particulate in resin base)
  - Calcium hydroxyapatite (coatings, powder, granules, porous/dense block)
  - Carbon (coatings, pyrolitic, vitreous)
  - Zirconium oxide (zirconia) (bulk)

5.2 The Challenge of New Applications

The field of biomaterials is undergoing rapid change and development. The search for inert materials has been essentially abandoned, with the exception of continuing interest in surface modification, both to reduce wear and debris formation and to render tissue reaction more benign. Major efforts center on interactive materials. Extensive efforts are being made to decipher the messages that cells receive from surfaces. It is now clear that some cell types can sense the chemical, morphological, and electrical aspects of surfaces independently and that preferred combinations of these aspects of the biomaterial–tissue interface selectively mediate cellular response. Molecular design, made possible by microbiological and tissue engineering techniques, to replicate specific amino acid sequences in polymeric proteins, has produced both novel materials and surface modifications exhibiting specific molecular sequences utilized by cells for cell–cell and cell–matrix communication and binding.

The exciting future lies, however, with the development of hybrid materials, with live cells included within a synthetic matrix and perhaps actually encapsulated so as to permit diffusion of small molecules but prevent interaction with the patient's immune system. Applications include hybrid synthetic skin and small-diameter blood vessels as well as encapsulated pancreatic islet cells for the treatment of diabetes.

These approaches are still only a stepping stone to the eventual future of biomaterials. The artificial heart and left ventricular assist devices, as temporary implants, are now seen as bridges to transplantation of whole organs from donors. Similarly, renal dialysis is viewed, for all but the elderly and those with multiple organ diseases, as a temporizing procedure until an immune-matched donor organ can be obtained. As control of tissue growth and elaboration *in vitro* becomes increasingly better understood, we can look forward to biomaterials serving as bridges until the implantation, or, better, replantation of cells, tissues, and organs grown from tissue removed from the specific patient under treatment. Such techniques are already in use in cancer therapy, involving selective growth of leukocyte subpopulations *in vitro* followed by transfusion to the donor. As these techniques become perfected and patients begin to be able to receive live tissues, containing their specific genetic code and immune factors, then biomaterials will have achieved its true promise of helping to alleviate human disability and disease.

GLOSSARY

Adaptation: The ability of tissues to adapt themselves to local requirements, including reaction to the chemical, physical, or electrical properties of implants.

Bioactive: The property of an **Implant** surface of adhering directly to soft or hard tissue without an intermediate layer of modified tissue.

Biocompatible Material: A material having acceptable host and material response in a *specific* application. (See **Response, Host; Response, Material.**)

Biomaterial: A nonviable material used in a medical device, intended to interact with biological systems. Classified into Biomaterial, Inert: A biomaterial that elicits little or no **Host Response;** Biomaterial, Interactive: A biomaterial that is designed to elicit or promote a specific **Host Response,** such as hard-tissue adhesion; Biomaterial, Manmade (or Manufactured): A biomaterial that is significantly processed from raw materials of inorganic or organic origin; Biomaterial, Native (or Natural): A biomaterial that is obtained from natural sources and is implanted essentially unprocessed; Biomaterial, Replant: A biomaterial consisting of live native cells or tissue, cultured *in vitro* from cells obtained previously from specific patients or donors; Biomaterial, Viable: A biomaterial that incorporates host tissue and/or live cells, and is capable of being actively remodeled and/or resorbed.

Carcinogenesis: Malignant, inheritable change in mammalian cells. Classified into Carcinogenesis, Chemical: (with respect to an implant) Carcinogenesis induced by the chemical composition of an **Implant** or its degradation products; Carcinogenesis, Foreign Body: Carcinogenesis induced by the physical form of an **Implant,** independent of its chemical composition.

Environment, Biological: Conditions encountered by an **Implant** within an animal or human body.

Environment, Pericellular: Conditions encountered by an **Implant** immediately adjacent to living cells within an animal or human body.

Epithelial Tissue: Skin and the lining of natural internal body cavities.

Extrusion: Resolution in which an **Implant** in contact with **Epithelial Tissue** is surrounded by a downgrowing extension of such tissue, directed toward extruding the implant from the body. Also called **Marsupialization,** from the resemblance of the tissue to a kangaroo's pouch.

Glycocalyx: A protective enveloping film formed on the surface of **Implants** by some types of bacteria.

Homeostasis: The maintenance of conditions necessary for mammalian life.

Hybrid Devices: Devices using cells from patient or donor sources cultured *in vitro* and combined with **Resorbable** or metabolizable supports and matrices.

Implant: A device placed within an animal or human body by the act of **Implantation.** Classified as Implant, Acute: A device that remains *in situ* for less than 30 days; Implant, Chronic (or Permanent): A device that remains *in situ* for 30 or more days; Implant, Intraoperative: A device removed within hours or days, at the termination of the surgical or therapeutic procedure; Implant, Percutaneous: A device that, after placement, penetrates the skin.

Implantation: Placement of a device or material within the body of an animal or human by a medical or surgical professional, in such a way as to breach one or more epithelial layers, and to leave materials and/or components in place after the initial procedure.

Implant Life History: Lifetime performance requirements for an **Implant.**

Incapsulization: Resolution in which the **Implant** is surrounded and walled off from normal tissue by a collagenous, relatively acellular tissue termed *capsule,* which much resembles scar tissue. In a bony location, the capsule may be mineralized and is called a *sequestrum.*

Inflammatory Response: The cell-mediated response directed toward stabilizing injured tissue, restoring physiological *status quo ante,* removing dead or damaged tissue elements and foreign material, and correcting the structural and functional loss due to the initial insult. The four classical signs of inflammation are redness, swelling, pain, and heat.

Integration: Resolution for a very limited number of materials, such as "bioactive" glasses of selected compositions, or some metals, such as pure titanium, for which direct "bonding" or apparent adhesion to normal tissue may take place.

Marsupialization: See **Extrusion.**

Oppenheimer Effect: Induction of tumors in rodents through a foreign-body mechanism; named after its discoverers, E. and B. S. Oppenheimer.

Osseointegration: Clinical stability of an **Implant** anchored in bone. Often taken to refer to implants with **Bioactive** coatings.

Osteolysis: Cellularly mediated bone loss (also called *small-particle disease*) secondary to wear-debris production by total joint replacement prostheses.

Phagocytosis: The process of internalizing small particles by mammalian cells.

Physiological Elements: Those nontrace elements (calcium, phosphorus, potassium, sulfur, sodium, chlorine, and iron), other than oxygen, hydrogen, nitrogen, and carbon, required for mammalian **Homeostasis.**

Pseudointima: Tissue, consisting of a firm fibrin clot with occasional islands of endothelial cells, formed by **Resolution** on interiors (blood-contacting surfaces) of cardiovascular **Implants.**

Resolution: The end state of the **Inflammatory Response** in the presence of an **Implant.**

Resorbable: Of an **Implant,** able to be dissolved or digested, and thus to disappear after **Implantation.**

Resorption: Resolution associated with **Resorbable Implants** in which the tissue site condenses to a collapsed scar or, in the case of bone, completely remodels to normal (regenerated) tissue.

Response, Host: The reaction of a living system to a **Biomaterial.**

Response, Material: The reaction of a **Biomaterial** to a living system.

Stress Shielding: A decreased density of bone, as a consequence of load sharing between an **Implant** and the hard tissue.

Three-Phase Junction: With reference to percutaneous **Implants,** that point where tissue, **Implant,** and air meet.

Tissue Engineering: Elaboration of cells and tissues outside a living organism, for replantation, by use of engineering methods and techniques.

Vroman Effect: The succession of molecular species adherent to surfaces of **Implants,** named after its discoverer, L. Vroman.

Wolff's Law: "The form being given, tissue adapts to best fulfill its mechanical function" (Wolff, 1892).

INTRODUCTION

Proteins perform a wide variety of tasks in living organisms (Stryer, 1988, and the preceding article Proteins and Enzymes): Some proteins have structural roles, for example, as constituents of muscle and fibrous tissue. Other proteins store or transport energy, electrons, or small molecules. Moreover, many different enzymes exist in living systems that catalyze a large number of essential reactions, and almost all enzymes are proteins. Antibodies are proteins elicited by the immune system to remove foreign materials from the organism.

To perform these diverse functions, protein molecules have specific three-dimensional structures, designed and fine-tuned by evolution over billions of years. Perutz and Kendrew solved the first protein structures with atomic resolution using x-ray crystallography (Perutz *et al.*, 1960; Kendrew *et al.*,

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

1960). The remarkable detail and intrinsic beauty of the molecular structures led to the misconception that proteins are rigid molecules, and most attempts to understand protein function have been based on rigid models. For example, the specificity and efficiency of an enzymatic reaction have been explained by complementary interactions between rigid enzyme and substrate that were likened to the fitting of a key within a lock.

In the past 20 years, the static view of proteins has undergone a complete revision. It is now generally recognized that proteins are fluctuating entities; they constantly change the details of their conformation, and the x-ray structure reveals only an average over the many different conformational substates that the molecule can assume within one conformation. This development toward a dynamic picture of proteins was promoted by advances in experimental techniques that allow the study of motions on all relevant time scales and by advances in theory. Furthermore, the availability of powerful computers makes it possible to study protein motions on time scales up to a few nanoseconds using molecular dynamics (MD) simulations.

At present, the detailed mechanisms by which structure and dynamics give rise to the particular function of a given protein are still only partially understood. Research focuses on a few proteins that have been characterized well enough to allow for the detailed study of the structural dynamics. Of particular importance are heme proteins, especially the oxygen-binding myoglobin and hemoglobin.

We begin this article with a brief overview of the structure and dynamics of proteins. We then explain some essential concepts of protein dynamics. The wide field of molecular dynamics simulation of protein dynamics is introduced in Sec. 3. In Sec. 4, we give an overview of some major experimental techniques with which motions in proteins are studied. Since not all techniques can be covered, the reader is referred to the books listed under Further Reading at the end of the article.

1. PROTEIN STRUCTURE AND DYNAMICS—OVERVIEW

1.1 Structure

Proteins are linear polymers of amino acids, which are covalently linked by peptide bonds, as illustrated in Figs. 1 and 2 of PROTEINS AND ENZYMES. The polypeptide chain is intrinsically flexible since many of the covalent bonds permit rotations. The monomers of the polypeptide chain are chosen from a set of 20 different amino acids, which have the same backbone structure (except for proline) but differ in structural and chemical properties of the sidechains. The amino acids can be divided in two classes, hydrophilic residues, which are more soluble in water, and the less soluble hydrophobic residues. Hydrophobic residues are neutral and relatively nonpolar, whereas hydrophilic residues may be charged or possess dipole moments.

The structure of a given protein is encoded in the DNA (deoxyribonucleic acid) in a linear sequence of nucleotide triplets. In the ribosome, this information is used to synthesize a linear polymer chain of amino acids, called the primary structure of the protein. In the proper environment, the polypeptide chain folds into its compact, characteristic three-dimensional structure. This process occurs spontaneously for simple proteins. Many proteins are subsequently modified by attachment of prosthetic groups, metal ions, or carbohydrates.

The native structure of a globular protein represents an efficient packing of the atoms, comparable to that in a dense liquid. The interactions that lead to the compact, native structure are not fully understood; thus it is currently not yet possible to predict the three-dimensional structure from the amino-acid sequence. The attractive interactions that determine the native structure include protein–protein, protein–solvent, and solvent–solvent interactions. The most important type of protein–protein interaction is hydrogen bonds. Many groups along the chain are hydrogen-bond donors and acceptors. Upon folding, hydrogen bonds to water molecules are replaced by internal hydrogen bonds. Hydrogen bonds between the amide and carbonyl groups of the amino-acid backbone are established by regular folding arrangements of the backbone, like α helices and β sheets. These folding patterns are called secondary structure. In addition to hydrogen bonds, weakly directional dispersion (van der Waals) forces lead to tight packing of internal protein groups. In some proteins, one or a few disulfide bridges between cysteine residues establish additional covalent cross links.

The three-dimensional arrangement of the polypeptide chain is termed tertiary structure. Hydrophobic sidechains are predominantly found in clusters in the interior of the protein, excluded from the polar solvent. Charged amino-acid sidegroups are located on the exterior, where they can favorably interact with water molecules. In the interior, charged groups are normally paired with groups of opposite charge. In larger proteins, the tertiary structure can be subdivided into domains. In many proteins, spontaneous aggregation of different polypeptide chains creates oligomers; this structural arrangement is called quaternary structure.

Since the interactions that stabilize the three-dimensional structure are weak and only weakly directional, a folded protein molecule does not exhibit a unique state of lowest free energy. The ground state is highly degenerate, so that in each conformation, the protein exists in a large number of almost isoenergetic structures, called conformational substates. They can be represented as minima in a multidimensional conformational energy surface. While the overall structure of the conformational substates is the same, they differ slightly in the arrangement of the atoms. However, their functional properties may be vastly different.

1.2 Dynamics

A polypeptide chain consists of fairly rigid groups of atoms, linked by bonds that permit rotations. Examples of rigid groups are the CONH unit of the backbone and the phenyl group of the phenylalanine amino acid. Within the rigid groups, only small relative displacements of the atoms occur because of the large energy expense of changing bond lengths and angles and rotating around multiple bonds. Substantial displacements arise from torsional motions around single bonds, which are easily rotated. Since proteins are densely packed, conformational rearrangements can only occur in a concerted way; for one group to move, neighboring groups have to give way. Therefore, the dynamics of proteins show strong analogies to the dynamics of viscous liquids. Motions on time scales ranging from $\sim 10^{-14}$ s up to macroscopic time scales are observed. An overview of the properties of protein motions under physiological conditions is given in Table 1 (McCammon, 1984).

On picosecond time scales, molecular groups vibrate in cages created by neighboring groups and, on the protein surface, by the solvent shell. These motions are of rather small amplitude. Large-scale displacements occur as collective motions involving several residues and therefore happen on time scales of nanoseconds and longer. Since the topological arrangement of the atoms changes in these motions, they are described as transitions between conformational substates.

2. CONCEPTS OF PROTEIN DYNAMICS

A number of concepts play a crucial role in protein dynamics. These concepts also form part of the intellectual framework of condensed matter physics and chemical dynamics. However, the special features of protein structure and biological function add a new dimension. The concepts apply to all biomolecules, including proteins and nucleic acids.

Table 1. Typical features of internal motions of proteins.

Motion	Spatial extent (nm)	Amplitude (nm)	Logarithm of characteristic time (s)
Relative vibration of bonded atoms	0.2–0.5	0.001–0.01	−14 to −13
Elastic vibration of globular region	1–2	0.005–0.05	−12 to −11
Rotation of sidechains at surface	0.5–1	0.5–1	−11 to −10
Torsional libration of buried groups	0.5–1	0.05	−11 to −9
Relative motion of different globular regions ("hinge-bending")	1–2	0.1–0.5	−11 to −7
Rotation of medium-sized sidechains in interior	0.5	0.5	−4 to 0
Allosteric transitions	0.5–4	0.1–0.5	−5 to 0
Local denaturation	0.5–1	0.5–1	−5 to +1

2.1 Protein States, Substates, and Motions

Frequently, protein molecules exhibit a few structurally well distinguishable states or conformations. For example, an enzyme exists in the substrate-free or substrate-bound state; the oxygen-storage protein myoglobin exists in the deoxy state Mb or ligand-bound state, MbCO or MbO_2. Each of the states of a working protein has an overall structure determined by the amino-acid sequence. However, because of the complexity of a protein, a given protein state consists of many conformational substates (CS). The conformational substates of a given protein state have the same overall structure and perform the same biological function, but differ in structural details and possibly in other properties, such as the rate at which the function is performed. The conformational energy surface of a protein is rugged with many energy minima and maxima—the energy minima are the conformational substates (Frauenfelder *et al.*, 1979; Frauenfelder *et al.*, 1988). Conformational transitions can occur in two different ways:

1. Equilibrium fluctuations. Since proteins are mesoscopic systems, they show considerable fluctuations of energy, entropy, and volume, due to their interaction with the thermal bath (Cooper, 1976). Consequently, their molecular structure fluctuates continuously.
2. Nonequilibrium relaxations. These occur as a response to a perturbation. For example, absorption of a light quantum or dissociation of a ligand can leave the molecule in a nonequilibrium state from which it subsequently relaxes.

In the linear response regime, both types of motions are connected by fluctuation–dissipation theorems (Landau and Lifshitz, 1980).

2.2 Nonergodicity, Temperature, and Time Scales

The rugged energy landscape of proteins leads to a strong dependence of protein motions on temperature and time. Within a given time interval, for example the characteristic time of a particular measurement, a protein molecule may not be able to visit all conformational substates. *Nonergodicity* is the term that characterizes this situation. At physiological temperature, a protein may be able to explore all substates of its rugged conformational energy surface on a time scale of microseconds, and the protein is *ergodic* on this time scale. However, as temperature is decreased, equilibrium fluctuations slow, and the protein becomes more and more confined in a subregion of conformational space within a given time interval, until finally, the protein molecule is caught in a local minimum on any reasonable experimental time scale (Palmer, 1982). For example, carbonmonoxy-myoglobin (MbCO) in glycerol/water solvent has been shown to experience a transition to a glasslike state at $T_g \approx 180$ K (Frauenfelder *et al.*, 1991).

2.3 Reaction-Rate Theory for Proteins

Chemical reactions are the basis for all aspects of biological processes, from transfer of matter, charge, and information to enzyme catalysis. *Transition-state theory*, derived from studies of two-body interactions of small molecules in gas phase, provides the starting point for understanding biological reactions (Frauenfelder and Wolynes, 1985): If we consider the two-state reaction $B \to A$, where all molecules are in state B at time $t = 0$, and neglect back transitions $A \to B$, the time dependence of the fraction $N(t,T)$ of species B at time t and temperature T is given by a simple exponential, $N(t,T) = \exp[-k_{BA}(T)t]$. If the reaction is thermally activated, the rate coefficient $k_{BA}(T)$ is expressed by an Arrhenius relation,

$$k_{BA}(T) = A_{BA} \exp[-H_{BA}/RT]. \qquad (1)$$

Here, H_{BA} is the activation enthalpy, and the pre-exponential A_{BA} includes an attempt frequency, a transmission factor, and an activation entropy S_{BA}. The gas constant $R = 8.314$ J K^{-1} mol^{-1}. H_{BA} is schematically illustrated in Fig. 1(a). The activation free energy G_{BA} can be expressed in terms of the activation enthalpy H_{BA} and entropy S_{BA}, $G_{BA} = H_{BA} - TS_{BA}$. In elementary transition-state theory, the pre-exponential $A_{BA}^{*} = \nu_0 \exp[S_{BA}/R]$, where $\nu_0 \approx 10^{12}$ s^{-1} in small-molecule, gas-phase reactions. In biological reactions, the activation entropy plays a crucial role,

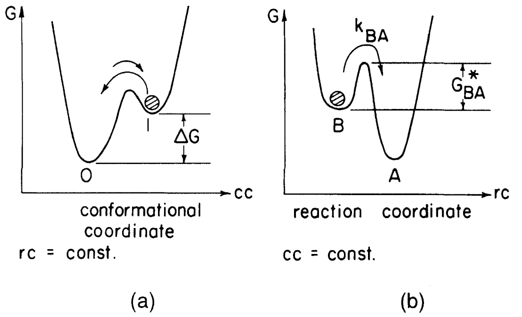

FIG. 1. Two cross sections through a highly simplified energy hypersurface of a protein. (a) At constant reaction coordinate (e.g., B in panel b) the protein possesses two conformational substates 0 and 1. (b) At constant conformational coordinate (e.g., 0 in panel a) the protein possesses two states. The bullet represents the protein–ligand system.

and ν_0 and the pre-exponential A_{BA} can differ considerably. For example, in the binding of CO and O_2 to myoglobin or of NO to azurin (Az) at low temperature, the pre-exponential $A_{BA} \approx 10^9\ s^{-1}$ (Steinbach *et al.*, 1991; Ehrenstein and Nienhaus, 1992). This implies that a typical activation entropy barrier S_{BA} for bond formation in protein reactions is given by $S_{BA} \approx -7R$.

Biological reactions can proceed by quantum-mechanical tunneling (Chance *et al.*, 1979). In this situation, the Arrhenius relation, Eq. (1), is inappropriate and must be replaced by a more general quantum-mechanical expression. Molecular tunneling has been observed in CO binding to myoglobin below 10 K; electron tunneling is involved in the charge separation in photosynthetic reaction centers at all temperatures.

2.4 Time and Temperature Dependence of Conformational Motions

Relaxation methods are frequently used in studies of protein motions. The sample is rapidly brought to a nonequilibrium state by a perturbation. The return to equilibrium is characterized by a relaxation function $\Phi(t,T)$. Simple systems show exponential (Debye) behavior. In proteins, the complexity of the system often results in a nonexponential time dependence of the relaxation function, analogous to relaxation processes in glasses (Frauenfelder *et al.*, 1991). The time dependence in both glasses and proteins can usually be well parameterized by a stretched exponential:

$$\Phi(t,T) = \exp(-[\kappa(T)t]^{\beta}), \tag{2}$$

where $0 < \beta < 1$. In proteins, $\beta \approx 0.3$–0.5 has been observed, indicating that the relaxation extends over many orders of magnitude in time. The effects of the rugged energy surface of the system are also reflected in the temperature dependence of the characteristic rate coefficient, $\kappa(T)$. Fits to relaxation data for proteins using an Arrhenius relation, $\kappa(T) = \kappa_0 \exp[-E/RT]$, are good only over a small range in temperature. The locally determined activation energy E increases strongly with decreasing temperature. Empirical relations for $\kappa(T)$ derived from glass-forming liquids can be used to describe the temperature dependence of relaxation processes in proteins (Frauenfelder *et al.*, 1991; Frauenfelder and Wolynes, 1994).

2.5 Conformational Dynamics and Protein Reactions

A protein exists in a large number of different structures or conformational substates, and the rate of a protein reaction will generally be different for different substates. The kinetics of a biomolecular reaction is then controlled by both the reaction rate coefficients within the substates and the fluctuation rate coefficients among the substates. The simplest model that allows us to discuss the interplay between the reaction and conformational transitions uses only two different protein states, A and B, along the reaction coordinate (*rc*) and two different conformational substates (0 and 1) along the conformational coordinate (*cc*). We stress that a single conformational coordinate with only two substates is an oversimplification and that there may also be additional protein states along the reaction coordinate. Figure 1 illustrates the model: Figure 1(a) shows a cross section through the energy surface at constant reaction coordinate, say $rc = B$. Figure 1(b) gives a cross section at constant conformational coordinate, say $cc = 1$. The rate coefficients for the reactions $B \leftrightarrow A$ depend on the protein substate: The rate coefficients for $B \rightarrow A$, for example, are written k^i_{BA}, where $i = 0, 1$ is the substate index. In the following, we assume an absorbing state A for simplicity and hence neglect the transition $A \rightarrow B$. The rate coefficients for transitions between conformational substates, $0 \leftrightarrow 1$, are given by κ_{ij}, $i \neq j = 0, 1$. The ratio of the relative populations of the two conformational substates 0 and 1 is $w_0/w_1 = \exp[-\Delta G(T)/RT]$, where the free-energy difference $\Delta G(T)$ between the two substates is $\Delta G(T) = \Delta H - T\Delta S$. Three different cases can be distinguished, dependent on the relative magnitudes of k^i_{BA} and κ_{ij}.

2.5.1 Distributed Kinetics When the rate coefficients κ_{ij} for conformational transitions are small compared with the rebinding rate coefficients, the survival fraction for the B states is biexponential, $N(t,T) = w_0(T_g) \times \exp[-k^0_{BA}t] + w_1(T_g) \exp[-k^1_{BA}t]$. This case is observed in proteins at low temperature, and the relative populations of the substates are frozen in at the glass transition temperature, T_g. In general, the number of conformational substates is very large so that the survival fraction can be described by a distribution (Frauenfelder *et al.*, 1988):

$$N(t,T) = \int g(H_{BA}) \exp[-k(H_{BA},T)t]dH_{BA}, \qquad (3)$$

where $g(H_{BA})dH_{BA}$ is the probability to find protein molecules with barriers between H_{BA} and $H_{BA} + dH_{BA}$. The distribution function $g(H_{BA})$ is essentially temperature independent below T_g. Substates that are described by distributions such as $g(H_{BA})$ are called *statistical substates.* Figure 2 illustrates the nonexponential time dependence of the rebinding kinetics of MbCO following photodissociation at temperatures between 60 and 160 K. The temperature-independent distributions of activation enthalpy barriers for the low-temperature recombination of MbCO and AzNO are also shown in Fig. 2.

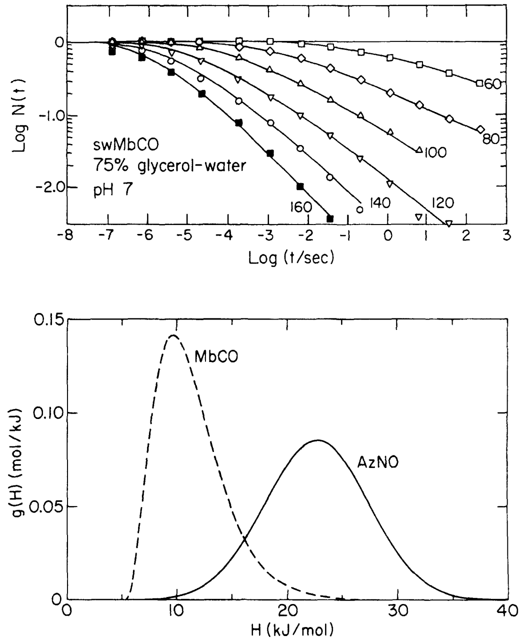

FIG. 2. Upper panel: rebinding kinetics of CO to Mb after flash photolysis between 60 and 160 K. Lower panel: activation enthalpy distributions $g(H_{BA})$ for MbCO and AzNO. Solvent: 75% glycerol/buffer.

2.5.2 Averaged Kinetics If the rate coefficients κ_{ij} are large relative to k^i_{BA}, the survival fraction $N(t,T)$ is exponential, $N(t,T) = \exp[-\langle k_{BA}\rangle t]$, and the average rate coefficient $\langle k_{BA}\rangle$ is given by $\langle k_{BA}\rangle = w_0(T)k^0_{BA} + w_1(T)k^1_{BA}$. Here, the $w_i(T)$ denote the equilibrium populations at temperature T. In the case of a large number of conformational substates, the average rate coefficient must be expressed in terms of a distribution of rate coefficients. Experimentally, averaged kinetics are observed for reactions slow compared with conformational fluctuations, e.g., bimolecular rebinding of ligands to heme proteins at sufficiently high temperature.

2.5.3 Time-Dependent Reaction-Rate Coefficients The most complicated case arises when the time scales for conformational transitions and for the reaction are similar. Reaction-rate theory including dynamic modulation of the microscopic rate coefficients by a fluctuating environment is under active development. Protein motions can result in a time-dependent rate coefficient $k_{BA}(t,T)$ so that the survival fraction becomes nonexponential in time,

$$N(t,T) = \exp\left[-\int_0^t k_{BA}(\tau,T)d\tau\right]. \qquad (4)$$

A time-dependent rate coefficient has been used, for example, to model the bond formation step between CO or NO and myoglobin in flash photolysis experiments (Petrich *et al.*, 1991; Steinbach *et al.*, 1991). Motions are also necessary for ligands or substrates to enter or exit the binding site of a protein. For example, fluctuating gate models, in which passage of a ligand through the protein depends on the opening and closing of channels by conformational fluctuations, have been used to explain these dynamic phenomena (Beece *et al.,* 1980).

2.6 Viscosity Dependence of Reaction Rates and Protein Motions

Proteins function in solvents or lipid membranes of differing viscosity. Since proteins are flexible, their motions and, hence, biochemical reactivity are influenced by the solvent composition and viscosity. In particular, the transition rates between conformational substates depend strongly on the solvent viscosity η (Beece *et al.,* 1980). The transition-state expression, Eq. (1), does not properly include the effects of solvent viscosity on transition rate coefficients. The approach developed by Kramers is more appropriate (Frauenfelder and Wolynes, 1985). For proteins, a modified Kramers relation should be used because of shielding of the protein interior from the external solvent. The rate coefficient for conformational transitions in a wide range of solvents can be expressed as

$$\kappa = \kappa_0(\eta) \exp[-\Delta G^*/RT]. \qquad (5)$$

Here ΔG^* is the free-energy barrier for the conformational transition. The pre-exponential $\kappa_0(\eta)$ depends strongly on solvent viscosity, a fact not included in the phenomenological Arrhenius relation in Eq. (1) for a simple two-state, gas-phase reaction. The viscosity dependence arises since ligands and substrates enter a binding site of a biomolecule as a result of protein fluctuations that couple to the solvent.

2.7 Protein Dynamics and Function

Heme proteins such as hemoglobin and myoglobin have played the role of model systems in developing our present understanding of protein dynamics, as described in the previous sections. Here we briefly sketch the connection between protein motions and function for a simple biological process, the binding of small ligands such as CO and O_2 to myoglobin (Mb). The basic features of the reaction have been elucidated, but many details are still not entirely understood and are being investigated at present. In the simplest model, the ligand binding reaction can be described with the reaction energy surface in Fig. 3, which involves three states A, B, and S. State A refers to the ligand-bound state, say MbCO, where the CO molecule is bound to the heme iron. State B refers to the unbound state where the CO is in a relatively open region of the protein, known as the heme pocket. In state S, the ligand has escaped from the protein into the solvent; the protein in state S is called deoxymyoglobin. Two barriers are involved in the binding process. The inner barrier between A and B is associated with the final binding step at the heme iron, and the outer one between B and S may represent the gate between the heme pocket and the solvent.

At physiological temperatures, this energy surface is by no means static but dynamic as a result of fluctuations and relaxations of the protein molecules. The x-ray structures of myoglobin and hemoglobin do not reveal an open path to the binding site at the heme iron (Perutz and Mathews, 1966). Protein motions are essential for ligand escape from and entry to the protein. For the reaction surface in Fig. 3, this fact implies that the outer barrier between B and S fluctuates. Kinetic studies show that these equilibrium fluctuations are strongly affected by the solvent viscosity and composition (Frauenfelder *et al.,* 1991).

Another, functionally important dynamic

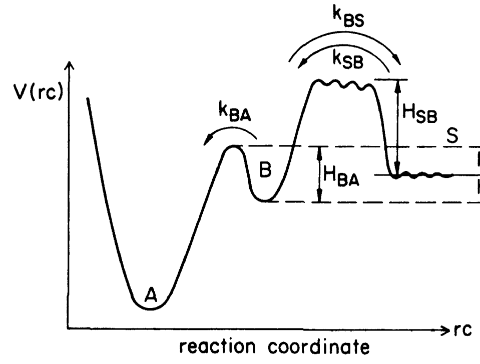

FIG. 3. Reaction energy surface of MbCO with three states, ligand bound (A), ligand in the heme pocket (B), and ligand in the solvent (S).

process affects the inner barrier between B and A. X-ray studies show significant differences in structure between the ligand-bound state A (MbCO) and the deoxy state S (Mb). For example, the iron in the ligand-bound state A is nearly in the plane of the heme group, while it is significantly out of plane by about 0.3 Å in deoxy Mb. Several kinetic and spectroscopic studies indicate that the protein relaxes to the equilibrium Mb structure after ligand dissociation. This relaxation has been described by a nonexponential time dependence of the type described in Sec. 2.4 (Steinbach *et al.*, 1991; Petrich *et al.*, 1991). More recent results suggest that the relaxation involves a sequence of discrete intermediate steps (Nienhaus *et al.*, 1994). The enthalpy barriers for binding from state B to state A increase considerably as the iron moves further out of the plane of the heme. The resultant slowing of the rebinding rate may be crucial for allowing efficient escape of the ligand from the protein. This relaxation of the inner barrier is also dependent on solvent viscosity (Ansari *et al.*, 1992).

2.8 Emerging Concepts

Proteins share essential characteristics with glasses and spin glasses. The dynamics of all these complex systems can be described theoretically with the concept of rugged energy surfaces. Glasses are simpler than proteins, and hence they can guide the formulation of concepts and theories of protein dynamics. The rugged conformational energy surface of a protein forms the scaffold for protein motions. Detailed knowledge of the organization of conformational substates (minima) within the energy surface is crucial for an understanding of protein dynamics and function. Ligand binding studies in myoglobin have yielded insights into the organization of conformational substates in the energy landscape.

2.8.1 Hierarchy of Substates A significant body of evidence implies that protein substates are organized in a hierarchical structure (Frauenfelder *et al.*, 1991). The hierarchical arrangement of substates may reflect the primary, secondary, and tertiary spatial structure described in Sec. 1. The most salient results are summarized in Fig. 4, which gives a schematic diagram of the hierarchical organization of conformational substates (CS) in myoglobin, the most extensively characterized protein from the point of view of its dynamic properties. The figure shows that MbCO assumes a large number of different structures. The top tier (CS0) corresponds to the largest differences in structures among CS. MbCO can assume at least three different conformations that are characterized by different CO stretch frequencies and different enthalpies, entropies, and volumes. Since the CS0 can be characterized individually, they are called *taxonomic substates.* Many proteins show evidence of taxonomic substates. The three CS0 in myoglobin bind CO with different rates, and their relative populations depend markedly on environmental factors such as *p*H, temperature, pressure, and protein–protein interactions. Taxonomic substates may be essential for protein function and control: External factors, for instance, can switch a protein from one taxonomic substate to another and change the reaction rate. This is also the crucial assumption of Koshland's *induced-fit model* of enzymatic function (Stryer, 1988; PROTEINS AND ENZYMES).

Within a given CS0, a protein can assume a large number of substates of tier 1, CS1. This follows from the observation that each individual CS0 of myoglobin rebinds CO, after photodissociation below about 160 K, with kinetics that are highly nonexponential in time. The nonexponential time dependence results from different proteins in the experimental sample becoming stuck in different CS, each with a different rate coefficient for rebinding at low temperature. The substates of tier 1 are *statistical substates* since their properties must be described by appropriate distributions such as $g(H_{BA})$ (see Sec. 2.5.1). The furcation continues: For example, glasslike behavior of the specific heat in proteins is observed below 1 K, implying that motions occur between two-level systems with very low barriers even at this low temperature.

2.8.2 Proteins, Glasses, and Spin Glasses The stretched exponential, Eq. (2), is an empirical relation that provides a consistent framework for analyzing experimental data in protein dynamics. This equation also emerges in experimental studies of glasses and spin glasses. In addition, both glass-

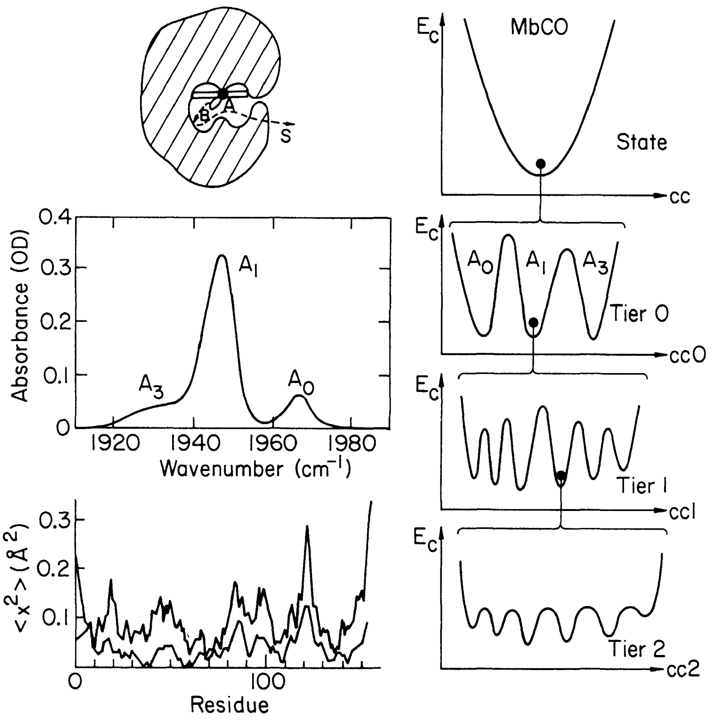

FIG. 4. Structure and conformational energy surface of MbCO. Right column: simplified scheme of the conformational energy, E_c, in three different tiers of the hierarchical energy surface, as a function of a conformational coordinate, *cci*. Note that in reality, E_c is a hypersurface in a many-dimensional conformational space. Left column: Top, coarse structure of MbCO including a possible binding path of the CO ligand from the solvent (S) to the pocket (B) and the iron binding site (A), with an expanded view of the binding geometry. Middle, infrared spectrum of the stretch bands of CO bound to the heme iron; three bands can be distinguished that are assigned to the three taxonomic substates A_0, A_1, and A_3 in the right column of the figure. Bottom, mean squared displacements of amino acids (backbone averages N, C_α, C) of met myoglobin at 300 K (upper) and 80 K (lower) as function of residue number.

forming liquids and proteins experience transitions to long-lived metastable states. This suggests connections among proteins, glasses, and spin glasses. However, an understanding requires theoretical justification of these relations and their connection to the rugged conformational energy surface. The random-energy model (REM) in which the energy minima in the rugged energy surface have uncorrelated free energies has been developed to describe spin glasses and has also been applied to neural nets and molecular evolution (Mezard *et al.*, 1987). The REM has also been successfully applied to protein folding (Frauenfelder *et al.*, 1991). This suggests that complex systems including glasses, spin glasses, neural nets, and proteins share essential properties and that a theory of dynamics on complex energy surfaces may become a reality. However, biomolecules go far beyond physical systems in one crucial aspect: the connection between dynamics and function and between dynamics and evolution. Biomolecules may provide superb systems for development of both theoretical and experimental understanding of complex systems (Frauenfelder and Wolynes, 1994).

3. MOLECULAR DYNAMICS SIMULATIONS

Molecular dynamics (MD) simulations (see SIMULATION BY MOLECULAR DYNAMICS) afford the most detailed theoretical look at the dynamic behavior of proteins (Brooks *et al.*, 1988; McCammon, 1984). Molecular dynamics studies of the atomic motions of proteins and nucleic acids are of relatively recent origin, dating from the first simulation of the atomic motions of a small protein, pancreatic trypsin inhibitor, in 1977 (McCammon *et al.*, 1977). Since then progress has been rapid as a result of the development of faster computers and improved computer algorithms and software. The most important limitation of a molecular dynamics simulation is that it is approximate because of the use of finite-difference techniques and approximate interaction potentials. A second limitation arises from the very large range of time scales involved in protein motions and reactions (Table 1)—relevant times range from $\sim 10^{-14}$ to ~ 1 s. Current simulations can extend to $\sim 10^{-8}$ s, and large-scale parallel processor arrays may extend simulation times to $\sim 10^{-6}$ s, depending on the size of the protein and the number of solvent molecules included. Current MD simulations involve numerical solution of the coupled classical equations of motion for the interacting atoms of a protein. A full treatment of chemical reactions must include a quantum-mechanical approach. However, MD simulations have been useful for determining thermodynamic properties of proteins as well as providing information concerning protein motions themselves. We discuss the essential aspects of MD and some applications to protein dynamics.

3.1 Essentials of Molecular Dynamics

In a molecular dynamics simulation, classical equations of motion for all atoms of the biomolecule are solved by various numerical techniques to obtain the time evolution of the protein structure. Trajectories of proteins have been calculated at constant energy and at constant temperature. Most MD simulations of biomolecular dynamics have been based on potential energy functions that are sums of the types of interactions used in the description of simpler molecular systems. A typical potential function has the form

$$V = \tfrac{1}{2}\sum_{\text{bonds}} K_b(b - b_0)^2 + \tfrac{1}{2}\sum_{\substack{\text{bond}\\\text{angles}}} K_\theta(\theta - \theta_0)^2 + \tfrac{1}{2}\sum_{\substack{\text{dihedral}\\\text{angles}}} K_\phi[1 + \cos(n\phi - \delta)] + \sum_{\substack{\text{nonbonded}\\\text{pairs}}}\left[\frac{A}{r^{12}} - \frac{C}{r^6} + \frac{q_1q_2}{Dr}\right]. \tag{6}$$

The first sum includes a term for every covalent bond in the biomolecule. The second term includes deformation energy for valence angles among covalent bonds for each atom; the third term accounts for intrinsic deformation energy for rotating about an axis through covalently bonded atoms. These three terms represent variations in the covalent binding energy of the protein. The first two terms are treated in the harmonic approximation, which is reasonable at temperatures where fluctuations in the bond lengths and angles are small. The three terms in the sum over nonbonded pairs of atoms separated by a distance r correspond respectively to the core repulsion, dispersion, and electrostatic interactions. The Lennard-Jones 6–12 and the electrostatic potentials in the last sum represent a potential of mean force rather than a simple potential energy if the dielectric coefficient $D \neq 1$ is used to describe any charges that are not explicitly included in the model. Various energy minimization algorithms are used to explore the rugged conformational energy surface of the protein.

3.2 Some Applications of Molecular Dynamics to Myoglobin

The number of applications of molecular dynamics to biomolecules is large and growing (Brooks *et al.*, 1988): MD is used to refine protein structures obtained by x-ray diffraction and NMR, to obtain free energies and other thermodynamic properties of both wild-type and genetically engineered mutant proteins including solvent, to explore the conformational energy surface and map the multiple minima, and to calculate trajectories of protein–ligand and enzyme–substrate reactions. Solvent molecules can be explicitly included in the MD simulations, and the effects of protein hydration can be systematically explored.

The most detailed information may well be available for the oxygen-storage protein myoglobin, which is sometimes called the "hydrogen atom of biology":

1. Molecular dynamics calculations provide the motions of non-hydrogen atoms in myoglobin extending over 300 ps. This dynamic information, together with energy minimization, was used to map the conformational energy surface of Mb (Elber and Karplus, 1987).
2. Molecular dynamics simulations were also used to calculate incoherent neutron-scattering spectra of myoglobin from 80 to 325 K (Smith *et al.*, 1990). These simulations involve time scales (0.3–100 ps) that overlap experimental time scales. The simulated mean square displacements $\langle x^2 \rangle$ for hydrogen atoms are in excellent agreement with the incoherent neutron-scattering data (see Fig. 6 and Sec. 4.3).
3. Trajectories for escape of oxygen from the binding site in Mb have been calculated using molecular dynamics (Case and Karplus, 1979). The trajectories identified a small number of possible pathways for ligand escape from the protein and rein-

forced the importance of protein motions in the escape process. Barriers of ~20 kJ/mol for ligand escape were estimated for the relaxed myoglobin structure.

4. Molecular dynamics simulations of the heme–imidazole environment in Mb subsequent to ligand dissociation have provided insights into the nonexponential time courses for rebinding observed even at room temperature for times less than 300 ps (Petrich *et al.*, 1991).

These simulations have demonstrated the importance of both conformational substates and protein relaxation among the substates in producing nonexponential time courses.

4. EXPERIMENTAL METHODS

Since proteins show an impressively rich spectrum of dynamic phenomena, a particular experimental technique is only sensitive to certain aspects of the motions. To understand the complex dynamics of proteins, different approaches have to be used yielding complementary results. Here we describe important experimental techniques that have been used to probe protein dynamics and to develop and refine the concepts of Sec. 2. Excellent introductions to the various techniques are given by Cantor and Schimmel (1980).

4.1 X-Ray Crystallography

X-ray crystallography is the most important technique to determine the molecular structure of proteins. Since x rays are scattered by electrons in the protein crystal, the method yields the electron density in the molecule, from which atomic coordinates of the non-hydrogen atoms are determined. The periodic arrangement of molecules in a protein crystal gives rise to a periodic pattern of reflections due to constructive interference of the waves at scattering angles that fulfil the Bragg condition (Fig. 5). The structural in-

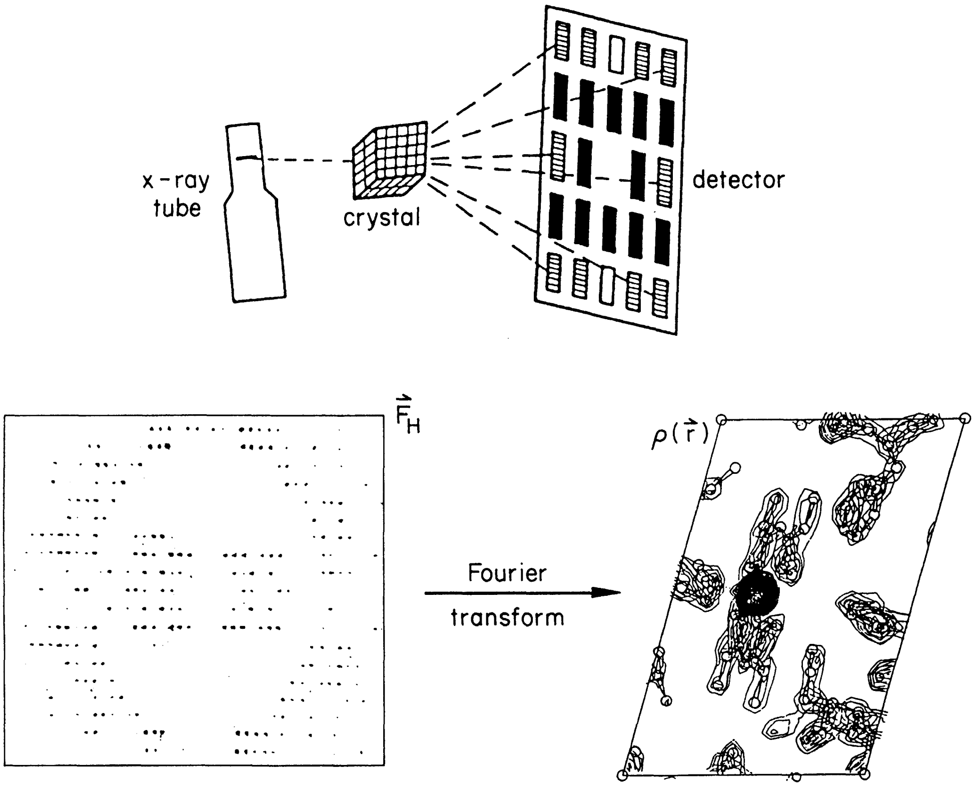

FIG. 5. X-ray structure analysis. The intensities of reflections from x rays scattered by a protein crystal are measured. The electron density $\rho(\mathbf{r})$ is obtained as the Fourier transform of the structure factors $\mathbf{F}_H$.

formation is encoded in the intensities of the reflections, which are the squares of the (complex) structure factors. For a protein structure analysis, the intensities of a large number of reflections (typically 10^4–10^5) are measured.

The electron density is the Fourier transform of the structure factors, and both amplitudes and phases of the structure factors have to be determined. Apart from scaling factors, the amplitude is simply the square root of the intensity. Phases are measured in indirect ways—for example, by additional measurements on crystals where reference scatterers are introduced at well-defined positions in the unit cells (isomorphous replacement).

The presence of conformational substates in proteins implies that the positions of the atoms vary slightly among different molecules in the protein crystal. If we assume an isotropic, Gaussian spread of the atoms around their average positions, the x-ray scattering amplitude of each atom j is decreased by the Debye–Waller factor,

$$f_{\mathrm{DW}} = \exp[-8\pi^2\langle x_j^2\rangle^x(\sin^2\theta)/\lambda^2]. \qquad (7)$$

Here, the mean squared displacement, $\langle x_j^2\rangle^x$, characterizes the disorder of the atom j. We use the superscript "x" to indicate that the mean squared displacement was determined by x-ray crystallography. The scattering angle is denoted by θ, and λ is the wavelength of the x rays. The reflections become weaker with increasing $\langle x_j^2\rangle^x$, and θ.

The preliminary model that is obtained by Fourier transformation is improved by inserting additional information about bond geometry in a least-squares fit procedure called restrained refinement, which improves the agreement between the observed structure factors and those calculated from the model. In high-resolution data sets, $\langle x_j^2\rangle^x$ of each atom is taken as an adjustable fitting parameter in the refinement (Petsko and Ringe, 1984).

Different types of disorder contribute to the mean squared displacement in protein crystals. These contributions are assumed to be uncorrelated, so that the mean squared displacement of an individual atom in the protein, $\langle x^2\rangle^x$, can be written as a sum,

$$\langle x^2\rangle^x = \langle x_s^2\rangle + \langle x_v^2\rangle + \langle x_c^2\rangle. \qquad (8)$$

In protein crystals, the molecules may occupy the unit cells in slightly different ways, which leads to static lattice disorder, represented by $\langle x_s^2\rangle$. The term $\langle x_v^2\rangle$ indicates harmonic vibrations of the lattice, a dynamic disorder contribution to the mean squared displacement. The interesting term in the context of protein dynamics is $\langle x_c^2\rangle$. This term represents "disorder" arising from the inhomogeneous ensemble of protein molecules in different conformational substates.

Energy and time are conjugate variables. Since x-ray crystallography does not measure the energy exchange between the x-ray photons and the sample, the method inherently lacks time resolution; it cannot distinguish between static and dynamic disorder. Information about motions is obtained indirectly (Frauenfelder *et al.*, 1979): Since thermal energy drives fluctuations among the CS, transitions among conformational substates can be slowed by lowering the temperature, until finally, a static distribution of protein molecules is obtained.

As an example, Fig. 6 shows the average mean squared displacement of all non-hydrogen atoms, $\overline{\langle x^2\rangle^x}$, as a function of temperature for myoglobin (Parak *et al.*, 1987). As the temperature is lowered, $\overline{\langle x^2\rangle^x}$ decreases, but a

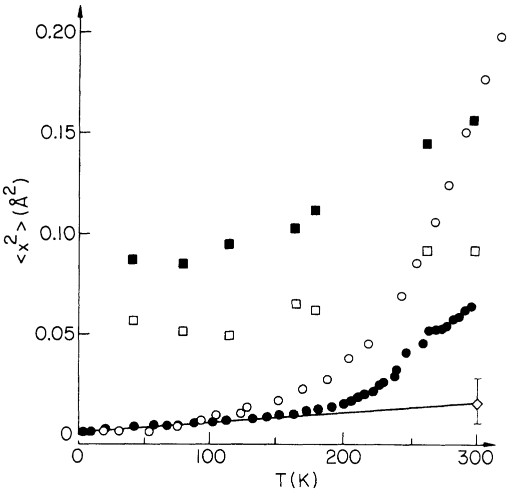

FIG. 6. Mean squared displacements, $\langle x^2\rangle$, measured as a function of temperature. Filled squares, $\overline{\langle x^2\rangle^x}$, average of non-hydrogen atoms (x-ray diffraction); open squares, $\langle x^2\rangle^x_{\mathrm{Fe}}$ of the heme iron (x-ray diffraction); filled circles, $\langle x^2\rangle^\gamma$ of the heme iron (Mössbauer spectroscopy); open circles, $\langle x^2\rangle$, average of hydrogen atoms (incoherent neutron scattering); open diamond, $\langle x^2\rangle^x$ due to lattice vibrations (RSMR).

large amount of disorder prevails at low temperatures. At room temperature, the proteins fluctuate rapidly among the conformational substates. As the temperature is lowered, protein fluctuations get more and more restricted to substates in lower regions of the conformational energy surface, and the spatial distribution narrows. Since there are many with similar conformational energies but slightly different structures, a significant amount of disorder remains even below 100 K. There, the thermal energy is insufficient to overcome the barriers, and the molecules are trapped within a static ensemble of conformational substates.

An isotropic Gaussian distribution is a rather crude model for the disorder. In general, atomic potentials are anharmonic and anisotropic. Recently, algorithms have been developed to use crystallographic data as restraints in molecular dynamics (MD) simulations, such that the MD simulation generates an ensemble of conformational substates, the average of which is restrained to be consistent with the observed crystallographic data (Gros *et al.*, 1990). Then, the disorder of an individual atom is given by the distribution within the ensemble of slightly different structures generated by the MD simulation.

The intensity lost by crystal disorder appears as a thermal diffuse scattering (TDS) background that varies smoothly with scattering angle. Analysis of the TDS background yields information about spatial correlations of the displacements. For example, correlated motions of molecular segments within a protein molecule can be revealed.

X-ray structure analysis used to be a tedious procedure involving measurement times of several weeks. With the advent of powerful x-ray sources and area-sensitive detectors, measurement times have become short enough to follow a chemical reaction—for example, ligand binding—using x-ray crystallography (Rasmussen *et al.*, 1992).

4.2 Mössbauer Spectroscopy

Mössbauer spectroscopy (see MÖSSBAUER EFFECT) involves the absorption of γ rays by atomic nuclei. Normally, a radioactive source is employed that emits γ quanta during a nuclear decay into the ground state. When the nuclei are embedded in a solid matrix, a fraction of the decaying nuclei transfers its entire energy to the γ photons, which leads to an extremely small linewidth of the radiation. These γ quanta can be resonantly absorbed by nuclei of the same kind in the sample under study.

Most often, ^{57}Fe is used, a nucleus that is produced by the decay of ^{57}Co. It emits γ radiation with an energy $E_0 = 14.4$ keV. The energy width Γ of the Mössbauer line is extremely small, 5×10^{-9} eV, reflecting the lifetime $\tau = 141$ ns of the excited nuclear state ($\Gamma\tau = h/2\pi$, where h is Planck's constant).

To measure an absorption spectrum, the γ quanta are counted while the energy of the source line is scanned across the sample resonance. The energy scan is performed using mechanical transducers that move the source relative to the sample, giving rise to a Doppler energy shift $\Delta E = (v/c)E_0$, where v is the source velocity and c is the velocity of light. Mössbauer spectra give the transmission through the sample as a function of source velocity. Since the nuclear levels are sensitive to charge density, magnetic fields, and electric-field gradients in the vicinity of the nucleus (*hyperfine interactions*), the energy levels of the absorber are usually shifted with respect to the source and split into multiple lines. From the Mössbauer spectra, information about the electronic structure at the nucleus can be extracted; it is, therefore, an important technique to characterize electronic properties of iron-containing active sites in proteins. Motions in iron-containing proteins are reflected in the spectra in three different ways:

1. Hyperfine parameters. Motions around the Mössbauer atom change the local fields and, consequently, change the hyperfine parameters, i.e., the positions and splittings of the lines. Information about the motions is usually obtained from the temperature dependence of the hyperfine parameters.
2. Quasielastic lines. Diffusive motions with characteristic times on the order of the coherence time of the radiation (141 ns for ^{57}Fe) or less lead to broad, quasielastic lines that can be understood as a Doppler effect from the motions. The widths of the lines reflect the time scales of the motions. Mössbauer spectroscopy with ^{57}Fe

is sensitive to diffusive motions with characteristic times in the range 10^{-6}–10^{-11} s. Both glass-forming liquids and proteins exhibit wide temporal distributions of dynamic processes, indicating close analogies between a protein and a glass.

3. Temperature-dependent changes of the spectral area. At temperatures near 0 K, all motions except for zero-point vibrations are arrested, and the area of the Mössbauer spectrum is maximal. With increasing temperature, the onset of fast, vibrational motions leads to a decrease of the spectral area. In the Gaussian approximation, the fractional area is related to the mean squared displacement through the Lamb–Mössbauer factor,

$$f_{\mathrm{LM}} = \exp[-k_0^2\langle x^2\rangle^{\gamma}]. \tag{9}$$

Here, k_0 denotes the magnitude of the wave vector, $2\pi/\lambda$, with $\lambda = 0.86$ Å for ^{57}Fe. The mean squared displacement, $\langle x^2\rangle^{\gamma}$, includes only displacements from motions fast compared with the coherence time of the radiation.

As an example, Fig. 7 shows spectra of deoxymyoglobin crystals at 200 and 283 K (Frauenfelder *et al.*, 1988) consisting of quadrupole doublets. The doublet spectra arise from the coupling of an electric-field gradient and the nuclear quadrupole moment. Note the drastically decreased area and the appearance of a broad, quasielastic component in the spectrum at 283 K. The line broadening indicates diffusive motions of the Mössbauer nucleus with time scales around 100 ns. Figure 6 shows the temperature dependence of $\langle x^2\rangle^{\gamma}$ for deoxymyoglobin crystals (Parak *et al.*, 1987). The dynamics below ~200 K are governed by harmonic vibrations, as evidenced by the linear temperature dependence. Above 200 K, $\langle x^2\rangle^{\gamma}$ increases much more steeply, indicating that fluctuations among conformational substates on time scales faster than ~100 ns become thermally excited. By contrast, the individual mean squared displacement of the iron obtained from the x-ray structure analysis, $\langle x^2\rangle^{x}_{\mathrm{Fe}}$, does not show such a pronounced change. This different behavior is a consequence of the fact that the x-ray method cannot distinguish between static and dynamic disorder. In protein crystals, the dynamic disorder at high temperature turns smoothly into static disorder at low temperature.

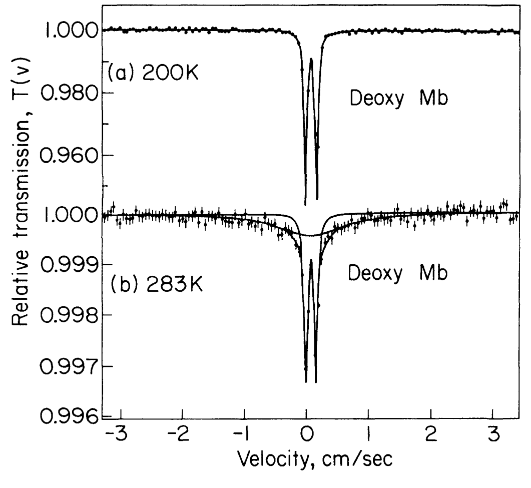

FIG. 7. Mössbauer spectra of deoxymyoglobin crystals at 200 and 283 K. Note different vertical scales for the two curves.

The Mössbauer effect is also used in scattering experiments. Rayleigh scattering of Mössbauer radiation (RSMR) combines the spatial sensitivity of x-ray diffraction experiments with the temporal sensitivity of the Mössbauer technique. It is essentially an x-ray scattering experiment using a Mössbauer γ source instead of an x-ray tube. The sample need not contain Mössbauer nuclides, as the γ quanta are scattered by the electrons in the sample. The exchange of energy in the scattering can be examined by introducing a resonant absorber in the scattered beam. Only γ quanta that have been scattered without (or with very small) energy exchange with the sample can still be absorbed resonantly in the absorber. RSMR is in principle a more powerful technique than Mössbauer absorption spectroscopy, since it allows investigation of spatial correlations of protein fluctuations. For example, RSMR experiments on myoglobin single crystals have shown that lattice vibrations ($\langle x_v^2\rangle$ in Eq. 8) in protein crystals are only a minor contribution to the total disorder at room temperature (Fig. 6) (Nienhaus *et al.*, 1989).

4.3 Neutron Scattering

Neutron scattering is used as a crystallographic technique in a way similar to x-ray diffraction. The neutron wavelength is given by the de Broglie relation, $\lambda_0 = h/mv_0$ (h = Planck's constant, m = neutron mass, v_0 = neutron velocity). Thermal and cold neutrons from a nuclear reactor are useful for crystal structure analysis, since they have wavelengths on the order of atomic distances. Neutrons interact with the atomic nuclei in the crystal, and the strength of the interaction is given by the scattering length b. X-ray diffraction cannot resolve hydrogen atoms, whereas neutron scattering can because of the substantial coherent neutron-scattering length of hydrogen. Furthermore, the large contrast between hydrogen and deuterium in neutron scattering is exploited in studies of hydrogen-exchange processes.

The high energy resolution of neutron scattering makes it possible to analyze the energy exchange between neutrons and target. Inelastic and quasielastic neutron scattering are powerful methods to study motions in proteins on time scales ranging from 10^{-13} to 10^{-7} s (Middendorf, 1984; Doster *et al.*, 1989). The intensity of incoherent scattering is dominated by the hydrogen atoms. Consequently, neutron spectroscopy yields mainly information about the (average) dynamics of the hydrogen atoms. In Fig. 6, the temperature dependences of the mean squared displacements of ^{57}Fe and the hydrogen are similar. The amplitudes are larger for the hydrogens, as expected for lighter atoms; furthermore, the iron is located in the less flexible interior of the protein.

4.4 Nuclear Magnetic Resonance

In recent years, nuclear magnetic resonance (NMR) spectroscopy (see MAGNETIC RESONANCE AND QUADRUPOLE RESONANCE, NUCLEAR) has developed into a powerful tool for investigation of the structure and dynamics of proteins in solution (Wüthrich, 1986). Since nuclei are characterized by a spin angular momentum that can only assume discrete values with respect to a chosen quantization axis, the energy of the nuclei splits into discrete levels in a magnetic field, because of the interaction between the field and the magnetic moment associated with the spin. Most important for NMR on proteins are the nuclei $^1_1$H, $^{13}_6$C, $^{15}_7$N, and $^{31}_{15}$P, which all have spin quantum number $\frac{1}{2}$, giving rise to two energy levels in a magnetic field. Transitions between the levels are induced by irradiation with radio-frequency (rf) photons with energies matching the energy difference among the nuclear levels. Since the lower energy level is more populated than the upper level in thermal equilibrium, resonant absorption of energy occurs. The local magnetic field at the nucleus differs from the external field because the surrounding electrons induce an additional field. Since each nucleus has a slightly different environment, the individual resonances occur at different frequencies; this effect is called *chemical shift*. The large number of protons in a protein molecule leads to complex, crowded spectra with many overlapping resonances. For the determination of protein structures, data are collected using two-dimensional (2D) and multidimensional NMR techniques involving special rf pulse sequences that disperse the resonances and identify neighboring nuclei through measurement of *spin–spin interactions.* Correlated spectroscopy (COSY) experiments probe the connectivity of nuclear spins by through-bond interactions. Nuclear Overhauser enhancement spectroscopy (NOESY) establishes the proximity of nuclear spins by measuring through-space dipolar interactions. The three-dimensional structure is obtained by sequential assignment of resonances along the polypeptide backbone.

Protein motions affect the spin interactions by changing the magnitude and direction of the local magnetic field with respect to the external field. In solution, rapid overall reorientation of the protein molecules averages the nuclear spin interactions to their isotropic values, leading to sharp resonances, which is essential for high-resolution NMR structure determination. Large biomolecules can be too immobile for solution NMR, or crystals and amorphous samples are to be investigated. For these applications, high-resolution solid-state NMR techniques are available, where rf irradiations and mechanical sample spinning replace molecular motions as line-narrowing mechanisms. Dynamic information is obtained from NMR in three different time ranges:

1. Slow processes ($\tau \gtrsim 10$ min) are monitored by successive acquisition of NMR spectra during the time course of the reaction, for example, in hydrogen exchange studies.

2. Processes on an intermediate time scale ($\tau \approx 1\text{–}10^{-5}$ s) are reflected in the particular shape of the spectrum, and line-shape analysis reveals the time scales of the nuclear motions. Consider a nucleus that can assume two distinct positions in the molecule. The different environments give rise to two peaks at frequencies ν_A and ν_B. Two sharp resonance lines are observed as long as the residence time τ in either of the positions is longer than the inverse of the frequency separation of the two lines, $\tau \gg \Delta\nu^{-1}$. Jump processes are usually thermally activated, so that with increasing temperature, the jumps become more frequent. Concomitantly, the lines broaden and the separation decreases, until they finally merge into a single line, as sketched in Fig. 8.

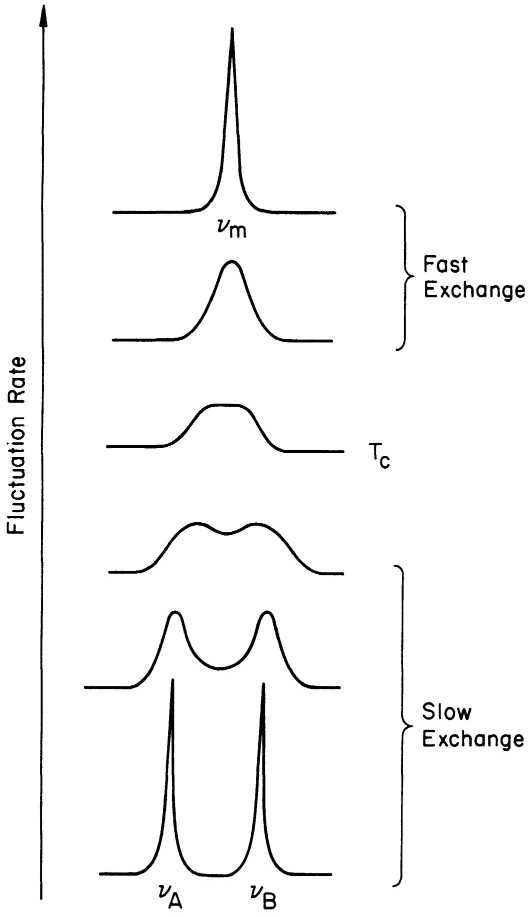

FIG. 8. NMR spectrum of a nucleus with two distinguishable positions, as a function of fluctuation rate.

3. Fast processes ($\tau \lesssim 10^{-9}$ s) are studied with relaxation-time experiments—that is, spin–lattice relaxation (T_1), spin–spin relaxation (T_2), and cross-relaxation rates in nuclear Overhauser enhancements.

4.5 Hydrogen Exchange

Polar side-chain protons and main-chain peptide-group protons exchange with protons from the solvent. Hydrogen exchange (Englander and Kallenbach, 1984) requires transient breaks of hydrogen bonds and accessibility of the sites to the solvent. Consequently, the method is sensitive to conformational fluctuations of protein molecules. The experimentally observed exchange rates span many orders of magnitude. Hydrogen-exchange experiments reveal that the protected, hydrogen-bonded protons are exchanged by way of local unfolding of small structural segments as cooperative units. Three different experimental approaches are used to monitor the exchange:

1. NMR. The protein is dissolved in heavy water (D_2O). The amplitudes of the proton resonances are proportional to the concentration of ^1H at a particular site. Exchange rates of well-separated resonances can be determined by measuring spectra at different times after transfer into D_2O, since hydrogen resonances disappear as the protons are exchanged for deuterons. Fast exchanges can be studied through line-shape analysis.
2. Neutron diffraction. Protein crystals are soaked in D_2O. The scattering lengths of ^1H and ^2H are distinctly different, and, therefore, deuterons and hydrogens are distinguishable in the density map.
3. Tritium exchange. The protein sample is incubated with tritiated water for a certain amount of time that may be varied from minutes to days to select a population of hydrogens within a certain range of exchange rates (exchange-in phase). Then, the tritiated solvent is separated from the protein using biochemical procedures. Tritium (^3H) is a radioactive isotope of hydrogen, and the number of tritium decays immediately after removal of the tritiated solvent is proportional to the fraction of sites where hydrogen has been replaced by tritium. The tritium atoms

will subsequently exchange with the solvent (exchange-out phase). A second exchange of the solvent is performed after a certain delay time, terminating the exchange-out phase. Nuclear decays after the second exchange are due to tritium atoms that have not exchanged out during the delay time, and hence the decrease in radioactivity measures the fraction of protons that have escaped from the protein into the solvent during the delay period. By varying the length of the exchange-out phase, the distribution of rates is obtained.

4.6 Fluorescence Spectroscopy

Fluorescence spectroscopy (Lakowicz, 1983) is based upon the emission of light by fluorescent molecules, which typically decay into the ground state 1–10 ns after electronic excitation. Both the intrinsic fluorescence (aromatic side chains, prosthetic groups) and the fluorescence emitted by dyes attached to protein molecules are extremely sensitive to a wide range of interactions and perturbations during the lifetime of the excited state that influence the fluorescence emission, including proton-transfer reactions, ligand binding, solvent-cage relaxation, local conformational transitions, and diffusional processes. The method is highly sensitive so that only minute amounts of material are needed.

Rotational diffusion and segmental motions are studied by measurement of fluorescence anisotropies. The sample is illuminated with linearly polarized light, and only a minor fraction of the sample, with transition dipoles for absorption preferentially parallel to the polarization vector, is excited. This principle is called *photoselection.* Since emission and absorption transition dipoles are sterically coupled, photoselection introduces an anisotropy in the fluorescent emission that is averaged out by orientational motions of the fluorophore. Measurements of the anisotropy decay yield information about the time scales of the motions.

Collision of fluorescent molecules with oxygen (and heavy atoms like iodide or cesium ions) leads to fluorescence quenching. This process requires diffusion of the quencher to the fluorescent group within the lifetime of the excited state. When the fluorophores are on the exterior of the protein, studies of collisional quenching allow determination of the rates with which small molecules diffuse to the protein. When the fluorophore is buried in the interior, permeation of the protein by the quencher can be studied.

Fluorophores show time-dependent spectral shifts, since polar groups reorient themselves after excitation in response to the changed dipole moment. Time-resolved measurements of the fluorescence emission spectrum reveal the time scales on which the protein reacts to the change of the electric field after excitation.

Time-dependent fluorescence measurements are performed most directly in the time domain with pulse response measurements. In recent years, frequency-domain experiments have become very popular. In these measurements, the sample is continuously illuminated by a modulated excitation beam, and both phases and modulation amplitudes of the resulting fluorescence emission are registered as functions of the excitation frequency (Gratton *et al.,* 1984).

4.7 Transient Optical Spectroscopies

The availability of pulsed lasers and fast optical detectors makes transient optical spectroscopy a powerful tool for the study of protein dynamics over an enormous time range (10^{-14}–10^{6} s). External perturbations are applied that force the system out of equilibrium, and the subsequent relaxation toward equilibrium can be monitored by measuring transient optical spectra (Eigen and de Mayer, 1974). A nonequilibrium situation can be created in various ways—for instance, by a temperature jump (irradiation with microwaves or infrared laser pulses, and by current pulses), pressure jump, electric-field jump, pulse radiolysis (irradiation with high-energy radiation), or photoexcitation (flash photolysis).

Photoexcitation is a frequently used relaxation technique. Intense monochromatic laser pulses are ideal for triggering a variety of different reactions in proteins. Often, the protein relaxes back to the initial state within a short time so that repetitive excitations can be performed at high frequency (signal averaging). Many systems are damage resistant and do not change their kinetic properties even after thousands of flashes. Figure 9 shows a classical example of photoexcitation, the photocycle of bacteriorhodopsin, a molecule that utilizes light energy to pump protons across the cell membrane (Lozier *et al.,* 1975; Mathies *et al.,* 1991). When chemical bonds are broken by the laser pulse, the photoexcitation technique is referred to as flash photolysis.

A number of spectroscopic techniques are used to monitor the spectral changes after photoexcitation. Different spectral regions give complementary information. Transient spectra are observed in different ways, dependent upon the time scales: Slow processes ($\tau \gtrsim 10$ s) are observed with conventional dispersive or Fourier-transform spectrometers. On intermediate time scales ($\tau \gtrsim 10^{-9}$ s), transient changes at single wavelengths can be monitored continuously as a function of time after the laser flash. To obtain experimental data on entire spectra, gated optical multichannel analyzers (OMA) are used. The time dependence is obtained by opening the detector gate for a short time at various time delays after the laser pulse. On fast time scales ($\tau \lesssim 10^{-9}$ s), pulse/probe techniques are employed: The laser pulse is split, and one part is used for photoexcitation, whereas the other part, shifted in time by an optical delay line, is used to probe the transient spectrum.

Protein spectra are generally inhomogeneously broadened as a result of the presence of conformational substates. The inhomogeneity can be shown using selective photoexcitation of subpopulations by illumination at different positions across the band (*spectral hole burning*). If the band position of a homogeneous subpopulation is coupled in a systematic way to a kinetic variable—for example, the enthalpy barrier for ligand rebinding—band shifts are observed as the reaction proceeds (*kinetic hole burning*) (Campbell *et al.,* 1987, Ormos *et al.,* 1990).

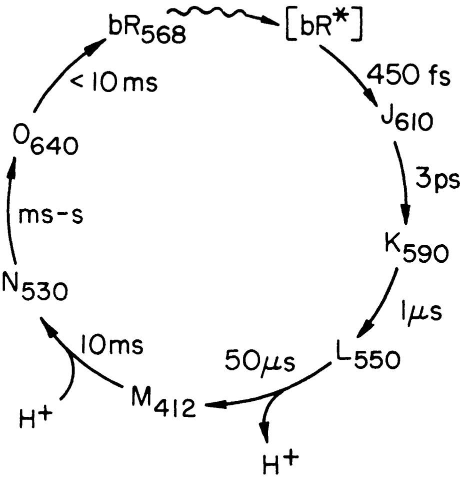

FIG. 9. Photocycle of bacteriorhodopsin, showing the predominant intermediates and the transition rates. Subscripts are absorption maxima in nanometers.

Linear dichroism (LD) experiments determine the absorption as a function of the polarization of the monitoring beam. LD experiments in combination with photoselection (see Sec. 4.6) monitor reorientation of the absorbing chromophores. *Circular dichroism* (CD) experiments are based on the fact that biological molecules show optical activity and absorb left-circularly and right-circularly polarized light differently.

4.7.1 Ultraviolet Spectroscopy Ultraviolet (UV) spectroscopy is based upon electronic transitions induced by the absorption of UV light. The peptide unit dominates the spectrum around 200 nm. The spectrum changes in a characteristic way with the type of secondary structure. From 230 to 300 nm, the aromatic sidechains of phenylalanine, tyrosine, and tryptophan and the histidine and disulfide sidechains absorb. The absorption of prosthetic groups may also fall into the UV region. UV absorption and CD spectra depend upon the folding pattern and are used for structural and kinetic studies, for instance, of helix-coil transitions.

4.7.2 Visible/Near-Infrared Spectroscopy Many biological molecules show strong absorbance in the visible (VIS) and near-infrared (NIR) regions of the spectrum, due to the presence of metal ions and prosthetic groups with extended π-electron systems, like chlorophyll, heme, flavin, and retinal. The bands are sensitive to the polypeptide environment and reflect structural changes, oxidation states, and the binding of ligands, making transient visible spectroscopy an excellent technique for physical studies of enzyme action. As an example, the visible spectra of heme change markedly upon photodissociation of a ligand like oxygen or carbon monoxide. The absorption bands in the visible are superb markers for the binding of ligands to heme proteins (Fig. 10).

4.7.3 Infrared Spectroscopy In protein molecules, absorption in the infrared (IR) region of the electromagnetic spectrum arises from transitions between vibrational levels due to bond stretching and bending. IR vibrations occur between 5 000 cm^{-1} (2 μm) and 200 cm^{-1} (50 μm). The contribution from a particular bond is usually weak, so that concentrated samples are needed. Water absorbs strongly in the region where protein bands are found, but the problem can be alleviated by the use of D_2O instead of water. IR spectra are superpositions of a large number of overlapping bands. Specific information is obtained by IR difference spectroscopy, where spectra are taken before and after photoexcitation. The absorbance difference spectrum contains only lines from bond changes resulting from the photoprocess. Often, only a few lines are observed, which can be assigned to particular bonds by site-directed mutagenesis or isotope labeling techniques.

Fourier-transform infrared (FTIR) spectrometers are routinely used for infrared studies of protein dynamics. Collecting FTIR spectra takes on the order of seconds to minutes, so that only slow processes, like ligand binding at cryogenic temperatures, can be studied. For samples that allow repetitive photoexcitation, step-scan and stroboscopic FTIR techniques are used with time resolution in the microsecond region. Technology for direct IR detection on the picosecond time is not yet available. To probe on fast time scales, the IR beam is mixed with visible light in a nonlinear crystal, and the intensity at the sum frequency in the visible is monitored.

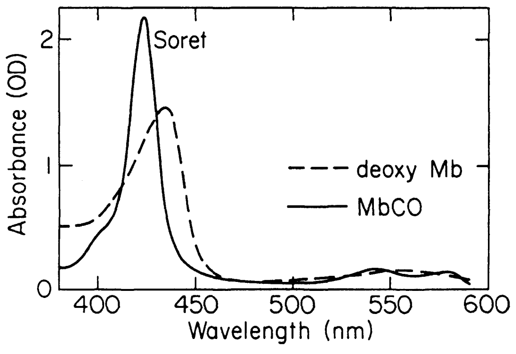

FIG. 10. Absorption spectra of carbonmonoxymyoglobin (MbCO) and deoxymyoglobin (Mb) in the visible. The Soret band on the blue side of the spectrum is the strongest electronic transition in heme proteins.

4.7.4 Raman Scattering For Raman experiments, the sample is illuminated with monochromatic light. Besides the elastic (Rayleigh) line, the scattered light contains sidebands (Stokes and anti-Stokes lines) resulting from energy exchange between photons and sample through vibrational transitions. Therefore, the method is closely related to IR absorption. Instead of electric dipole changes, Raman bands arise from polarizability changes due to nuclear motions. For small, centrosymmetric molecules, IR and Raman activities are mutually exclusive; hence IR absorption and Raman spectroscopy complement each other. In large, asymmetric molecules, the same vibrational bands are often seen with both techniques. An advantage of Raman spectroscopy for biological samples is that water scatters weakly and does not obscure much of the spectral range, as it does with IR absorption. Raman bands are usually weak and difficult to study, unless they are coupled to electronic transitions: By exciting at an electronic absorption wavelength, an enormous signal intensity enhancement is observed. This technique, called *resonance Raman scattering,* can be used for the study of biological samples in dilute solutions. Since resonance enhancement is limited to modes coupled to the chromophore, the spectrum is greatly simplified. Most often, the chromophore is located at the active site, so that resonance Raman spectroscopy focuses in on the most interesting region.

4.7.5 Other Experimental Techniques The techniques that are discussed above are the most frequently used tools for experimental studies of protein dynamics. Other popular techniques include EXAFS, electron microscopy, electron paramagnetic resonance, photoacoustic spectroscopy, differential scanning calorimetry (DSC), and ultracentrifugation (and other hydrodynamic techniques). For a general introduction to these techniques, see Cantor and Schimmel (1980) and Hoppe *et al.* (1983).

5. PROTEIN DYNAMICS—A REPRISE

Proteins are dynamic systems because of their structure and the various competing interactions among their constituent atoms. On the basis of studies of deuterium/hydrogen exchange in proteins, Linderstrøm-Lang and Schellman held the view as early as 1959 that a protein did not possess a unique structure but instead "exists mainly as a group of structures not too different from one another in free energy, but frequently differing considerably in energy and entropy" (Linderstrøm-Lang and Schellman, 1959). In 1966, Perutz and Mathews pointed out that the x-ray structures of hemoglobin and myoglobin do not allow access of the ligand to the binding site, and hence they concluded that the proteins must have flexible elements that permit a dioxygen molecule to reach the binding site at the heme iron (Perutz and Mathews, 1966). Klotz (1966) and Weber (1972) suggested that a protein with a given primary sequence exists in many conformational states and is dynamic. Flash photolysis studies of small-ligand binding to myoglobin established the functional relevance of the manifold of protein conformational substates (Frauenfelder *et al.*, 1988). In particular, it was shown that an ensemble of proteins below about 160 K is described by an inhomogeneously broadened distribution of rate coefficients for ligand rebinding after photodissociation. The spatial disorder in proteins due to the manifold of conformational substates was demonstrated with x-ray diffraction (Frauenfelder *et al.*, 1979).
